Board convened to meet at Washington, D. C., April 25, 1904, for the physical examination of a candidate for admission into the Revenue Cutter Service.—Detail for the Board: Assistant Surgeon-General L. L. Williams, chairman; Assistant Surgeon-General W. J. Pettus, recorder.

Board convened to meet at San Francisco, Cal., May 9, 1904, for the physical examination of an officer of the Revenue Cutter Service.—Detail for the Board: Passed Assistant Surgeon W. G. Stimpson, chairman; Assistant Surgeon Carl Ramus, recorder.

SOCIETY REPORTS

GERMAN SURGICAL ASSOCIATION.

XXXIII Congress, Held at Berlin, April 6, 7, 8, and 9.

[Specially reported for *American Medicine* by Lawrence Hendee, A.B., M.D., Instructor in Anatomy, Cornell University, Ithaca; Z. S. Volontärarzt, Chirurgische Klinik, Königsberg, I/Pr., Member of the German Surgical Association, with due acknowledgment of Dr. Wohlgenuth, authorized reporter for the German Medical Press, and the members of the Association, who kindly furnished abstracts.]

[Continued from page 698.]

The Increased Weight-carrying Capacity of the Bone Ends of Amputation Stumps through Their Being Covered by Tendons.—WILMS demonstrated several patients in whom on operation he had covered the bone ends by a layer of tendons. The results appeared to be good.

Discussion.—BUNGE (Königsberg) held that the covering the bone end with tendon was unnecessary. He referred to his method, reported in the Congress, 1901, in which he removes the periosteum for a distance of about 1 cm. above the cut surface of the bone and also the medulla for about 2 mm. to 3 mm. By this means he never has seen a painful stump and within a short time the patient is able to bear his weight on the stump.

Bone Suture in Subcutaneous Fractures.—KÖNIG (Altona) advocated this method, particularly in those cases in which there was great displacement with impossibility of complete reduction, fractures in the neighborhood of a joint and in those when there were indications of delayed or impaired union. The operation should be performed within 10 days from the time of injury. By this method he had always had a rapid recovery and excellent function.

Discussion.—NUTZEL (Frankfurt a/M) reported 43 cases of bone suture covering the clavicle, tibia, fibula, femur, and humerus. He considered that by such a procedure in fracture of the femur one can always be sure of a better result with less shortening than by the usual method. BARDENHAUER (Cologne) was opposed to this method as being unnecessary in the majority of cases. He demonstrated by diagrams his method, apparently somewhat complicated, of traction and countertraction through a system of weights and pulleys. He reported 13 cases of fracture of the femur treated by his method in which there was not more than 2 mm. to 4 mm. of contraction. In conjunction with his system of weights and pulleys he causes slight passive movement of the leg on the eighth day and again on the fourteenth day. After the fifteenth day the traction is removed. GEISLER discussed the value of the plaster dressing in connection with traction.

Bone Transplantation for the Healing of a Pseudoarthrosis or Bone Defects.—MANGOLDT (Dresden) reviewed the cases of Bramann (Halle) and Müller (Rostock), then reported two cases of his own. One case was a pseudoarthrosis of the tibia situated about 8 cm. below the knee-joint and due to an osteomyelitis with total unions of the shaft. In the second case there was a bone defect on the posterior side of the shaft of the femur. In both cases bone transplantation was performed. Strips of periosteum with a thin layer of bone attached taken from the outer and inner surfaces of the sound tibia were used. Good results in both cases. In the first case of tibia pseudoarthrosis the patient was able nine months after operation to stand on the former diseased leg. In form the regenerated tibial shaft appeared like the normal. In the second case of bone defect in the femur, the cavity was entirely filled in and closed six months after operation. In conclusion he considered the free transplantation of periosteal strips with bone attached to offer great success especially in the young; the chief precaution in the operation being aseptis. He recommended the taking of the strips from the tibial surfaces, of ulna or ribs.

Method of Wrist-joint Resection, with Demonstration of Patient.—TJETZE (Breslau). The patient was able to move the fingers freely, both extension and flexion being strong—while the hand was also slightly movable in flexion and extension.

Pathology of the Knee-joint.—BECHER (Berlin). Demonstration consisted of charts showing the microscopic picture of various pathologic conditions of the capsule of the joint.

Early Operation for Tuberculosis of the Kidney.—KÜMMEL (Hamburg) first spoke of 280 kidney extirpations—of which 84 were tuberculous. He considered the tuberculous infection of the kidney to come through the blood channels and that the tuberculous kidney was the chief, if not the only source of infection for tuberculous ureteritis and cystitis. He dwelt on the great necessity of early diagnosis of tuberculous nephritis, and the improved methods of its diagnosis and location. Under this heading he considered of great diagnostic importance the catheterization of the kidney, mentioning Joseph's (Heidelberg) method. With the diagnosis positive, extirpation of the diseased kidney should follow. The prognosis varied in proportion to the early diagnosis. In tuberculous cystitis, operative procedure was of little value, the treatment being practically symptomatic.

Tuberculosis of the Kidney and the Results of Its Operative Treatment.—KRÖNLEIN (Zurich), in introduction, spoke of the anatomy and pathology of tuberculous

kidney based upon 51 cases operated upon by him in the last 15 years. Of these 51 cases, 13 were in men and 38 in women; in 92% the kidney on one side only was involved, and 8% double-sided kidney tuberculosis. In the 92% involving one side only, it was distributed in equal proportion between the right and left sides. An ascending tuberculosis was not met with in his experience; the infection coming in each case through the blood channels. In 12 cases it appeared without tuberculous foci in other parts of the body. In other cases it appeared early in combination with foci in other parts; in combination 22 cases with lung tuberculosis; 16 cases in combination with tuberculous cystitis; 12 cases with bone and joint tuberculosis; and 9 cases with genital tuberculosis. In 34 cases he made a total extirpation of the diseased kidney. The operation was always extraperitoneal. Results. Two patients died shortly after operation (complicated with lung tuberculosis); 6 patients died from 2 to 9 months after operation (complicated with lung tuberculosis); 2 patients died—one 6 years and one 10 years after operation. The remaining 24 patients are still alive. The following is the table of their observation; all are in good condition; in each event the year since operation is given: One case, 14 years; 2 cases, 10 years; 1 case, 9 years; 1 case, 6 years; 3 cases, 5 years; 6 cases, 4 years; 2 cases, 3 years; 1 case, 2 years; 7 cases, 1 year—total 24 cases. In the 10 fatal cases, 9 came to autopsy. In the 9 cases, 6 had a sound remaining kidney; in 2 the remaining kidney was tuberculous; and in 1 the remaining kidney showed a nontuberculous parenchymatous nephritis.

ARRENS (Ulm) reported the results of two cases of **nephrotomy**. One was a case with a solitary kidney, and the other for a stone of 28 years' duration. TREPLIN (Hamburg) reported cases of **double-sided renal calculus**. ENDERLEIN (Marburg) reported on the results of experimental and histologic investigation of **hydronephrosis** and its treatment.

The New Method of Operative Treatment of Chronic Nephritis.—BAKES (Trebitsch) reviewed the work of Edebohls, of New York, claiming that Edebohls' statistics were somewhat unreliable, and that he could not recommend in full Edebohls' procedure.

Discussion.—ROSENSTEIN (Berlin) considered that as yet Edebohls has not performed his operation on a single typical chronic nephrosis. STERN (Düsseldorf) has experimented with Edebohls' method on animals with very poor success and is not satisfied with the method. RIEDEL (Jena), KÜMMEL (Hamburg), and FRANKE (Braunschweig) declared that they had very poor results from the operation. (No one in the meeting spoke in its favor.)

Increasing the Resistance of the Peritoneum against Infection in Gastric and Intestinal Operations.—MICKULICZ-RADECKI (Breslau) held that the most careful asepsis is often insufficient to prevent infection of the peritoneum in severe operations on the stomach or intestines. In small or short operations the resistance of the peritoneum is often sufficient to overcome the small amount of infection that may occur, especially when special measures—as emptying the intestine before operation, compression, etc., are taken. The natural resistance of the peritoneum is not, however great enough to withstand infection of special virulence or quantity. The infection most frequently encountered is a polyinfection, usually the *Bacillus coli communis* with streptococci. The statistics show that the mortality from the severer intestinal operations is due to peritonitis following the operation. He reasoned that the resistance could be increased by producing a hyperleukocytosis. MIGATE (Breslau) with the assistance of Professor Flugge, have been conducting a series of animal experiments along these lines. The intraperitoneal injection of normal salt solution gave a hyperleukocytosis, but not of a very high grade. They found energetic nucleic acid gave the highest results. In animals, the leukocytosis following the subcutaneous injection of nucleic acid reached its highest point seven hours after injection and in man 12 hours. In man, a leukocytosis of 25,800 has been observed after its use. In animals they found the peritoneal resistance against infection by the stomach and intestinal contents increased 20 to 30 times. He reported 34 cases in man that had been injected as a preventive measure previous to operation. Of the 34 cases, 7 were stomach resections, 15 gastroenterostomies, while the remaining were various forms of severe abdominal operations. Excellent results were obtained in each case. In his technic of injection he uses 50 cm. of a 2% solution of neutralized Hefe nucleic acid obtained from the chemic factory of Borring (Mannheim). This he injects into the breast 12 hours before operation. In closing, he also advocated the flushing out of the peritoneal cavity with normal salt solution after each severe operation on either stomach or intestine.

Clinical and Experimental Investigations into the Difference in Pathogenic Qualities of the Intestinal Contents as Directed against the Peritoneum.—BRUNNER (Münsterlingen). The paper consisted mostly in the demonstration of charts and preparations.

Subcutaneous Artificial Nourishment.—In Stomach and Intestinal Operations and in Various Inflammatory Conditions of the Peritoneum.—FRIEDRICH (Greifswald) first spoke of the great advantages of this method when nourishment by mouth or rectum could not be taken or retained and when operative interference was not warranted. He had conducted experiments for some time with different solutions and

varying success. In his past experiments he had used olive oil 100 cc. per day, with fair success, reported in the Congress of 1902, grape sugar solutions of 3% to 4% strength, with even better success, not being satisfied with the results he had in conjunction with Siegfried (Physiology Inst Leipzig) sought for an albumoid preparation permanent in character. In pepsin peptone, made by Haden-Radebank bei Dresden, he found such a preparation. The injection of this substance caused no blood changes, rise in temperature or other symptoms and neither peptones nor albumins appeared in the urine after its use. It appeared not only to supply but also to preserve the body albuminoids. Used alone he found a 7% solution gave the best results. At present he is experimenting in its use in combination with normal salt solution and grape sugar solution.

PAYR (Graz) reported a case of **thrombosis** in the veins of the omentum and mesentery following an abdominal operation.

Ulcer of the Lesser Curvature.—RIEDEL (Jena) had tabulated the results of 58 cases, *i. e.*, 28 cases of isolated and 30 cases of multiple ulcers. In the isolated cases the ulcers were distributed as follows: In 17 cases, in the pyloric region; in 5 cases, in the anterior wall; in 3 cases, in the posterior wall; in 2 cases in the smaller curvature; and in 1 case, in the greater curvature. Of the 30 cases of multiple ulcers, 17 had ulcers on both walls, 2 with ulcers on the lesser curvature and anterior wall, 4 with ulcers on the lesser curvature and posterior wall, and 7 were complicated with pyloric ulcers.

Volvulus of the Stomach.—BORCHARD (Berlin) showed numerous diagrams demonstrating volvulus of the stomach in its various forms and stages.

The Status of the Problem of Perityphlitis.—BÜNGNER (Hanau) devoted the introduction of his paper to the review of the anatomic points of origin and relation to the surrounding tissues of the appendix. He presented charts illustrating his classification of appendicitis from the anatomopathologic standpoint. He subdivided the acute form as follows: 1. Epityphlitis and perityphlitis: (a) Simplex; (b) propria; (c) adhesive; (d) serofibrinous. 2. Epityphlitis and perityphlitis suppurative: (a) Intraperitoneal; (b) extraperitoneal. 3. Progressive epityphlitis and perityphlitis purulent. 4. Perityphlitis and epityphlitis with general peritonitis. 5. General pyemic infection. The chronic form he subdivided into that with stenosis, obliteration, hydrops, and empyema.

Review of the Clinical Symptoms of Appendicitis in Connection with the Pathology of Appendix and Abdominal Cavity.—LAUENSTEIN (Hamburg) distinguished two great groups in appendicitis. 1. Appendicitis initialis. This group he further subdivides into catarrhal, chronic, granulosa, and hemorrhagica. 2. Appendicitis perforative. In appendicitis initialis the pathologic changes are limited to the appendix, and in the most cases affect the mucosa only. These pathologic changes are epithelial necrosis, swelling, infiltration, and ecchymosis. In the diagnosis between appendicitis initialis and perforative, the author claimed the pulse had little value. In fact, he considered the pulse in general in appendicitis had more value from a prognostic rather than from a diagnostic standpoint. He entered somewhat deeply into the differentiation between the two types by means of the physical symptoms. He considered the blood examination often of uncertain value.

Intestinal Obstruction from Adhesions Following Appendicitis.—FEDERMANN (Berlin) presented a patient on whom he had operated with success for such a condition. He considered the pulse and temperature as important diagnostic signs in this condition.

CORDAN (Harburg) presented a short paper on the influence of the changes in the bloodvessels of the appendix mesentery in the development of appendicitis.

MEISEL (Freiburg), further investigations of the circulation in acute appendicitis.

Agreement in the Treatment of Acute Appendicitis.—SONNENBURG (Berlin) also advocated the teaching of the general public more about the disease, so they would report themselves early enough in the disease to be successfully treated.

The Favorable Time for Operation in Appendicitis.—KAREWSKI (Berlin) advocated immediate operation in acute cases.

Ureter and Bladder Resection in Hysterectomy for Carcinoma of the Uterus.—DEPAGE and MAYER (Brussels) reported 4 cases, in 3 of which they resected portions of both ureters, together with hysterectomy because the lower part of the ureters were involved in the carcinomatous mass. In the fourth case was a carcinoma of the bladder. In the three cases of hysterectomy, with ureter resection, the cut ends of the ureters were brought down into a button-hole like opening in each side of the bladder, and there sutured. In the case of bladder resection the right ureter was united to ascending colon and left to the descending colon. They claimed success in each case.

The Diagnostic Value of the Trochanterispina Line.—SHORMAKER (Gravenhage). The paper was illustrated by charts and diagrams showing the value of this line for diagnostic purposes—especially in fractures and dislocations. After reading his paper he showed a new instrument devised by him for rib resection.

REHN and STRAUSS (Frankfurt, s/M) both reported several cases of an interesting and peculiar bladder tumor,

occurring in the workmen of a neighboring dye factory. Göbel (Breslau) remarked on the similarity of these cases to those due to the so-called Bilharzia tumors from parasites.

The Treatment of Exceedingly Large Hernia.—MADE-LUNG (Strasburg) reported a case in which the contents of the sack was so great it was impossible to return them all to the abdominal cavity.

Discussion.—KAUSCH (Breslau) and BRAUN (Göttingen) reported similar cases. HELFERICH (Kiel) mentioned the danger of shock in the sudden reduction of such large hernias. BRODNITZ (Frankfurt a/M) reported a case he had treated by alcohol injections, with good results. He advocated this method in very young children.

Chronic Colitis and its Treatment from Surgical Experience.—BECK (Karlsruhe) advocated the surgical interference in uncomplicated cases of inflammation of the colon.

BORCHARD (Posen) reported a case of **intestinal obstruction** from a fresh syphilitic growth. Colostomy and after-treatment for the syphilitic condition brought about complete recovery.

The Etiology of Congenital Atresia of the Intestine.—KREUTZER (Erlangen). The paper was illustrated by charts showing the development of the esophagus and intestine.

REHN (Frankfurt a/M) demonstrated a specimen of **invagination of Meckel's diverticulum** with secondary invagination of the small intestine.

KLAPP demonstrated on a dog in which the **total anesthesia** extending to the head following the use of an oil cocain 1% solution injected by **lumbar puncture**. He has substituted gelatin for the oil with equal results. As yet he has not tried his oil or gelatin cocain solution on man.

Treatment of Stomach and Rectum Carcinoma.—PETERSEN (Heidelberg) took up the question from the prognostic standpoint based on statistics. The author in conjunction with Küferle and Colmers has examined 212 rectal and 66 stomach carcinomas. As the various types give an entirely different prognosis, he recommends the removal of a piece, when possible, before operation in order to make a more specific diagnosis of the variety. In all cases he recommends radical operation. The tabulated results of his cases are as follows:

STOMACH. RECIDIVE, 53 CASES.

1. Adenomatosum.....	24% of cases; recedive, 88%
(a) " simplex.....	9% " 85%
(b) " mucocyst and papilloma..	6% " 50%
(c) " gelatinosa.....	9% " 100%
2. Solidum.....	57% of cases
(a) alveolar.....	13% " 68%
(b) diffuse.....	32% " 55%
(c) gelatinosa.....	12% " 88%
3. Mixed forms.....	19% of cases " 100%

RECTUM. RECIDIVE, 125 CASES.

1. Adenomatosum.....	82% of cases; recedive, 80%
(a) " simplex.....	65% " 84%
(b) " mucocyst and papilloma..	9% " 100%
(c) " gelatinosa.....	8% " 100%
2. Solidum.....	11% of cases
(a) alveolar.....	7% " 100%
(b) diffuse.....	1% " 100%
(c) gelatinosa.....	3% " 100%
3. Mixed forms.....	7% of cases " 100%

Topography of the recedive based upon 34 cases of the stomach and 38 of the rectum. Stomach, organic, recedives, 56%; recedives in the lymph-nodes, 3%; recedives from metastasis, 41%; rectum, organic, recedives, 7%; recedive occurring in the connective tissue around the rectum, 50%; recedive occurring in lymph-nodes at some distance, 3%; recedive arising from metastasis, 40%, the metastasis being subdivided into 7% occurring in the lung and 93% in the liver.

The Results Following the Allowing of Compresses to Remain in the Abdominal Cavity after Operation.—REISE (Britz) had pursued a series of investigations in animals, allowing compresses, etc., to remain in the abdominal cavity after operation. No particular disturbances occurred in any case.

BARDENHAUER (Cologne) reported the results of his cases: (a) **Resection of the shoulder-joint** with notes on the after-treatment. (b) **Fractures and luxations in the neighborhood of the shoulder-joint.** (c) **Total resection of the scapula and head of humerus.** RECRINK (Freiburg) reported cases of **resection of the shaft of the long bones** for malignant tumors. BÖTTICHER (Giessen) demonstrated a preparation from a case of **bone cyst in the humerus.**

HERMES (Berlin), and KATZENSTEIN (Berlin) demonstrated patients operated for **cryptorchismus**, with a description of their operative technic. WENDEL (Marburg) reported a case of **thrombosis of the inferior vena cava** following an operation for an epinephroid tumor. SENER (Crefeld) presented a paper on the **prevention of carcinoma return** after operation for mammary carcinoma. KAUSCH (Breslau) the effect of **diabetes on surgical treatment.** HILDEBRANDT (Berlin) presented several röntgen ray pictures, showing **arteriosclerosis**, involving the anterior and posterior tibial arteries, occurring in **diabetes.** JORDAN (Heidelberg) reported a case of **pyemia** running a chronic course.

Officers Elected.—KRONLEIN (Zurich) at the close of the Seventh Session was elected president of the Association for the ensuing year. KÖRTE (Berlin) read the names of the new members received after the opening of the Congress.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

RHEUMATISM.

BY

EDW. A. CRUEGER, M.D.,
of Philadelphia.

Rheumatism, a disease of as yet undiscovered origin, prevails extensively over wide geographic limits, and especially in temperate climates. Although the disease has afflicted humanity from a very remote period, still from the literature on the subject it would appear to have been differentiated from other maladies of a similar character comparatively recently. Even now the distinction between rheumatism and other arthritides is not always clear at first examination. However, it is possible and generally easy to make a differentiation by the therapeutic reactions which fulfil all the practical and scientific requirements. Perhaps there are very few maladies which directly or indirectly entail more numerous and widespread morbid manifestations, yet fortunately for the sufferers, it is not only possible to relieve all these diseased states, but with a single exception they are all curable. This exception will be mentioned later.

In regard to the etiology of the disease it is considered, by many observers, to be due to a microbe which finds the field for its growth and development in the cartilaginous structures in any part of the body, though for peculiar reasons some of these cartilages are more easily invaded than others. This microbe has not yet been isolated and perhaps it never will be, as the conditions necessary to its existence occur only in the living body and postmortem changes may render it unrecognizable. However, conclusions can be drawn from the analogies between this disorder and those of a known microbic origin. These analogies are not complete, but they are at least suggestive. In one essential point the resemblance is strong. The disease is self-limited and will disappear when the pabulum which it needs is exhausted, or in other words, the disease will run its course and the patient will recover in a certain time. In acute articular rheumatism this time is about six weeks.

In regard to the morbid anatomy, there may be said to be two distinct conditions, primarily an inflammatory swelling of the invaded cartilages with all the local inflammatory symptoms, and, secondarily, the systemic intoxication due to diffusion and absorption of poisons generated in the diseased structures.

It would be useless to describe all the clinical manifestations of rheumatism, especially as the essential points will be alluded to under the head of differential diagnosis. In this, as in many other diseases, we must distinguish between the disease itself and the results of the disease. Thus the arthritis is rheumatism but purpura or migraine is the secondary effect.

The principal interest in rheumatism must, however, be the differential diagnosis and treatment. The sufferer cares very little what he has, so long as he can be and is speedily cured; and the physician must know what to treat in order to effect a cure.

Rheumatism and gout present many similar symptoms. Gout, however, is more apt to be symmetric, the corresponding joints on both sides of the body being affected at the same time, at least in the most common expression of gout which we encounter in this country. Rheumatism will by preference attack the large joints or the heart, while gout occurs most frequently in the small joints. Gout is more common in the aged, while rheumatism is more prone to affect those in the most vigorous decades of life. The duration of gout is usually longer than that of rheumatism and the depression of spirits and melancholia are more of a feature in gout than in rheumatism. Rheumatism is a specific disease, while gout is a condition due to the retention in the system of morbid metabolic products, hence both diseases may, and very often do, coexist; but this relationship also occurs between gout and other diseases. In almost any state in which the temperature is high or continuous, gout exists as a complication.

It has been claimed that pain is of a different character in the two diseases, but this is probably more or less fanciful, though absolute rest will give more relief to rheumatic than to gouty pains. Rheumatism is apt to be associated with circulatory disturbances, while gout is apt to be associated with digestive disturbances. Tophi and Heberden's nodes are the evidences of gout.

Most conclusively, however, the salicylates or salicin will relieve the pain in rheumatism. They intensify the pain in gout.

It is not usually difficult to decide between sprains or bruises, dislocations, fractures, or other traumatic injuries and rheumatism. Here the history of the accident together with the examination will make it a simple matter.

Tuberculous joint disease is often mistaken for rheumatism, and in the early stage it may be difficult to decide, especially if there are no collateral symptoms to guide one. After the disease has existed for some time it is usually a simple matter to differentiate them. Rheumatism is polyarticular, usually associated with circulatory disturbances, and is relieved by salicin; while tuberculous arthritis is usually monarticular, is accompanied by other evidences of tuberculosis and is not benefited by salicin or the salicylates.

Osteitis, periosteitis and bursitis are traceable to injuries and can usually be differentiated by the history, and always by the reaction to salicin. Neuritis and neuralgia follow the course of nerve trunks.

The peculiar dislocations and knobby deformities of arthritic deformans are unlike rheumatism. They are symmetric, obstinately rebellious to treatment and have for their concomitants peculiar nervous symptoms which do not associate with rheumatism. Gonorrheal arthritis follows a primary urethritis and is monarticular. There are, moreover, two essential features in which rheumatism differs from all other arthritides; the character of the temperature and the peculiar odor of lactic acid so often noticeable in the perspiration. The temperature will distinctly rise as each new joint is involved and decline as the joint becomes less painful. This is leaving out of consideration the results of treatment.

Rheumatism is the only disease in which there is an odor like that of sour milk and in which salicin or the salicylates will give prompt relief to the pain. A rheumatic joint is, of course, likely to present a characteristic appearance, but as other conditions may present a similar appearance it has no diagnostic importance.

It must also be borne in mind that rheumatism often complicates or is complicated by any of the other arthritides, or indeed, more than one of them, and then only the rheumatism would be relieved by the specific agent.

In addition to affecting the articulations, rheumatism often occurs either primarily or secondarily in any part of the body where cartilage exists; most usually the heart, lumbar muscles, larynx, and aponeuroses of any of the voluntary muscles. In each case the symptoms are those due to inflammation and pressure. Fortunately it is very rare indeed that there is not also some arthritis present which will assist in making the diagnosis.

Before discussing the treatment it will be necessary to state that the disease is acute, subacute or chronic, in accordance with the clinical manifestations. While the acute and subacute varieties respond readily to treatment, chronic rheumatism cannot be cured by specific treatment. Chronic rheumatism is more than rheumatism. It is principally fibrous tissue formed as the result of the long-continued presence of an irritant; the rheumatic germ if we admit such to be. This is the exception alluded to in the beginning of the paper.

Salicin has the same specific action in rheumatism that iron has in anemia, mercury in syphilis, or quinin in malaria. It must be given in doses of sufficient size, for the failures attributed to it are due either to the fact that the drug has been prescribed for other diseases than rheumatism or that too small doses have been used. There is no essential difference between salicin and the salicylates, except that salicin may be used in larger doses, and does not disturb the stomach. It is also free from the injurious effect on the heart for which some observers have blamed the salicylates. It is probable, however, that this is, at least, an exaggeration.

The initial dose of salicin in any case of rheumatism of ordinary severity should be 1.3 gm. (20 grains) an hour, and this continued until the pain is relieved; or if the dose proves to be insufficient, then it should be increased to 1.6 gm. or 2 gm. (25 gr. or 30 gr.) and this dose kept up until relief is obtained. If there is still no decided amelioration of the symptoms, it is either not rheumatism or it is complicated with some other condition, and it becomes necessary to revise the diagnosis. However, if the case is one of uncomplicated rheumatism, and the pain be markedly relieved or entirely controlled in from six to twelve doses of the size mentioned, as is usually the case, the intervals of administration should be increased to two hours, and this kept up for about six doses, and then a dose of half the size used at the same interval, and this continued until either all the symptoms (such as swelling, stiffness, etc.) entirely disappear or the symptoms exacerbate, due either to a new joint becoming involved or the original one flaring up again, when the initial dose and same treatment should be repeated.

After the rheumatism and its causative factor have been removed, the stomach will no longer tolerate the remedy, but will exhibit symptoms of acute gastritis, which will at once disappear when the remedy is withdrawn. It appears to be simply a chemic reaction between the poison of the disease and the remedy, one neutralizing the other in the human body, which is practically a test-tube and is sensitive to the action of either the toxin of the disease or the remedy, either of which acts as a poison when in excess, and either of which is capable of exactly neutralizing the other.

Experience has shown that the doses mentioned are the quantities usually necessary to produce this neutralizing effect, but there is no reason why they should not be increased if necessary. Contrary to this, it might be possible to control a very mild case with smaller doses.

The doses mentioned refer to salicin. The doses of the various salicylates are from .13 to .78 gm. (2 gr. to 12 gr.). They are all more irritating to the stomach, even in rheumatism, than salicin, though it does sometimes appear that they act more promptly than salicin in relieving the pain, but even then they have to be withdrawn and salicin substituted in a short time. The patient should be confined to bed, or at least kept perfectly quiet until all inflammatory symptoms disappear. However, this need not concern us, for salicin, even in therapeutic doses, is very apt to cause somnolence and slight stupor, which will disappear when the remedy is discontinued.

Unfortunately, one attack of rheumatism does not confer immunity to subsequent infection; but, on the contrary, once a rheumatic always a rheumatic; this is probably due to germs or their spores lying dormant in the body and developing when resistance is lowered sufficiently. The secondary effects of rheumatism will disappear when the cause is removed. The complications must be treated on their merits.

A NEW METRIC MEDICINE GLASS.

BY

M. I. WILBERT, Ph.M.,
of Philadelphia.

Apothecary to the German Hospital, Philadelphia.

In an article on "Popular Dose Measures, and their Relation to the Use of the Metric System in Prescription Writing," published in *American Medicine*, February 15, 1902, there is described, and figured, a tumbler-shaped metric medicine glass that has been in use in the German Hospital, Philadelphia, for a number of years.

A series of experiments that were made some time after the publication of that paper, led to the conclusion that this medicine measure, in common with all measures of its particular type, was not as accurate as one might wish, and that owing to the comparatively wide area of the base, it was difficult indeed to measure, even approximately, the smaller quantities required. This inherent defect of all tumbler-shape measuring glasses will be more appreciated when the fact is recalled that one and two teaspoonful doses are prescribed relatively more frequently than any of the larger quantities.

In summing up my experiments with dose measures, it occurred to me that a medicine glass having a comparatively small diameter at the lower gradations would be more desirable, and would have some important advantages over the usually wide or squatty tumbler-shape measures now in use.

After considerable discussion as to the feasibility of making a moulded, conical glass that would be sufficiently inexpensive to be used as a medicine glass, and after submitting several models and offering a number of suggestions, we were finally successful in inducing one of the large manufacturers of hollow ware to undertake and make for us a moulded glass that would conform to our ideas and requirements.

The resulting medicine measure, a picture of which is appended, is of inverted cone-shape, with a heavy base or foot. It is 75 mm. high, over all, and has an inner diameter of 50 mm. at the lip, while at the base the inner diameter is but 10 mm. At the one teaspoonful mark, which is 25 mm. above the bottom, the inner diameter of the glass is about 20 mm., while at the two teaspoonful mark, 35 mm. above the bottom, the diameter is but little more than 27 mm.

Specimens of this medicine glass shown at the meeting of the American Pharmaceutical Association at Mackinac Island (August, 1903) were favorably commented on by a number of the members.

As will be noted this glass conforms to one of the most reasonable requirements for measures of capacity, and one that should be insisted on for all measures intended for liquids, namely, that the height of the contained liquid at any given graduation, should be greater than its diameter.

The evident advantages possessed by a graduated conical glass, to measure differing quantities of liquid, are so apparent that it is surprising indeed that this particular shape has not been suggested or used before as a popular dose measure.

In actual practice these glasses have proved to be even more satisfactory than was at first expected. In addition to

being infinitely more accurate as dose measures, particularly for the one and two teaspoonful quantities, they also facilitate the administration of doses of liquid medicines. This latter is due to the fact that the short sloping sides of the glass make it possible to bring the edge of the glass to the lips of the patient without slopping or spilling any of the contained liquid, while the comparatively wide mouth of the glass facilitates drinking from it. In addition to this the glass has no sharp corners and is therefore very readily cleaned and easily kept clean.

The most surprising advantage, however, is the durability that the glass has been demonstrated to possess. This particular shape has been in use at the German Hospital, Philadelphia, for nearly a year, and during that time, despite the fact that there has been a decided increase in the number of patients treated, we have broken less than one half the number of medicine glasses that were used for a similar period of the previous year. This is all the more surprising as it had been argued that a glass having a foot like a goblet, would necessarily be more fragile than one having straight sides. The manufacturers themselves have become so impressed with the advantages of this particular glass that they are now about putting on the market a medicine glass, graduated in drams and ounces, having the same style and shape.

In reference to metric graduations, it may be well to say that comparatively few physicians appear to appreciate the fact that the ordinary household utensils, ordinarily used as medicine measures, really conform, very closely, to metric quantities and do not even approximately correspond to the usually accepted equivalents of drams and ounces. The average teaspoon, for instance, will hold, when even full, almost exactly 5 cc., or about 30% more than the usually accepted equivalent, one dram. The tablespoon, on the other hand, seldom exceeds the usually accepted equivalent, or about 15 cc., and very seldom, if ever, holds more than the equivalent of three teaspoonfuls. It is true, that many physicians have themselves discovered this discrepancy and found that the average two or

four-ounce bottle, instead of holding 16 or 32 doses of one teaspoonful, respectively, as usually supposed, only holds 12 or 24 of such doses, when measured by means of the ordinary teaspoon. The equivalents, therefore, that have been adopted in France, Belgium, and other countries, where the metric system of weights and measures has been thoroughly established, are not arbitrary ones, chosen to fit in with that particular system, but are based on fact and experiment, and may well be borne in mind by all, even such as do not use the metric system in their routine work.

Considerable attention is being directed at the present time to the unification of standards of strength and quality, particularly of the more potent drugs and their preparations. Some attention has also been paid to the unification of doses and dose measures, so that, probably in the near future, we may have some international agreement on the equivalents to be used for the various household utensils used as dose measures, very much similar to the recommendation adopted by the recent "International Conference for the Unification of Potent Drugs and Preparations" in regard to drops and droppers. This item in the accepted protocol, it will be remembered, was a recommendation to adopt a normal drop measure or tube, the exterior diameter of the dropping surface of which should be 3 mm. and deliver 20 drops of distilled water to a gram or cubic centimeter (at 15° centigrade). In the meantime, however, while we are waiting for such action to be taken it may be well for physicians to recognize, or remember, the fact, that a very serious discrepancy does exist between the quantities usually regarded as a spoonful by them, and the quantities that are measured out by attendants or patients, either with a tumbler-shape medicine glass or the more generally used spoon. This discrepancy may, and probably does, account for a very large proportion of the so-called idiosyncrasies, abnormal susceptibility or, on the other hand, nonsusceptibility, to many of the more potent medicaments on the part of some patients, and certainly does not tend to foster accurate or close observation or to promote the progress of therapeutics along rational lines.

Free Hotel for Chicago's Cripples.—A summer resort for the exclusive patronage of the children of the Crippled Children's School, of Chicago, will be opened this summer near one of the Wisconsin lakes. To these who are unwelcome at the hotels built for the more fortunate the proposed summer resort will be a Saratoga, only during July and August the guests will pay nothing. The hotel is to be built by the Crippled Children's Vacation and Lunch Association. So soon as the site has been settled on, a hotel or "country house," equipped to meet the especial requirements of the cripples, will be built, and no expense spared to add to its comforts and conveniences.

"The Champion Fit Thrower of Harlem."—It is stated recently that on a public street in New York a man was seen to fall apparently with a convulsion. A crowd of curious persons gathered about him, many of whom were women, who expressed sympathy for the unfortunate man; an ambulance was ordered, and when the ambulance surgeon saw the man he recognized him as one known as the "champion fit thrower of Harlem." The bystanders, especially the women, were angered and called the surgeon a "brute," who, yielding to their wishes, took the man to a hospital. Various devices were adopted there to prove that the patient was not in a genuine fit. He withstood the sharp jabs of pins and the torture of fire without a wince, but when one of the surgeons suggested putting the man into a scalding hot bath he jumped from his cot and tried to flee from the room. Then he acknowledged the sham, and was sent, a prisoner, to jail.

Inoculation of Swine to Prevent Cholera.—Another valuable antitoxin has been discovered as the culmination of a long series of experiments, extending over a number of years, conducted by the Department of Agriculture. The animal industries of this country will probably be as greatly benefited by the preventive inoculation of swine for hog cholera as by any discovery in this domain that has been made in recent years. The basis of the immunity experiments has been the use of attenuated and disease-producing liquid, or dried blood, taken from infected animals, or the use of this blood mixed with blood from immune animals, in which the immunity has been increased by the injection of large doses of disease-producing blood obtained from hogs known to have the disease. The experiments have established the fact, that animals once thus immunized against this disease will resist repeated large doses of disease-producing blood, and also subsequent exposure to diseased animals in the field.

ORIGINAL ARTICLES

THE DIARRHEAS OF INFANCY AND EARLY CHILDHOOD.¹

BY

THOMAS MORGAN ROTCH, M.D.,

Boston, Mass.

Professor of Pediatrics, Harvard University.

So much work has recently been done by pathologists and bacteriologists in connection with diseases of the enteric tract that it has seemed to me that the results of the work of clinical investigators in these diseases should not only be revised, but should be reported. This is especially necessary at this time when bacteriology needs the assistance of clinical observation to determine the questions of prognosis and treatment for diseases caused by certain special organisms which have lately come into prominence.

A word of explanation is perhaps called for as to the title of this paper, namely, "Diarrheas," especially as diarrhea is the name of a symptom of intestinal disturbance and not a disease. The word simply means abnormal peristalsis of the intestine caused by irritation of a part or the whole of the intestine.

The names which in the past have been used to represent the diseases of the enteric tract are now in the light of recent bacteriological research found to be wholly inadequate and often misleading. Striking examples of this statement are the terms summer diarrhea and dysentery, names commonly used and accepted everywhere, even by recent writers, and yet entirely unmeaning so far as representing any specific individual disease of the intestine and merely covering large and indefinite groups of enteric disturbances. If, however, we endeavor, in discussing these names, to adopt more appropriate terms derived from our knowledge of the various pathological conditions which have been found in the intestine we are at once met with greater difficulties, and are forced to acknowledge that we are little better off than when we used the old names of symptoms to represent actual diseases.

Our knowledge of the diseases of the intestine in infants is exceedingly limited, and yet if we expect students in different parts of the world to understand what disease is meant when it is being studied in connection with the writings of others, it is very necessary that some common nomenclature which can be accepted all over the world should be adopted provisionally. For this reason, in 1894, the American Pediatric Society adopted a provisional nomenclature of these diseases, drawn up by Dr. Holt and myself, and as we knew that only approximate conclusions as to the actual lesions which existed could be drawn clinically, we concluded that a practical clinical diagnosis should be made according to the region of the intestine in which the stress of the lesion existed rather than to attempt to designate all the pathological conditions which were present. In support of this view it is well to review the general principles which influence the symptoms and prognosis, and render the diagnosis of intestinal diseases exceedingly difficult, before attempting to discuss any one of them separately.

Clearing the ground in this way we may eventually be able to arrive at a clearer and more definite idea of what special disease is meant when certain names are used, and also learn to differentiate with greater success the individual members of the various groups, for this, in the future, will undoubtedly be of the utmost importance for intelligent and effective treatment.

In regard to the general etiology of the diseases of the intestine, it is now fairly well recognized that certain disturbances arise in the enteric tract which may be

designated as functional. The word "functional" is used here simply in the meaning of disturbance of the function of the intestine without known lesions. These disturbances may be due to nervous conditions, such as fright and dentition, to simple indigestion of food acting as a foreign body in the intestine, or to certain elements eliminated in the intestine which by irritation may not only produce certain symptoms, but which also later may render the tissues vulnerable to bacteria. This functional group of intestinal symptoms represents a prominent and important peculiarity of all diseases occurring in infancy, and one which would naturally be expected to assert itself at this early period of development by a great variety of clinical pictures, namely, symptoms produced by reflex causes, such causes not necessarily being primary in the intestine. By reflex we understand simply peripheral irritation with a resulting action.

In the case of eliminated elements we merely know that the symptoms seem to be produced by morbid products eliminated from the blood by the gastroenteric tract, as, for example, those in the diarrhea occurring in measles. This special etiological factor can be spoken of under the term eliminative, and this group of reflex intestinal disturbances, whether of nervous, digestive or eliminative origin, are all non-inflammatory, and may be classified under the term functional.

In counterdistinction to this great variety of functional diseases, which are especially prominent in infancy, is another group of intestinal disturbances which are caused by specific organisms. These organisms either of themselves or through their toxins may produce certain diseases of the intestine which we call *organic*, using the word "organic" simply in the sense that in these diseases we have recognized known lesions.

Allowing that the term inflammatory has never been explained in a thoroughly satisfactory way or based on unquestioned facts, I have found it clinically best to use it provisionally as of great aid in simplifying our nomenclature when discussing this organic group of intestinal disturbances. With this understanding, the organic group of intestinal disturbances may be divided into *non-inflammatory* and *inflammatory*, so far as the symptoms are concerned, although the determining line between these two conditions is at times very doubtful.

The general pathological anatomy of the gastroenteric tract of infancy is essentially that of the ileum and colon. Again, in the cases in which the more severe lesions are present, the stress of the lesion is usually in the lower ileum and colon, and very frequently in the colon only. The terms ileo-colitis and colitis seem, therefore, to have a provisional place in our nomenclature in place of the crude and misleading terms summer diarrhea and dysentery.

The great number of lymphatic nodules and the abundance of lymphatic plexuses are the principal anatomical conditions which influence the pathology of the enteric tract in early life. It is also noticeable that the pseudo-membrane in ileo-colitis may often be extensive, yet sloughing or perforation are exceedingly rare the younger the individual.

The number of flora which exists in the intestinal tract is very numerous and the varieties have not all as yet been differentiated. It is therefore possible that there may be in a bacteriological sense more diseases of the intestine than are at present recognized and that up to the present time we have from a clinical point of view been diagnosing and treating groups of diseases rather than special members of these groups.

There is little doubt that the bacteria may find their way by means of the stomach to the intestine and that the acid secretion which they meet in their way through it is not sufficient to prevent their arriving alive in the intestine. It has been shown by Knox and others that live bacteria may enter the intestine in water as well as in milk and other carriers. It is also commonly accepted

¹ Read before the Yale Medical Alumni Association, February 10, 1904.

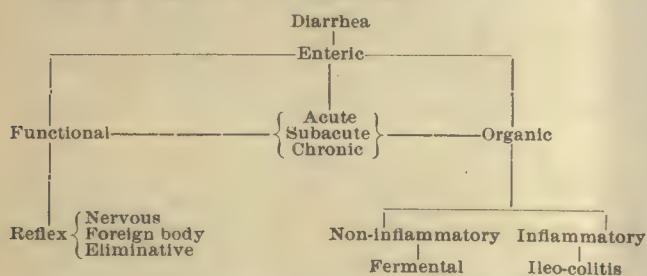

that the bacteria which are found in the intestine when it is in a normal condition do not necessarily cause any abnormal conditions, but that when the intestine has become irritated from any cause, bacteria are able to penetrate its mucous membrane, may become noxious and produce abnormal conditions of a serious nature.

It is now well known that vomiting as a symptom is often very misleading in infancy, so far as a differential diagnosis between the stomach and the intestine is concerned, and that in certain disturbances of the intestine vomiting occurs without disease of the stomach, showing that there is no characteristic symptom of gastric disturbance. On the other hand, the one specific symptom which points toward disease of the intestine is diarrhea, and the only symptom which as a rule can be relied on in diagnosing enteric disturbances is diarrhea. We must understand that marked diarrhea may exist during life and no lesion be found at the autopsy; that there may be serious lesions and yet no blood appear in the dejections and that blood may appear in the dejections and yet no serious lesions exist, the hemorrhage being only that comparable to epistaxis; also that serious intestinal symptoms during life are often proved at the autopsy to have been produced by no pathological lesions while grave lesions may be found at the autopsy when the intestinal symptoms during life were very mild. It is also to be noted that intestinal discharges are often very misleading in making a diagnosis.

Classification and Symptomatology.—Diarrhea or abnormal peristalsis is closely connected with all known clinical diseases of the intestine and in saying this I have, of course, set aside the various developmental conditions and conditions associated with constipation, for the reason that they have, so far as our present knowledge of this class of cases is concerned, no place in this discussion. It must also be understood that although the most frequent time for the occurrence of diarrhea in infants is during the summer months yet that this is only by comparison and does not imply that diarrhea may not occur at any time in the year and in any climatic surroundings.

Table A represents in tabular form a provisional nomenclature explaining what has just been said.

TABLE A.—PROVISIONAL NOMENCLATURE OF DISTURBANCES OF THE INTESTINE IN INFANCY REPRESENTED BY THE SPECIAL SYMPTOM DIARRHEA AND USUALLY SPOKEN OF AS SUMMER DIARRHEA OR DYSENTERY.

Functional.—Under functional are classified certain nervous disturbances, represented by diarrhea, which occur presumably in infants because their nervous system is so easily affected and is so unstable and undeveloped, that without any known lesion, exaggerated peristalsis causing diarrhea may arise from heat, cold, fright and like causes in no way connected with organisms. In the same way foreign bodies such as food or by eliminated irritants may by simple reflex irritation cause such nervous disturbances as to produce diarrhea. In these cases either the small or the large intestine or both may be affected and so far as we know the mucous membrane is either normal or simply hyperemic. There is more or less serous exudation in the intestine, but intestinal decomposition, inflammation, pathological lesions or causative pathogenic organisms are not present pri-

marily. As a rule there is not much abdominal pain and the diarrheal discharges are small in number and not very large. There may be a certain amount of restlessness, pallor and exhaustion. There is occasionally vomiting evidently from reflex irritation, but it is rarely extensive. The temperature is as a rule not raised or is raised very slightly. The pulse is rather weak and is somewhat accelerated. The odor of the discharges is somewhat increased, but not excessively so; there is usually a good deal of flatus. The color of the discharges is lighter than normal but is seldom green. These symptoms, unless they are exaggerated by a recurrence of the cause, by improper food or by bad treatment, usually disappear in a few days on removal of the cause of the nervous disturbance.

Very little is known about the eliminative causes of diarrhea but they seem to represent a conservative effort of nature to dispose of toxins resulting from chemical or bacteriological disturbances in various parts of the body.

There are also certain cases of intestinal indigestion which have not yet been proved to have any pathological lesions or to be caused by organisms and which therefore must be classified as functional. The rapid recovery of the acute form of these cases of indigestion, following a simple laxative and by the regulation of the diet, is so marked that in them we would hardly expect to discover a specific organism as their cause. It is in the chronic form of functional disturbance of the intestine that we should in the future endeavor to determine by careful research whether some specific organism is not involved in the disturbance and is preventing recovery, for as I have already stated although these disturbances may arise in the intestine primarily from other causes than a specific organism, yet, after certain periods of irritation, the intestine becomes vulnerable and infection may take place either from one organism or from a number. It is this class of cases which is least understood and which offers a great field for future investigation.

Organic.—Having discussed the general principles of the disturbances of the intestine represented by diarrhea and explained the class of cases which is understood to be classified under the term functional we can in like manner take up the organic class which includes:

(1) The non-inflammatory cases represented by toxic conditions produced by bacteria or their toxins and (2) the inflammatory cases. In this sense the organic diseases of the intestine may be divided into two groups. (1) *Fermental* which represents the non-inflammatory cases and (2) *Ileo-colitis* which represents the inflammatory cases.

Fermental.—The fermental class holds a position midway between the functional forms of intestinal disturbances and the organic with its pronounced lesions. It includes conditions which arise from acid fermentation and albuminous decomposition and which are produced by microorganisms. The disturbances which arise in this class represent the greater portion of the diarrheal diseases which occur in infancy, especially during the warm months of the year, though they may occur at any time in the year. In these cases the condition of the mucous membrane may be normal or there may be a desquamative catarrh. The process may go no farther, or it may be followed by inflammatory changes in the intestinal mucous membrane. The symptoms of fermental diarrhea may be acute, subacute or chronic.

Acute Fermental Diarrhea.—The group of symptoms which represents acute fermental diarrhea is in all probability produced by a variety of organisms, some of which have been differentiated and some have not. It is well, however, to look clinically upon the symptoms as a group, in order that we may be aided in differentiating this class of cases without marked intestinal lesions from the more serious class in which marked lesions are found. This does not necessarily mean that there is a sharp distinction between the fermental diarrheas and

those diarrheas which occur in the class of inflammatory cases, which we shall consider later and which have been already spoken of as ileo-colitis. In fact, we have considerable evidence that, given an infection of the intestine, it is merely a matter of degree or of length of time as to whether one class or the other, fermental or ileo-colitis, is produced. Of great significance in these cases is the temperature, which in the fermental class of cases evidently represents a toxic condition from its sharp rise and after 24 to 48 hours speedy decline by crisis, but when the process has gone further, as in the cases of ileo-colitis, the temperature does not fall to normal rapidly, but continues raised for a number of weeks and regains its normal line by lysis. In other words, the temperature chart gives us the most valuable aid in differentiating between a form of intestinal disturbance represented by a lack of marked pathological changes in the mucous membrane and one which is represented by marked pathological changes. Fermental diarrhea is in its onset represented by a high temperature and often active vomiting. After a variable period of general discomfort and restlessness diarrhea sets in. The diarrhea is very variable and, although it may be accompanied by much prostration and various nervous disturbances, yet it may disappear after a few days; in other instances, especially in the warm weather, it may last for months. The color of the discharges is commonly some variety of green or greenish-yellow and the odor is often very offensive, sometimes being excessively sour, one which is supposed to arise from acid fermentation, and at other times the extremely foul one of albuminous decomposition. The discharges are generally accompanied by considerable pain and a large amount of gas; they are usually not more than a dozen in number, and are large in amount in comparison with those which occur in ileo-colitis. As a rule, there is no blood, excepting in very small amounts; there is also more or less mucus. There is not, as a rule, much abdominal tenderness or tenesmus of notable grade.

The onset of fermental diarrhea however, is so often characterized by the toxic symptoms of a sudden rise of temperature, followed after a day or two by a normal temperature, that when we meet with this occurrence we are usually justified in eliminating the inflammatory and more serious intestinal lesions, though we are not justified in concluding that the same organism may not under certain conditions go further and produce marked lesions of an inflammatory character.

In some of the more severe cases certain special symptoms become so prominent as almost to produce a different type of the disease. Most important of these are excessive vomiting, attacks of hyperpyrexia and extreme restlessness and insomnia. There is usually rapid and great loss of weight. The symptoms are often so severe that the disease has a serious aspect, but in a considerable number of cases after the intestine has been thoroughly emptied, the temperature falls and the nervous symptoms subside. In cases which are not prolonged by fresh irritation or by unwise treatment, recovery often takes place quite rapidly. Albuminuria occurs in about 15% of all cases; casts, usually hyaline or fine granular, occur in about 60% of the cases of albuminuria. (Morse.) The renal condition in these cases is a degenerative one and not a true nephritis. This class of cases with intense symptoms is often exceedingly difficult to differentiate as this same set of symptoms may represent the initial stage of a number of diseases, especially the acute exanthems.

Subacute Fermental Diarrhea.—Another form of fermental diarrhea is represented by the subacute variety which with its slow onset, without vomiting and with the infrequency of the discharges is not as a rule difficult to differentiate from other acute diseases with heightened temperature and from the acute functional intestinal disturbances in which latter there is usually an absence of fever and very rapid recovery. The diagno-

sis, however, in these cases, if we have the symptoms only to rely upon, must often be held in abeyance for a number of days.

Chronic Fermental Diarrhea.—The cases of acute fermental diarrhea are at times prolonged for many weeks and even months and thus produce a chronic form of diarrhea which so far as I can determine does not necessarily signify that an ileo-colitis is present. This chronic form occurs especially in infants who are suffering from rachitis, syphilis, and general tuberculosis, also in those who have chronic bronchopneumonia.

Ileo-colitis.—The inflammatory form of intestinal disturbances, ileo-colitis, merely represents a large group of diseases each presumably having its own specific organism as a cause and possibly in the future its own pathological findings. Under this term are included all the more marked and grave lesions of the intestine. Eliminating however the cases of ileo-colitis which are produced by the tubercle bacillus, the typhoid bacillus and the *Amoeba coli* we are left with a group of intestinal lesions which probably represents a number of different diseases from an etiological standpoint. These have as yet only been partially differentiated and therefore it will be interesting in a general way to speak of these pathological conditions. It is this group of diseases which up to the present time has been spoken of under the term dysentery. I have already stated that the term dysentery should be dropped from our nomenclature; it merely means difficult defecation and must therefore represent the symptom tenesmus which though definite as a symptom may or may not occur in connection with marked pathological lesions or necessarily with any lesion at all. By using the term ileo-colitis as representing a group of symptoms we avoid the necessity of understanding by this term any one disease or symptom and this term can cover certain organic inflammatory diseases of the intestine with more or less pronounced pathological lesions.

On making a careful study of the various lesions which occur in this class of cases I have found that it simplified the subject to divide them into:

1. Simple catarrhal inflammation which includes the non-ulcerative form of follicular inflammation.
2. Follicular inflammation with ulceration.
3. Pseudomembranous inflammation.

All these three forms differ essentially in their prognosis and they are so often represented by the same symptoms that they can be differentiated only in the most general way. A symptom common to all these pathological conditions is found in the temperature, which, usually high at the onset, is as a rule moderately raised throughout the whole course of the disease and falls after a number of weeks by lysis. In this way we can usually differentiate these diseases from the non-inflammatory conditions and especially from the fermental class of cases in which, as I have already stated, the temperature falls by crisis.

The pathological lesions found in connection with the catarrhal non-ulcerative follicular and the ulcerative follicular approach each other so closely and the symptoms are so similar that a distinction between them is usually impossible.

The pseudomembranous form of ileo-colitis may be primary or secondary. The primary form represents what is usually spoken of as epidemic or sporadic dysentery. The secondary form is that which follows certain infectious diseases. In the pseudomembranous form of ileo-colitis the ileum and colon are chiefly affected. The disease is characterized by the presence of a membrane on the surface of the mucous membrane which extends into it and is due to a combination of fibrinous exudation and necrosis.

These cases of ileo-colitis may be either acute or chronic.

Acute Ileo-colitis.—The symptoms of the various forms of acute ileo-colitis vary greatly, but in a general way

they can be recognized by a group of symptoms which differ from those of the fermental diarrheas. The symptoms, however, of the different forms of ileo-colitis are very unsatisfactory and unreliable for differential diagnosis. The onset may be preceded by a fermental diarrhea or it may be acute from the beginning and have prodromal symptoms of not more than a few hours. The temperature is elevated, the pulse accelerated and there is a rapid loss in weight and strength. The discharges vary greatly, from 10 to 20 or even 50 in the 24 hours, and are comparatively small in amount. When the lesions happen to be in the rectum there is tenesmus both before and after a discharge and in the beginning of an attack an almost constant desire to have a movement. The discharges contain fecal matter at first, but soon become small, and consist of mucus, sometimes with pus, blood and shreds of membrane. The odor may be very offensive, but when the mucus predominates there is very little odor. The color and consistency are extremely variable. The general consistency is lessened and the color is a mixed green, brown and yellow. Blood, when present, is usually from congestion of the bloodvessels and from straining rather than from ulceration, so that we cannot determine from the presence of blood whether ulceration is present or not. The abdomen is soft and not tender or distended according to the time of the disease early or late when we see the patient.

Table B represents the chief general differential symptoms between acute fermental diarrhea and acute ileo-colitis.

TABLE B.—DIFFERENTIAL SYMPTOMS IN ACUTE FERMENTAL DIARRHEA AND ACUTE ILEO-COLITIS.

Acute fermental diarrhea.	Acute Ileo-colitis.
(a) Small intestine mostly.	Large intestine mostly.
(b) 10 to 12 discharges.	10, 15 to 50 discharges.
(c) No or little blood.	Blood.
(d) Mucus.	Mucus.
(e) No tenesmus.	Tenesmus.
(f) Not much abdominal tenderness and pain.	Abdominal tenderness and pain.
(g) No or slight lesions.	Lesions marked.
(h) Temperature high 104° F. for one or two days, and then falling sharply by crisis.	Temperature may be high at first (103° F. to 104° F.) but usually soon moderates (98° to 101° F.) and falls gradually by lysis to normal after some weeks.

In ileo-colitis there may be delirium and convulsions. Vomiting may occur at times. The urine is nearly always diminished in quantity, and sometimes contains a small amount of albumin, especially when the temperature is high. Casts may also be found. The renal condition in these cases is a degenerative one, and not a true nephritis. Acute nephritis is rare.

The clinical picture of all the inflammatory forms represented by ileo-colitis differs somewhat according to the lesions present; thus, it is usually found that in simple catarrhal ileo-colitis, when ulceration has not taken place, that the symptoms are milder and that there is apt to be vomiting. This variety begins to improve generally in one or two weeks, and may recover entirely in another week. In some cases, however, simple catarrhal ileo-colitis may be represented by symptoms of a very severe type, may run a rapid course, and may terminate fatally. When the inflammation is simple follicular without ulceration, the patients are very apt to recover.

When follicular ulceration has taken place, gastric symptoms are not apt to be present. The temperature is not as a rule high, and the course of the disease is rather slow, irregular, and prolonged. The patient fails steadily, and usually dies. A remission in the symptoms and an improvement in the character of the fecal discharges should lead us to infer that ulceration has not taken place.

Pseudomembranous ileo-colitis is rare in infants, but when it occurs it is the most severe of all the forms. The

temperature is high, 103° F., 104° F., or 105° F. There are apt to be blood and membranous detritus in the discharges. The progress of the disease is usually rapid and without remission, and death may take place in a week or ten days. Nervous symptoms, such as restlessness and delirium, are quite prominent.

I shall purposely omit the class of cases which is spoken of as cholera infantum, as so little is known about these cases, and as they may possibly be found later to be merely a severe form of fermental diarrhea.

The differential diagnosis of the different forms of ileo-colitis, which has just been discussed, from the fermental diarrheas depends chiefly on the continued heightened temperature, the more frequent discharges, the small amount in each, the presence of blood, and possibly of pus or membrane, and the tenesmus.

The prognosis of these cases of ileo-colitis when uncomplicated depends upon whether ulceration has occurred, in which case it is less favorable than when it has not occurred.

Chronic Ileo-colitis.—When the diarrhea has continued for some months after the acute symptoms have subsided the disease becomes chronic.

The pathological conditions in these cases are great thickening of the muscular tissues, pigmentation in the mucous membrane and very extensive ulceration.

Symptoms.—There may be no especial pain or tenderness and the temperature may be normal. The appetite often returns but the child does not gain in weight or it loses. The discharges are not so frequent as during the acute stage of the disease, falling to six to eight or even to two or three in the 24 hours. The discharges have a lessened consistency and contain mucus and undigested food. There may at times be exacerbations of the symptoms and the child is very apt to die of some intercurrent disease. The duration may be many months.

Conclusions.—The conclusions as to the diarrheal diseases occurring in infants which we were warranted in accepting up to 1897 were as follows:

1. There were no unvarying symptoms which as a group enabled us to diagnosticate special lesions in the acute cases or in the chronic cases and in the latter class it was not only impossible to determine which part of the enteric tract was affected but even to be able to state definitely that there was a primary specific disease of the intestine or even if there were marked lesions present.

2. In acute cases it was possible to determine usually whether the small intestine or the large was most markedly affected this being accomplished by the small number and comparatively large size of the dejections representing chiefly the small intestine, and the large number and small amount representing chiefly the large intestine.

3. That the temperature was of considerable aid in differentiating the non-inflammatory diarrheas represented by the fermental group from the inflammatory diarrheas represented by the ileo-colitis group; that is, absence of marked lesions in the former and presence of marked lesions in the latter; the temperature being high and falling by crisis in the former and high or moderate and falling by lysis in the latter.

4. That knowing where the stress of the lesion is situated, our treatment should be by the mouth in diseases affecting the upper part of the intestine and usually of the fermental class and by the rectum in diseases affecting the lower part of the intestine and usually of the ileo-colitis class.

5. That pus or pus and blood in the intestinal contents were usually of serious import as they pointed toward marked grave pathological lesions.

Bacteriology; Recent Investigations and their Clinical Significance.—What has so far been discussed in this paper is the knowledge regarding intestinal disturbances in infants which we had up to 1897, when bacteriological findings all over the world—notably in Japan—threw new light upon the subject.

Valuable pioneer work in the field of the diarrheas of infants was done by Booker many years ago, and his statement that his conclusions led him to believe that "no single organism is found to be the specific exciter of the diarrheas of infants" has been confirmed by the latest investigators of today. Time and space do not permit me to mention all the workers in this field, or the names of all the flora found in the enteric tract. The name Escherich will always be closely connected with observations which show that in the intestine of infants during health, the *Bacillus lactis aerogenes*, especially predominates in the upper part of the enteric tract, while the *Bacillus coli communis* holds the same position in the lower part.

It may, however, be said that in diseased conditions the difference between the flora in the upper and lower parts of the intestine is much less marked than in health. A great variety of bacilli had already been described as infesting the intestine of infants when Shiga's observations in Japan awakened new interest in and gave fresh impetus to the study of this class of cases. Thus I might mention the *Bacillus acidophilus* described by Moro and Finkelstein. A number of forms of bacilli pathogenic for man have also been isolated from the intestinal contents of infants suffering from diarrhea, and among others such pathogenic cocci as the *Staphylococcus pyogenes aureus*, *Staphylococcus pyogenes albus*, *Streptococcus pyogenes*, *Bacillus proteus vulgaris*, *Bacillus pyocyaneus*, and certain virulent forms of the colon bacillus.

In 1897 Shiga in Japan first isolated from the intestinal contents of patients suffering from so-called dysentery a bacillus which is called the *Bacillus dysenteriae* (Shiga). Shiga found that the *Bacillus dysenteriae* had many of the characteristics of the colon bacillus, but differed from it in a number of ways, such as in its failure to produce gas from the fermentation of sugar.

Following Shiga's discovery, Flexner in 1900 found this organism to be the cause of epidemic dysentery among the American soldiers in the Philippines. In connection with Flexner's work, that of Strong in Manila should be mentioned and soon after Kruse in Germany found the *Bacillus dysenteriae* in the intestinal contents of patients suffering from the so-called "asylum dysentery." This bacillus is now well recognized all over the world. It has been found in the diarrheal diseases occurring in China, Constantinople and other parts of Europe. It has been successfully isolated in America by Vedder and Duval in epidemics of dysentery and also by Bassett and Knox in connection with their valuable work in search of this organism in milk and drinking water.

According to the results obtained by Knox, since the *Bacillus dysenteriae* is related biologically to the colon and typhoid bacilli, which are usually conveyed to man through water, it is logical to suppose that it may also be carried in this way as well as in milk. As cases, however, have occurred where only sterile water and sterile milk were used as food it would seem that carelessness on the part of the attendants can account for a certain number of cases. Another cause of danger is infection from flies and other insects. Zahorsky in St. Louis and Park and Dunham in the Seal Harbor epidemic have also isolated this bacillus. Advanced and most valuable work has been carried out in the Bronx epidemic by Park.

Wollstein and others have shown that the Shiga bacillus is not present in the intestinal contents of healthy infants nor in the newly born. Wollstein from a study of 114 cases established the identity of diarrheal cases occurring in the winter with those in the summer; in most of these cases the Shiga bacillus was found when there were both blood and mucus; in many of the negative cases there were large quantities of mucus and undigested food, but no blood.

As stated by Flexner in a paper read before the Pediatric Society, in Washington, in 1903, Shiga con-

ceived the idea that among the host of organisms that can at all times be cultivated from the diseased intestine, if the organism causing the pathological lesions was present that the chances were that it would produce such changes in the blood as to cause agglutination, and would thus be proved to be the cause of the lesions. He observed that by means of the so-called Widal test it was possible to pick out of all the organisms which might be isolated in cultures from the discharges from the diseased intestine, that particular one which probably was the cause of the disease. He worked with an epidemic of dysentery and discovered that in all cases a single organism could be picked out by means of this agglutination reaction. When he came to study the properties of this organism he found that it differed from all the previously identified bacterial bacilli. Then he found that it agreed perhaps best with the typhoid bacillus. It differed somewhat from the typhoid bacillus in certain points which permitted its detection and separation from that group of organisms. It was also found that not only was this bacillus of Shiga present, so far as could be determined by clinical tests, but that the blood-serum of the individual who had this bacillus in the intestinal mucosa reacted definitely and positively.

Flexner found that the organism was not easy to obtain, on account of its similarity to other intestinal organisms, from formed stools or from feces. His success depended largely upon the condition of the fecal discharges. If blood occurred with the mucus in the stools the organism was obtained with greater ease than when mucus occurred with an absence of blood. According to Flexner, in searching for the organism a difficulty arises from the fact that it is not so very different from the colon bacillus and from the typhoid bacillus, as observed under ordinary conditions, so that one who is not familiar with it might easily be led astray in his work and in his results.

Pathology.—It is well in this connection to remember that two of the forms which belong to the dysenteric group have been definitely differentiated.

(1) The bacillary form or ileo-colitis caused by Shiga's bacillus; and (2) the amebic form or ileo-colitis caused by the *Amoeba coli*.

The form of ileo-colitis which is caused by the *Amoeba coli* is usually the chronic, and is especially characterized by deep ulcerations, while the bacillary variety represented by Shiga's bacillus may produce both the acute and chronic conditions, but especially the acute.

Knox describes a number of cases in which in infants affected by Shiga's bacillus death occurred and an autopsy was obtained. The lesions were slight; the mucosa pale and thin; the lymphatic elements in the intestinal wall moderately enlarged, and the mesenteric glands swollen. In some cases, however, the colon was extensively involved, the mucosa being thickened and often the seat of more or less extensive ulceration, the ulcers beginning usually at the summit of the swollen solitary follicles. The mesenteric glands were hypertrophied.

No false membrane was found in any of the cases. Knox did not find the lesions to correspond to the symptoms in all cases, the epidemic differing widely in this respect.

The lesions occurring in the ileo-colitis of infants probably differ but little from those which occur in older individuals, the difference being more in the type which is mild, the graver lesions occurring much less frequently than in adults.

According to Park, if the lesions of the small intestine and cecum are suitably localized the corresponding mesenteric glands become secondarily infected and swollen as in typhoid. The spleen is never involved. *Bacillus dysenteriae* (Shiga) probably does not enter into the general circulation, at least such complications as pneumonia and osteomyelitis are not met with.

There is still so much pathological work to be done

before we can recognize as in typhoid and tuberculosis which lesions represent especial organisms in this large dysenteric group that any further discussion of the pathological findings would be out of place in a clinical paper.

During the past summer I had some special work done for me at the Infants' Hospital by Dr. Charles Hunter Dunn, but it would not be practical to speak in this paper at length of the technic used in this work for detecting the *Bacillus dysenteriae*. It should be mentioned however that in order to establish a proof that the organism isolated from a case was the cause of the disease in that case, it was considered necessary to fulfil the following conditions:

1. The organism isolated from any case should show an agglutination reaction with a stock serum obtained through the immunization of an animal with the same type of organism.

2. The organism isolated from any case should show an agglutination reaction with the blood of the patient in dilution of about 1 to 200 at some period of the disease usually after six or seven days.

3. Stock cultures of these organisms obtained from other cases should show an agglutination reaction with the blood of the case under investigation at some stage of the disease.

4. The organism isolated should show all the proper cultural characteristics.

Agglutination does not usually take place until the end of the first week except occasionally in dilutions too low to warrant positive conclusions. The dilutions should be at least 1 to 200. In very marked cases Dunn has obtained agglutination in dilutions of 1 to 5,000. The agglutination lasts for at least three weeks.

The technic employed in Dunn's work was essentially that suggested by Flexner, with certain modifications originating with Vedder and Duval.

The bacteriological part of the work was carried out in the clinico-pathological laboratory of the Massachusetts General Hospital of which Dr. J. H. Wright is the director. I mention these details because in order to arrive at proper conclusions the bacteriological findings must be in the hands of experts.

The number of cases examined was 61, and they were taken at random from a large hospital clinic. They were all cases of diarrhea and no attempt was made to pick out special cases, but every one was taken as it came, so that the bacteriological findings should be unbiased by any idea that the *Bacillus dysenteriae* or any other organism when found should belong more to one of the classes of intestinal disturbances which I have endeavored to explain than to another.

In all the 61 cases examined for me by Dunn, when the *Bacillus dysenteriae* was found, the organism isolated was the "Mannit acid type." This is not the type of the original Shiga, but both types have been found in some of the examinations made in this country. This "Mannit acid type" is the same as that found by Park in the Bronx epidemic, and the same was found by Dr. Wollstein in all but one of Dr. Holt's cases.

The differences in these two principal types are as follows:

(A) THE "SHIGA TYPE."

1. Agglutinates in high dilutions only with the "Flexner serum."
2. Does not produce acid in Mannit media.

(B) "THE MANNIT ACID TYPE."

1. Agglutinates in higher dilutions with the "Harris" than with the "Flexner serum."
2. Does produce acid in Mannit media.

All other reactions and unusual peculiarities are practically identical in the two types. That is, the *Bacillus dysenteriae* represents a group rather than a specific type, and the specific types of this group are A and B as just described. Two other strains have been isolated differing slightly in their reactions to certain sugars from the above-mentioned principal types.

The following organisms were isolated in pure culture as shown in Table I.

TABLE I.

(A) NON-PATHOGENIC.

Bacillus coli communis.
Bacillus lactis aerogenes.

(B) PATHOGENIC.

Staphylococcus pyogenes aureus.
Staphylococcus pyogenes albus.
Streptococcus pyogenes.
Bacillus dysenteriae (Shiga.)

Of the foregoing organisms the *Bacillus dysenteriae* was found fulfilling the conditions considered necessary to establish it as the cause of the disease in ten cases; in other cases when it was found, the proof of its causal connection was not considered conclusive, in default of satisfactory agglutination reactions, and these cases were therefore not included.

In the remaining 48 cases the bacteriological findings consisted chiefly in sugar fermenting organisms with the occasional occurrence of a few pathogenic organisms. The 61 cases examined were clinically classified as tabulated in Table 2.

TABLE 2.

- | | |
|---|---------|
| 1. Chronic intestinal indigestion | 4 cases |
| 2. Fermental diarrhea | 48 " |
| 3. Ileocolitis | 9 " |

Of the cases classified as fermental diarrhea 37 were fairly typical. In the other 11, small specks of blood were present in the intestinal contents but they resembled clinically fermental diarrhea rather than ileocolitis. In the nine cases of ileocolitis the clinical picture was constant. The intestinal contents consisted chiefly of blood and mucus.

In the 48 cases of fermental diarrhea, were found as tabulated in Table 3.

TABLE 3.

- | | |
|--|----------|
| 1. No causative organism | 45 cases |
| 2. <i>Bacillus dysenteriae</i> | 3 " |

In the nine cases of ileocolitis were found as tabulated in Table 4.

TABLE 4.

- | | |
|--|---------|
| 1. No causative organism | 2 cases |
| 2. <i>Bacillus dysenteriae</i> | 7 " |

In the four cases of chronic intestinal indigestion no causative organism was found.

The clinical aspect of the cases in which the *Bacillus dysenteriae* was found was that seven of the cases were representative of the typical symptoms of ileocolitis described in the early part of this paper. The onset was sudden, there was fever, vomiting, marked prostration, diarrhea and tenesmus. There were about 6 to 20 dejections in a day and these were at first watery and green with mucus and with specks of blood. After one or two days they consisted almost wholly of blood and mucus. The temperature was irregular and continued longer than it did in the cases of fermental diarrhea.

Abdominal tenderness was present in more than half of the cases. Three of the cases showed the symptoms of fermental diarrhea and in one of these the clinical picture was typical. There was a sudden onset, sharp rise of temperature, vomiting, diarrhea and a number of loose green dejections with a bad odor and consisting of curds and mucus but no blood. The temperature remained raised for only a short time and the recovery was rapid.

In the other two cases no history of vomiting at the onset could be obtained, otherwise they presented the same clinical picture as the one just described. In none of the three cases were there even specks of blood in the dejections.

SUMMARY.

1. The analysis of these 61 cases showed that the *Bacillus dysenteriae* proved to be the cause of 16% of all the 61 cases examined. 2. The *Bacillus dysenteriae* may cause either the clinical type known as fermental diarrhea or that known as ileocolitis. In the 10 cases in which this organism was found it caused the symptoms of fermental diarrhea in 30% and those of ileocolitis in 70%. 3. Although a causal connection may be demonstrated between the *Bacillus dysenteriae* and fermental diarrhea, it was so demonstrated only in 6% of the cases of fermental diarrhea examined. 4. On the other hand, the *Bacillus dysenteriae* is probably the most frequent cause of ileocolitis, as it was so demonstrated in 78% of the cases examined.

In Park's numerous cases in which the *Bacillus dysenteriae* was found, the type was acute and the prominent symptoms were diarrhea, pain and tenesmus. Blood usually appeared on the second day and was present in considerable or great quantity for from two to five days

and then disappeared either quickly or gradually. The mild cases in general lasted about two weeks and in the malignant cases the patients died in a few days.

It is therefore very evident from what I have previously said that a symptomatology outside of the bacteriological findings cannot as yet be relied upon.

Diagnosis.—The presence of specks of blood in the intestinal contents does not necessarily mean infection with the *Bacillus dysenteriae*, since in all such cases this bacillus was not found.

In regard to leucocytosis, according to the results of Warfield and Knox, a high or low count could not be regarded as of diagnostic value. The differential count, however, showed that while there was no change in the relative ratio of the white cells in the normal infant, in the simple diarrhea or in malnutrition, that as the case became more severe in type there was a progressive increase in the polymorphonuclear neutrophilic cells and a decrease in the small mononuclear variety, and that this polymorphonuclear leucocytosis took place in both cases of acute intestinal poisoning (the fermental class) and in the more severe form (the ileo-colitis class).

The distinction between fermental diarrhea and ileo-colitis is principally connected with the extension of the pathological process, and this depends upon the nature of the infecting organism and the severity of the special infection. Thus a severe infection with a certain organism might cause ileo-colitis in one case, when in another case a milder infection with the same organism might cause fermental diarrhea. In like manner, an infection with an organism not Shiga's might cause fermental diarrhea or ileo-colitis.

The infectious diarrheas are probably caused by a variety of organisms. The *Bacillus dysenteriae* has been proved to be one cause, though not yet the sole cause, but it can most often be connected with the condition corresponding to ileo-colitis.

In conclusion, we must admit that a careful analysis of the means at our disposal for making a clinical diagnosis of intestinal disturbances accompanied by diarrhea, does not permit us to say that an exact diagnosis of the especial disease can be made without a successful and definite bacteriological finding. We are therefore at the present time, when a specific or causative organism is not found in the intestinal contents and when agglutination is not obtained, in the same position, so far as diagnosis and treatment are concerned, as before Shiga discovered the *Bacillus dysenteriae*, namely, that we can usually differentiate diseases of the small intestine from those of the large intestine, but that we cannot name the disease or the intestinal lesion.

Prognosis.—The prognosis at present must rest on our earlier clinical knowledge. Pus in the intestinal contents is especially serious, and the degree of general sepsis in the especial case is to be carefully considered and estimated by clinical experience.

Treatment.—In regard to the treatment of these diarrheal diseases which depend upon infection, no great advance has been made. From what I have already said in regard to the diagnosis of these diseases, we really know so little concerning the especial organisms which cause the greater number of enteric diseases represented by diarrhea that we can merely, assuming that we treat these diseases somewhat empirically, say that our position is simply this: We can usually determine whether it is the small intestine or the large intestine which is affected. Looking at the conditions from this point of view, it is probable that success in treatment will be best when the treatment is through the mouth when the small intestine is affected, and through the rectum when the large intestine is affected. We can also, when the group of symptoms is at all typical, usually determine the fermental class of cases with the probability of slightly marked lesions, and the ileo-colitis class of cases when the lesions are more or less decidedly marked. The treatment in

these cases is almost purely symptomatic, for we certainly have not found from past experience that germicides can be introduced into the intestine which will either kill the organisms which are producing the lesions or counteract to any degree the effects of their toxins. We know that bismuth can pass through the whole course of the intestinal tract, and I have a specimen from an infant to which bismuth was given and in which at the postmortem examination it was found coloring the mucous membrane far down into the colon. It is, therefore, rational to give bismuth, always bearing in mind its limited therapeutic properties. Clearing the intestine of bacteria by laxatives, supporting the strength of the patient, and combating the nervous symptoms and hyperpyrexia are the chief indications, and about all that in the past we have been able to accomplish. It is possible that in the future, when we can determine by bacteriological findings which special organism is producing the especial enteric disturbances, that we may by the serum treatment accomplish good results, but this is said with a proviso that the symptoms are not caused by a mixed infection.

A word here will not be out of place in regard to the treatment of cases of ileo-colitis caused by Shiga's bacillus. In the main the serum treatment has not been especially successful, and according to Park the using of the serum in 30 characteristic cases of mild and severe ileo-colitis gave somewhat doubtful results. In these cases 20 cc. was given every day for three days, and the good results when they appeared were noticed in from 12 hours to 36 hours. Some of the cases of the Mannit fermenting type were just as severe as those of the Shiga type. Park states in regard to infection with the Shiga bacillus that he is convinced that whatever the Shiga bacillus does, it does early. How much damage the streptococcus and staphylococcus which are constantly present can add to the effects of other bacilli, is a point which should be kept in mind.

The serum treatment is, of course, experimental. It must be remembered at the onset that this serum attempts to deal not with the disease, the effects of which are due to poisoning, as is the case with diphtheria; hence it is not a serum which acts as a therapeutic agent alone. What we have to deal with is an organism, and the serum must be able to attack the bacteria themselves and bring about their destruction. We have a recent communication from Kruse, who thinks he has used the serum in adults in Germany with excellent effect. What this serum will do in the case of children is a matter of experience, but its good effects are most likely to be gotten if it is used early. If we wait until the symptoms are more severe, the outcome is doubtful. The serum then, for the best therapeutic effects, should be given early. The serum, as tested on animals, is very effective. It has rescued guineapigs from infection almost without exception. There is not much doubt but that many of the most serious symptoms and results which arise in the later stages of bacterial infection are caused by a mixed infection, and that so far as the Shiga serum is concerned, we do not have any especial evidence that it can be of much aid when the infection is mixed. We must also allow for the difference of the virulence of the organism in different epidemics and the difference in type in regard to the responsiveness to the serum of the especial type, Mannit or not. Recognizing the difficulty of making an exact diagnosis in the beginning of a diarrhea, we should appreciate the importance of treating at once even what seems to be a most simple form of diarrhea.

Doctor Leaves Bequest to His Faithful Horse.—The late Dr. John Gilwee, of St. Louis, left a clause in his will as follows: "In case that my horse Tarry, which I have used for nearly 23 years, survives me, I order that \$2,000 of my estate be placed in trust at 6% per annum, and said interest used for his feed, and shelter and care so long as he lives, and after his death said \$2,000 shall be divided among my legal heirs." "Tarry" outlived his aged master, whom he had served so long and faithfully, and he is now enjoying his reward.

EXAMINATION OF THE TEST-BREAKFAST.

BY

MARK I. KNAPP, M.D.,

of New York City.

In this article I use the terms "test-breakfast" (Ewald's) and "test-meal" synonymously.

A diagnosis of the condition of the stomach cannot be made unless a test-meal is given. Otherwise, the diagnosis is mere guesswork, and wrong guesswork is the rule. We can no more diagnose the condition of the gastrointestinal canal without exact examination than we can ascertain the refraction of the eyes without exact examination; and absolute diagnosis, in gastrology, is most important. No diseases are so quickly amenable to treatment as diseases of the alimentary canal, provided there are no organic lesions. Diseases of the gastrointestinal canal, which have lasted for years, not only have ultimately resulted in cure, but showed the good effects almost immediately after the proper diagnosis was made and the corresponding treatment instituted. The popular idea, unfortunately shared even by the medical fraternity, that chronic dyspepsias are incurable, is absolutely groundless, unless we persist in calling everything we do not understand "nervous dyspepsia," and do not take the trouble to learn more; for, a test-meal examination from which we are to glean the patient's condition is about the most difficult and time-consuming means we possess. I hope that the diseases described by me as *organacidia gastrica*¹ and *insufficiencia pylori*² will prove a step forward in the proper recognition and cure of chronic dyspepsias.

In the diagnosis of diseases of the alimentary canal we have to deal almost entirely with problems of chemistry, therefore the test-meal, by which we decide, must have all the qualities of a standard. And consequently the quality, quantity and time of the test-breakfast must never be left to arbitrary judgment. For a test-meal examination the patient must be prepared by not permitting the introduction into his stomach of any food or drink for the 14 hours immediately preceding the test-meal. The first question must be: Is the patient's stomach empty after such a long fast? Very often the answer is in the negative. And, were the patient permitted to have his test-breakfast at home, the very important knowledge of the condition of the patient's fasting stomach is denied us. Thus we may fail to recognize hypersecretion and minor degrees of gastric dilation. It is my routine practice, first to ascertain whether the fasting stomach is empty or not, and, if not empty, to ascertain the nature of its contents. Such routine has led to successful treatment in cases in which prominent predecessors failed. Invariably, the stomach-tube must be introduced and the condition of the stomach ascertained before the test-meal is given for the first time. In introducing the tube, watch carefully whether it goes into the stomach smoothly. It may encounter some hindrance, some sudden check, which in a second or so will permit pushing the tube further into the stomach. This apparent hindrance is due to spastic contraction of the esophagus, caused by some irritable spot, and this spot may be either an erosion or a cicatrix caused by an erosion. Inquiry of the patient will often elicit the fact that hemorrhages occurred some time previously—probably thought to have come from the lungs—or that there is pain in the region corresponding to the spot. These are cases of ulcer of the esophagus.³ As the patient has to fast for 14 hours, the morning seems the most appropriate time for a test-meal examination. Accordingly, the last meal should be at 7 in the evening and the patient report for the test-meal, fasting, at 9 the next morning. The evening meal, prior to the test-breakfast, should consist of soup, meat, bread, potatoes, vegetables, dessert, and fruit, even at the risk of distress following such a meal. This is explained to the patient, who, sometimes, demurs at such a liberal

diet, but whose assent is easily gained on proper presentation. After this supper, no food or drink (medicines included) is allowed, until the test-meal. Should thirst annoy, permission is given to rinse the mouth with water.

The patient presenting himself for examination, the state of his stomach is ascertained before the test-meal is given, *i. e.*, whether the stomach is empty or not, and, if not, what are the contents. Thus the contents of the supposedly empty stomach may be either the remnants of the last meal, or decomposing and fermenting matter; or, there may be mucus or a mucoid fluid present in variable quantities. Lastly, pure mold growths⁴ of variable color and even in large quantities may be aspirated. Very often large quantities of the green mold are aspirated and misinterpreted as bile. The vomiting early in the morning of a "whole lot of green stuff" is undoubtedly known of by every physician. Such experience is related as frequently by children as by adults. Dark red mold, macroscopically resembling a hemorrhage, is also frequently aspirated, and, if in large quantity, a hemorrhage is thought of at once. Here proper differentiation is of imperative importance.

The contents aspirated from the fasting stomach are examined the same way as we examine the chyme. Free HCl may or may not be present. Sometimes a white fluid is aspirated, neutral or alkaline in reaction, which proves to contain pepsin, but no acids. I believe that a quantity of 30 cc. and over in the fasting stomach should be regarded as pathologic, exception being made when the aspirated contents prove to come from above the stomach, as, for instance, swallowed mucus. After this we are ready for the test-meal, which consists of 35 gms. of roll and 300 cc. of water. Occasionally the patient will object to such quantities of roll and water, but we must insist on its being taken. The reason for just such quantities being that, in Berlin, where this practice was first put in operation, a roll weighs about 35 gms., and a glass of water, of which 2 were given, equals about 150 cc.; and there is every reason for the test-meal being uniform, and universally of the same quality and quantity. Ewald and Boas, who first introduced this test-breakfast, chose as the beverage either water or weak tea. My test-breakfast consists of only roll and water, as with tea we introduce organic acids and fat, and the presence of organic acids in the stomach is always of import. Exactly 35 gms. of roll are weighed, and exactly 300 cc. of filtered water, of room temperature, are measured off. The patient should be instructed to masticate the roll thoroughly, and after eating the test-meal, should remain sitting perfectly quiet for exactly one hour; any exercise having a positive influence on chymification, usually for the worse. The patient should never be allowed to have his test-meal at home for the following reasons: 1. We fail to examine the fasting stomach. 2. The patient seldom has the facilities at hand for absolute precision in weighing and measuring the quantities of bread and water. Often he is told to take a slice of bread and two glasses of water, thus guessing at quantities and depending on his fondness for such a meal for what is taken. Can we be surprised that under such conditions our efforts at diagnosis are nothing more than guesswork? No wonder so much "nervous dyspepsia" abounds. For a correct diagnosis we must employ correct methods and means. Failing in these we must needs fail in our findings. What one considers a slice of bread another may think sufficient for three slices; likewise, different families use different sized glasses. Consequently, the patient should receive the test-meal at the physician's house, where quantities can and should be correctly measured and weighed.

One hour after the test-meal the stomach is aspirated. For this I use an 8-ounce Politzer rubber bag, which has no air valve. This rubber bag is united with the stomach-tube by means of a piece of hard rubber tubing of 3/4-inch

lumen and of about 3 inches length. This hard rubber tubing is thinner at both ends, one end fitting into the bore of the hard rubber end of the Politzer bag and the other end fitting into the stomach-tube.

The examination of the stomach contents will be discussed under (1) physical; (2) microscopic; (3) chemic. Under the first heading we note: Quantity, state of chymification, presence or absence of mucus; color, odor, and admixture of abnormal constituents. The normal quantity to be aspirated after the test-breakfast varies from 30 cc. to 50 cc. The roll should be well pulverized, should settle at the bottom with a thin fluid layer above it; there should be no mucus gluing the chyme together (floating mucus does not come from the stomach); the normal fluid is a rather light yellowish-brown and has a slightly sour-sweet odor. The larger the aspirated quantity, the longer has the chyme been detained in the stomach. This detention may be due either to an obstruction at the pylorus or to weakness of the muscular layer. In the majority of cases the aspirated large quantity is due to a stenotic condition of the pylorus. Compared with the frequency of such stenotic conditions a stenosis due to a pathologic-anatomic cause is relatively rare. Most often such a stenosis is due to a spastic contraction of the pylorus, which in turn is due to increased irritation of the pylorus. I have named this condition "stenosis pylori ab irritatione." If only a very small quantity of chyme is aspirated, or possibly none at all, then the pylorus, the very opposite of stenotic, is insufficient. The state of chymification is only an index of the activity of the muscular coat of the stomach and not of the dynamic capability of the stomach. Should the aspirated roll be very finely pulverized, then the muscularis has performed its function. Should the maceration of the roll have gone still further and the "floury layer" been produced, then the gastric muscularis has been very active, or hyperactive. When a large quantity of chyme is aspirated and the roll presents the appearance of the "floury layer," there is no atony of the stomach. But should the aspirated roll show little or no maceration, the muscularis may still not be liable. In order that the muscularis may contract and thus macerate the chyme, it must be kept within the stomach, that is, it should not escape prematurely. If the pylorus fails to offer the necessary resistance to the escape of chyme, there is nothing upon which the muscular coat of the stomach could contract. Consequently, the absence of sufficient pulverization of the roll should be interpreted as reflecting upon the condition and integrity of the pylorus. The practical difference is very great. Our therapy will be influenced by the proper recognition. So then, when a large quantity of chyme is aspirated and the solid part of it forms, on standing, a "floury layer," the condition of the stomach is not atony but hypertony, due to an irritated and an unduly long, spastically contracted pylorus.

Color and odor differing from what has been mentioned depend upon abnormal constituents in the chyme. Mold growths in the stomach have a decided influence upon the color and odor of the chyme. Great care must be taken not to announce a green colored chyme as containing bile, unless this has been actually found by proper tests. In the same way a dark red chyme should not be called hemorrhagic, unless the presence of blood is ascertained by positive and appropriate tests.

The microscopic examination shows the progress of digestion, the presence of gastritis, of mold, and of microorganisms. In normal digestion the concentric rings of the starch cells are clear and distinct, and if there is thorough diastatic digestion, beautiful blue-green lakes and vacuoles are seen within the starch cells. The starch cells in gastritis have a cloudy appearance, the concentric rings are not discernible, no green lakes are seen. These remarks are the result of my experiments. Different kinds of mold varieties are seen; they may also be of different color. Mold patches have no

distinct configuration, and have been described as detritus. Single sections of young mold filaments look like crystals, for which they have been mistaken. Microorganisms are usually present, and their presence is absolutely independent of the presence of free HCl. One of the chimeric assumptions we suffer from is that free HCl is antagonistic to the presence of microorganisms; microorganisms are present, together with even large quantities of free HCl. The microscope also reveals blood, mucus, cells, and other data of pathologic significance.

The chyme is filtered for the chemic examination. If there is not enough chyme, a piece of dry filter paper is immersed in the aspirated chyme and a drop of the reagent is allowed to fall on this paper and the reaction noticed. The filtered chyme to be titrated is aspirated with a pipet. I use pipets which have a bulb blown in the stem near the mouth end; this kind prevents any of the contents getting into the mouth. In employing the pipet aspirate slowly, so as not to get any air bubbles, as this is both annoying and delaying.

In approaching the chemic tests the questions are: Is the chyme acid? What kinds of acids are present? How much of each of the acids are present? Titration with the decinormal solution of sodium hydrate is used to find the amount of each acid. This solution is given into a buret which is graduated into .1 cc.

The acids to be determined are: Free HCl, organic acids, and the determination of combined HCl. To prove the presence of free HCl several indicators have been used. Chief among them are: Methyl-orange (dimethylamidoazobenzol or Töpfer's solution), a watery solution of congo-red, Günzburg's reagent, Boas' reagent, and tropeolin 00. Methyl-orange is used in a .5% alcoholic solution and gives a beautiful carmin-red color with free acids and also with some acid salts. Congo is chiefly used as congo paper; white filter paper is immersed in a watery solution of congo and then allowed to dry. The congo paper is usually made of a pink color, although some use it of a much darker red. With free acids, mineral and organic, it gives a blue color. Both these dyes react on weak organic acids and consequently they cannot be used to indicate only free HCl. Boas' and Günzburg's reagents are excellent, but they cannot be used for purposes of titration; their composition follows:

Boas' reagent:

Resorcin	5 gm.
Sugar	3 gm.
Dilute alcohol	100 gm.

Günzburg's reagent:

Phloroglucin	2 gm.
Vanillin	1 gm.
Alcohol	30 gm.

Both reagents should be kept in dark bottles. Of the two reagents Boas' is preferable for the reasons that it is much cheaper and as it is colorless the color it produces is better judged. Both reagents are used as follows: One drop of the chyme and one drop of the reagent are put into a white porcelain dish which is then heated over a Bunsen burner, not too near the flame. On evaporation a pink color appears with either of the reagents.

As indicators of only free HCl, the first two mentioned, methyl-orange and congo, should be unequivocally condemned. They not only react with free HCl, but with organic acids as well, and the methyl orange reacts also on weak solutions of the acid phosphates of calcium and of magnesium. This has been fully described in a former article.⁵ Since this last publication there have appeared several articles in which the methyl-orange and congo are still recommended on the plea that they are practically correct. There is no such thing as practically correct. Boas' and Günzburg's reagents are excellent but they cannot be used conveniently for titration. But best of all is the supersaturated

alcoholic solution of tropeolin 00. This is absolutely correct, cheap, practical and adapted for titration, and is the only one that should be used. I have proved the absolute correctness of tropeolin.⁵ This solution is prepared by putting an excess of tropeolin 00 into alcohol. In a day or two the solution is ready for use. It is of a dark cherry-red color, appearing like the ordinary tincture of iodine. The free mineral acids become purplish, cherry-red on the addition of a few drops of this solution. The end-reaction of the tropeolin is characterized by a clear amber color. Numerous times the tropeolin has shown absence of free HCl, which was then corroborated by Günzburg's and Boas' reagents, although the same specimens of chyme gave absolutely positive results with dimethyl. In my article on *gastrostia fungosa*⁴ I illustrated this. I cannot repeat too often that "fallacious tests lead to fallacious diagnoses and fallacious diagnoses to fallacious treatment." One stands aghast before the one who nonchalantly proclaims that "whilst we know that dimethyl and congo are not absolutely correct, yet they are practically so," and who, knowing that such methods of examination are faulty, still pronounces the case one of "nervous dyspepsia," simply because such cases do not yield to his treatment. Conservatism and scepticism are laudable virtues in every science, and especially in medicine. But when those, competent to say, admit the incorrectness of the dimethyl and congo as absolute indicators of free HCl it becomes their duty to take the stand for or against the indicator proposed by me as absolutely correct and eminently practical, and to prove their assertions. When the general practitioner seeks the aid of the specialist he does so with the intention of obtaining knowledge much more exact, much more scientific than his own. But when he simply gets a diagnosis which is "practically correct" and "impractically wrong," or a diagnosis of "nervous dyspepsia," then he soon discovers he had better save time and expense and treat the patient without the aid of the "gastrologist." As before stated both congo and Töpfer's solution should be unequivocally condemned as indicators for free HCl; they are worse than useless, because they deceive and mislead. Those who still declare their unaltered fidelity in these indicators should defend their position by absolute proofs.

The question of the presence of organic acids in the stomach is very important, and I have described 2 methods for their determination.⁴ (1) The floating test, and (2) by means of the methyl-orange. The first method is the direct one, and is carried out as follows:

To 1 cc. of filtered chyme is added 4 cc. of ether in a separatory funnel. The chyme and ether are shaken thoroughly until the organic acids are extracted by the ether. The funnel is now laid aside for a few minutes while 1 drop of a 10% solution of ferric chlorid is added to 2 cc. of distilled water in a narrow test-tube. The funnel is then taken up, and the chyme, which is the lower stratum, is allowed to flow off, and the clear ether is allowed to float slowly on the iron solution in the test-tube, the test-tube being held inclined. At the plane of contact between the iron solution and the ether extract appears a colored ring if some of the organic acids are present. This colored ring must be clear and transparent. There may often appear a yellowish ring, which with due stretching of the imagination, may be taken for lactic acid. But this ring is not transparent, and simply represents a little chyme which came in direct contact with the iron instead of the ether extract. The color of the ring varies with the variety of the organic acid.

This floating test is by far the most superior and the most delicate one for directly proving the acids. Lactic, malic, oxalic, and tartaric acids give a sulfur-yellow ring, also strong alcohol; succinic acid gives a dark mahogany, jasper-red ring. The acid phosphates of calcium, magnesium, potassium and sodium give no ring at all. We thus see the superiority of this over the Uffelman test. The most pronounced sulfur-yellow ring is the one produced by lactic acid. Furthermore, this floating test for lactic acid is very delicate, as lactic acid of an acidity of but 10 is easily

detected. Malic, oxalic, and tartaric acids require an acidity of at least 40 to show the reaction. This fact can be used to differentiate lactic from malic and tartaric acids. We simply have to add water to the chyme in order to bring down the acidity to 10 or 15, and if the reaction is positive, lactic acid should be diagnosed. When the quantity of organic acid is small, the characteristic reaction, the ring, will not appear at once. Then it is best to set the test-tube aside for about 10 to 15 minutes. This floating test can only be used for the qualitative determination. The other method to determine the presence and quantity of the organic acids is based upon the fact, demonstrated by me, that methyl-orange reacts also on weak organic acids, contrary to the hitherto accepted belief. I first titrate with tropeolin and after its end-reaction is reached I add the methyl-orange solution and resume the titration. The positive response to the dimethyl affirms the presence of organic acids, and by the titration we determine its quantity. Often tropeolin gives negative and methyl-orange positive results, in which case there is no free HCl; this fact can then be confirmed by Boas' or Günzburg's reagents. We should bear in mind that notwithstanding the accepted theory to the contrary, free HCl and organic acids do coexist. The presence of free HCl is absolutely no proof against the simultaneous presence of organic acids; for organic acids in large quantities are often together with large quantities of free HCl. In many diagnoses of hyperchlorhydria there is no hyperchlorhydria at all (if, in fact, not hypochlorhydria) but organacidia gastrica.

We proceed to the quantitative determination as follows: First, we determine, by titration, the free HCl, using the tropeolin solution as indicator. After the end-reaction of the tropeolin, 2 drops of methyl-orange are added, when, in the presence of organic acids, the amber-colored chyme will turn a beautiful carmin-red. We now continue the titration until the chyme turns a pale lemon-yellow, which is the end-reaction of the methyl-orange.

Given a specimen of filtered chyme, we proceed as follows:

Five cubic centimeters of the chyme are aspirated with the pipet and put into a clean glass beaker. Two drops of the tropeolin solution are now added. In the absence of free HCl the chyme becomes an amber color; if free HCl is present the chyme colors a cherry-red, the tinge of red varying in gradation with the quantity of the free HCl. Now we begin to titrate. Slowly, drop by drop, the NaHO is added from the buret into the beaker, which is best held with the left hand and shaken after each addition of NaHO. The end-reaction is reached when the beaker contents turn an amber-yellow color. The color change is best judged by looking down upon the angle formed by the wall of the beaker with its bottom. The NaHO is added until this angle shows no more red color. In this connection I would say that "practice makes perfect." After this titration, which gives the quantity of free HCl, we add to the very same specimen in the beaker 2 drops of Töpfer's solution and the titration is resumed. In the presence of organic acids the beaker contents color a carmin-red and now the NaHO is added drop by drop until a pale lemon-yellow color results. This titration determines the quantity of the organic acids. The general acidity is now determined by adding to the contents in the beaker, 2 drops of 1% alcoholic solution of phenolphthalein as the indicator. The titration is again resumed until the beaker contents turn a carmin-red. We calculate as follows: The reading of the buret is noted before any titration is begun. We will say this indicated 4.6. At the end of the tropeolin titration the buret indicated 5.8; at the end of the dimethyl titration 7.3, and at the end of the phenolphthalein titration 7.9. For the first calculation we read from 4.6 to 5.8 giving 1.2 cc. of the NaHO used. For the second calculation we read from where we left off, *i. e.*, from 5.8 to 7.3 giving 1.5 cc. For the calculation of the general acidity we read from the beginning of the titration, from 4.6 to 7.9, giving 3.3 cc. of 1/10 NaHO used. The calculations are expressed by so much percent; that is, it requires so many cubic centimeters of the decinormal sodium hydrate solution to neutralize 100 cc. of the filtered chyme. The word percent is omitted and we simply say the chyme shows free acids 30, by which we mean to express that it requires 30 cc. of the decinormal sodium hydrate to neutralize 100 cc. of the chyme in question. In the example given we used 1.2 cc. NaHO in the first titration; 1.5 cc. in the second, and 3.3 cc. in the third. But as we used 5 cc. of chyme,

which is 1/20 of 100, we must multiply by 20 the coefficients of each titration. Hence we have free HCl 1.2×20 , which is 24; free organic acids 1.5×20 , which is 30; and the general acidity is 3.3×20 , which is 66. The normal acidity may vary between 40 and 60 and the normal amount of free HCl between 20 and 40.

The test for combined HCl is a negative one. We do not test directly for such acid but the indicator we use reacts with all other acids save the HCl in combination. This test is used then when the question arises whether the stomach secretes any HCl at all. The indicator we use for such testing is the 1% watery solution of alizarin. We proceed in the following way:

First we determine the free HCl, organic acids, and the general acidity. We then take 5 cc. of the chyme and titrate, using the alizarin as indicator. The end-reaction of alizarin is indicated by the chyme turning purple. Suppose we proceed with the illustration given before to determine the combined HCl after the foregoing determinations have been made. Suppose the buret, before the beginning of the titration, reads 7.9, where we left off before, and, as the purple color is reached the buret reads 10.8; we have then used up 2.9 cc. of the NaHO which, multiplied by 20 means 58. As we have previously determined the general acidity to be 66, we then deduct 58 from 66 which leaves 8 as the equivalent for the HCl in combination. In the example given the chyme would show the following: free HCl 24; organic acids 30; HCl in combination 8; general acidity 66.

It is assumed that the acidity of the chyme, not otherwise accounted for is due to acid phosphates. I confess that as yet I have been unable to demonstrate the acid phosphates in the chyme of the test-breakfast and consequently I cannot vouch for the correctness of such assumption. However, I tested for the phosphates only according to my own method which consists in the decolorization of the red ferri rhodanid by phosphoric acid and by phosphates. This red ferri rhodanid solution consists of:

Distilled water	5 cc.
10% sol. ferric chlorid	2 drops
5% sol. ammon. sulfocyanid	5 drops

Instead of the ammonium sulfocyanid, another cyanid as sodium or potassium can be used. The reaction is performed in this manner:

One cc. of this reagent is put into each of 2 test-tubes. To one test-tube is added the chyme and to the other as much water as chyme was added to the first test-tube. In the presence of phosphates the red ferri rhodanid is either entirely discolored by the added chyme or nearly so. The test-tube to which water is added serves for comparison, to see whether the change of color, if any, in the test-tube to which the chyme was added, is due to the possible presence of phosphates or simply to dilution.

This test is a very delicate one. The chemic constitution of chyme does not hinder this reaction. This I have proved to my full satisfaction. The chyme was tested first for acid phosphates. When this test gave a negative result the merest trace of acid phosphate was added to the same chyme. The test then proved positive. Consequently this proves conclusively that the chemic constitution of the chyme was not against the applicability of my test.

Occasionally it is desirable to ascertain the deficiency of HCl. This is done by using as the titrating medium the decinormal solution of HCl, this is added to the chyme from a buret until the chyme, removed from the beaker with a platinum loop gives a blue color to congo paper. It is not good to use Boas' or Günzburg's reagent in such cases as too much of the chyme would be lost by the repeated abstraction of the chyme from the beaker.

Diastatic digestion, the conversion of starch into sugar, is recognized in the ordinary way by means of Lugol's solution. The saccharification of the test-meal I have not yet seen go beyond the production of erythro-dextrin. The best for the purpose is a very weak solution; 1 cc. Lugol's solution to 250 cc. distilled water.

Peptic digestion is recognized by the biuret reaction which is essentially Trommer's test for sugar in which the reagents are used in a very dilute form. To the chyme in the test-tube are added first a little of the weak solu-

tion of cupric sulfate and then the weak solution of caustic potash. The proteids give a reddish-violet color in this test.

As a rule pepsin is always present and, as said before, it may also be present in the fluid contents of the fasting stomach which are not acid at all. The best method for the pepsin determination is by means of Mette's tubes which are made in the following way:

Thin-walled capillary glass tubes of about 1 mm. or 1.5 mm. in diameter are filled with fresh egg albumen and thrown into water of about 90° C. to 95° C. remaining 15 minutes. These are then removed, dried and the ends closed by winding a small, thin piece of absorbent cotton around them, after which the ends are dipped in molten paraffin. The latter procedure is to prevent entrance of air so that the tubes can be made in quantities and kept for future use.

To determine the presence and action of pepsin, a piece about an inch and a half long of the prepared Mette's tube is cut off with a file, and the ragged end filed straight and smooth. This piece of tube is then put into a petri dish of 10 cc. capacity, the dish filled with the filtered chyme, and covered to prevent evaporation. For such determinations the acidity of the chyme must be brought up to a standard. The best would be to accept the acidity of 30 free HCl, as the strength for the comparative pepsin determinations. After we have determined the free HCl, we bring the chyme to represent free HCl 30. For that purpose we may have to add some of the decinormal sodium hydrate solution to bring down a higher acidity, or add some of the decinormal hydrochloric acid solution, until the required standard strength is reached. The petri dish, provided with chyme and albumen tube, is covered and put into an incubator, the temperature of which must be kept between 37° C. and 40° C. for from 12 hours to 20 hours. This time may be varied to suit the wishes of the experimenter, but the same length of time must be observed in all comparative experiments. The petri dish is then removed from the incubator, the capillary tube dried, and the column of the digested albumen is read off in millimeters. Normally about 5 millimeters of albumen are digested.

Rennin is another ferment of gastric secretion. It will coagulate milk, and this latter property is used as the method to determine the presence of rennin. Usually 5 cc. to 10 cc. of filtered chyme, carefully neutralized, are mixed with 10 cc. of neutrally reacting milk, and put into an incubator which is kept at a temperature of 37° C. to 40° C. for about half an hour to an hour. The coagulated milk, after removal from the incubator, proves the presence of rennin or its zymogen.

The stomach is supposed by some also to secrete a fat-splitting ferment. This theory needs verification, although I am inclined not to ignore it entirely. I have repeatedly seen under the microscope a large quantity of fat globules in the chyme of one patient, while the chyme of another patient, who partook of the same roll and water, examined under precisely the same conditions, showed very few fat globules. However, I am not ready to give a decisive answer.

The presence of alcohol in the chyme I simply mention.

TWO FATAL CASES OF "LANDRY'S PARALYSIS," WITH AUTOPSY FINDINGS IN ONE OF THEM.¹

BY

THEODORE DILLER, M.D.,
of Pittsburg, Pa.

Neurologist to the Allegheny General Hospital.

"Landry's paralysis" is, to my mind, a designation of a not very definite symptom-complex; and yet it is a name which is of some use, and which we are not yet ready to discard. But, with advancing knowledge, the name will be less and less needed. At present, it indicates merely a certain clinical course only—one in which rapidly ascending motor paralysis (rarely descending) is

¹ Read at a meeting of the Philadelphia Neurological Society, held March 22, 1904.

the dominant feature. Multiple neuritis, poliomyelitis, or both together, may produce the symptom-complex. It is a question today whether anything else can produce it. The few cases examined by the present-day technic, in which no changes have been found postmortem, do not answer this query in the affirmative, since in these cases death may have occurred before sufficient time had elapsed for the anatomic changes to become evident.

In the *Journal of Nervous and Mental Diseases*, September, 1902, I set forth at some length my views as to the so-called "Landry's paralysis."

CASE I.—A salesman, aged 37, was admitted to the Allegheny General Hospital, September 2, 1903. He had been a "hard drinker." Eight weeks before admission he complained of weakness in his legs and began to use a cane. This weakness steadily increased, and the patient, after a few days, was compelled to take to his bed. After he had been in bed about one week, he complained, for the first time, of sensory symptoms—pain and tenderness in the back and about the chest, abdomen and legs, and, to a less degree, in the arms. In the meantime, he had steadily continued to lose strength in the legs, and impairment of motion in the arms had also become apparent.

Ten days before admission, the patient suffered an attack of "gagging and smothering," and since then similar attacks have frequently recurred. There was no loss of control over the sphincters until the night before admission, when involuntary discharges through both occurred.

On admission (September 2) his legs were almost completely paralyzed. By the greatest effort, he was able to execute only slight movements in his toes. His arms were very weak, although he retained more power in them than in the legs. Double wrist-drop was present, and the grasp was very feeble. He was able to contract feebly the muscles about the shoulders. No atrophy was apparent. Hyperesthesia was present all over the body, including the face. Pressure over the extremities was painful. Tactile sense was everywhere present. The mind seemed unclouded.

The patient's condition steadily declined (muscular paralysis of the extremities becoming complete) until September 7, on the evening of which day he died, apparently of respiratory failure. The patient's mind was clear except during the 24 hours preceding death; and during this time it grew increasingly cloudy and delirious. For a few hours before death he was in a condition of stupor.

When examined by me a few hours before death, the patient was cyanotic; respirations were of the superior costal type and were very labored and shallow; the diaphragm was apparently paralyzed, for the abdominal movement was slight.

An autopsy was performed about six hours after death. The brain and spinal cord were removed. In the former a moderate degree of congestion of the pia was noted. It contained several small hemorrhages. The cord appeared normal. Portions of the left sciatic and ulnar nerves were removed from the thigh and upper arm respectively. The liver was enormously enlarged, to four times its normal size. It was rather soft, and of a dark mahogany color.

Several cultures of the cerebrospinal fluid were made in different media. These were subsequently examined by Dr. R. G. Burns, who reported the presence of *Staphylococcus pyogenes aureus* in all of them.

The brain, cord and peripheral nerves were at once placed in a 5% to 10% solution of formaldehyd; and a few days later they were sent to Dr. Wm. G. Spiller, of Philadelphia, who furnished me with the following report on October 9, 1903:

"The posterior roots of the lumbar region do not stain as well as the anterior roots, by the Weigert hematoxylin method; but this may be because formalin was used in the hardening fluid, as this interferes with the staining of the roots by the Weigert hematoxylin. The posterior roots appear to be normal when they are stained with acid fuchsin. The white matter of the spinal cord does not appear to be degenerated, as shown by the acid fuchsin and Weigert hematoxylin stains.

"Sections stained by thionin, show much alteration of the nerve cells in the anterior horns of the lumbar region. Many of the nerve cells of the anterior horns show central chromatolysis, and some have their nuclei peripherally situated, a condition described by Marinesco as "reaction at distance." The left sciatic and ulnar nerves are partially degenerated as shown by the Weigert hematoxylin and Marchi methods. The alteration is that of multiple neuritis."

Remarks.—The clinical manifestations of this case, therefore, ran their course in about nine weeks. The symptoms of ascending motor paralysis proceeding to an extreme degree and producing death by respiratory paralysis, the late appearance of pain and tenderness, the noninvolvement of the sphincters until five days before death, the unclouded mind seen in this case, form a most striking symptom-complex, pretty closely conforming, except in its rather long course, to the classic picture of Landry's paralysis. The striking anatomic

changes in the anterior horn cells and the peripheral nerves doubtless afford at least a partial explanation for the symptoms. That the staphylococcus discovered in the cultures by Dr. Burns was responsible for these changes is regarded by him as very doubtful, since this microorganism is omnipresent and was probably accidentally introduced into the cultures.

In this case of "Landry's paralysis" it would seem that the lower motor neuron was progressively involved from below upward. While Dr. Spiller's report points only to motor involvement, the late appearance of sensory symptoms points to at least a secondary and partial involvement of the sensory apparatus.

The anatomic changes with their resultant symptoms in this case may have been due to alcoholism. But the clinical course and the greatly enlarged spleen tend to support the view that the anatomic changes were due to an infection. Unfortunately, through an oversight, the liver and spleen were not examined under the microscope.

I am greatly indebted to Drs. Burns and Spiller for their respective reports on this case.

CASE II.—A farmer, aged about 45; was formerly a free drinker, but had not been drinking for the past couple of years. His general health has been good and he denies syphilis.

Early last September, while unloading coal, he felt a sudden severe pain in the small of his back. It gradually grew less during the next week and had about disappeared at the end of 10 days, when he began to lose strength in the legs and this has continued up to the present time. Three weeks later the arms began to lose strength and this has also continued up to the present time.

Examination.—December 19, 1902. No pain; occasional paresthesia. Patient cannot walk or stand alone; but he walks with the support of a friend. Grasp of hands is quite feeble; knee-jerks are absent; there are no objective or subjective symptoms. Legs are flaccid, somewhat wasted, but there is no distinct atrophy. Sphincters intact. Bulbar nerves intact. Mind is clear.

I saw the patient only once, but his physician, Dr. Bemis, writes under date of February 8, 1904.

"When I last saw you, about a month after my examination, the paralysis in the upper extremities was advancing very slowly if at all, but that in the lower limbs was complete with great atrophy and marked enlargement and tenderness of the nerve trunks. I saw Mr. M. at intervals of about a week. The condition as stated continued without any perceptible change until March 11, 1903, when I saw him. His nurse reported him to have been more helpless for a few days. I found the temperature 100°, the first time there had been any elevation. His breathing was shallow and irregular and the pulse intermittent. There was a tendency for food to accumulate in the cheeks and in the pharynx so that he was compelled to cough a good deal after eating. I remained with him over night. In the morning he seemed better. Breathing was regular and deeper and the pulse steady but quick. Notwithstanding that he seemed better, I was satisfied that the paralysis was advancing and beginning to affect the respiratory centers. I told his sister that he was much worse and as there might be urgent need of help before I could return again, which I expected to do on March 15, I would stop and arrange with the village doctor to go to see him if needed. On Sabbath morning I received a telephone message that he had died during the night.

"Dr. Timmons, of West Alexander, was called in Saturday as arranged and was with him until he died. The greatest trouble was dyspnea.

"The outcome confirmed the diagnosis which you made the last time I saw you—an ascending paralysis associated with neuritis."

To recapitulate briefly, there was a progressive paralysis beginning in the legs, involving later the arms, and finally the nerves innervated by the bulb, this last-named involvement producing death about six months after the date of the initial paralysis. During the first four months, the disease was of a purely motor type. "Enlargement and tenderness of the nerve-trunks" were features of the last two months of the illness.

Remarks.—This case may be regarded as one of multiple neuritis predominantly of the motor type. But, in view of the postmortem findings in the first case, of the atrophy, of the ascending type of the paralysis and bulbar involvement, I believe it is highly probable that a postmortem examination would have revealed degenerative changes in the motor cells of the cord and bulb.

It seems most likely that the entire lower motor neuron was involved, as in the first case.

The case, therefore, to my mind, is one of more than, if not other than, multiple neuritis. It presents clinical features different from those seen in ordinary multiple neuritis, not only in its predominantly motor character, but especially in its feature of ascending paralysis. As I have elsewhere shown,¹ sensory symptoms are common in so-called "Landry's paralysis." The sudden initial pain in this case is a curious symptom which I am at a loss to explain.

The case is, clinically, a highly typical one of "Landry's paralysis" except only in its long course. Shall it be so called? If not, how shall it be labeled?

THE REMOVAL OF SEPTAL SPURS AND THE CORRECTION OF DEVIATIONS OF THE SEPTUM BY MORE RATIONAL METHODS.

BY

CHARLES NELSON SPRATT, B.S., M.D.,
of Minneapolis, Minn.

On reading the discussion¹ of a paper, read before the Laryngological Society of London, entitled, "The After-treatment of Intranasal Operations," by Henry T. Butlin, I was impressed by the fact that much of the prolonged after-treatment and many of the unsatisfactory results could have been avoided, had the operators more frequently done the so-called "flap-operation," thus securing healing by first intention. Adhesions, perforation, prolonged healing, frequently seen after the usual methods of operating on the septum, are difficulties not encountered when the mucosa is preserved. What surgeon would remove from the face or scalp an atheromatous cyst, by slicing it off and leaving a great raw surface to heal by granulations? In a laparotomy, raw surfaces are covered, when possible, with peritoneum. Likewise modern surgery demands healing by first intention after operations on the septum. It is a lamentable

of his patient in mind and who desires rapid healing, and aims to avoid, so far as possible, postoperative complications, will employ more rational and careful methods. These remarks refer to operations on the septum, as in most cases of nasal stenosis a cure can be established by such operations. It seems self-evident that a turbinate ought never to be sacrificed if sufficient room can be obtained by the removal of a spur or the

Fig. 2.—The same in longitudinal view. The mucosa over the spur has been reflected upward—a portion of the cartilage has already been resected. The posterior portion of the spur to be removed by means of the chisel.

correction of a deviation of the septum. The turbinates have a function—spurs do not.

The pernicious idea, viz., the removal of the turbinates and thus avoiding operations on the septum, as the former is easier, is unworthy of serious thought.

Heylen,² in 1847, published a method for the treatment of deformities of the septum, which consisted in first reflecting a flap of mucous membrane from the projection and then removing the cartilage or bone with scissors. This old and excellent method is seldom employed, and is scarcely more than mentioned by most American works on rhinology. Some of the German textbooks mention the operation, but as a rule do not impress one with its advantages. Without the help of cocaine and adrenalin, the flap operation was doubtless difficult, as the field of operation would be so obscured by blood that careful, neat work would be impossible, and the pain of the operation would require an unusual amount of courage on the patient's part. With the use of these drugs hemorrhage is rarely excessive, and the operation is performed without pain. I will first describe the operation, then state its advantages and the objections raised by some.

Fig. 1.

Fig. 3.

Fig. 1.—Cross section showing septum with large spur in addition to marked deviation. It is not well united for the usual saw operation or the Asche. Fig. 3.—Cross section of Fig. 1. Cartilage removed and mucosa adherent to that of the opposite side.

fact, that most rhinologists do not consider healing by first intention essential to good nasal surgery, or to be worth the effort. Relief of nasal stenosis is the only object in view and the slow healing by granulation is a matter of course. The most inexperienced operator can, with saw, spoke-shave, enchondrotome or the barbarous trephine, relieve the nasal stenosis. But he who has the welfare

The mucosa of the septum and turbinates is rendered anesthetic by three or four applications of an 8% solution of cocaine in adrenalin chlorid, 1 to 4,000. A Sajous or Krieg knife is introduced posterior to the spur, and a longitudinal incision is made through the mucous membrane beneath the spur as low down on the septum as possible, and parallel to the floor of the nasal cavity. At the anterior end of the spur this incision is continued directly upward, at right angles to the original incision. On freeing the mucous membrane from the cartilage a large triangular flap with its base above is formed. This flap is next folded up, between the septum and middle turbinate, and held there by a small piece of gauze. Hemorrhage from one of the branches of the nasopalatine artery may obscure the field of operation, but this is easily controlled by pressure. If the

¹ Op. cit.

blood is wiped away, the white cartilage is plainly seen. This projecting cartilage is best removed with a chisel. The chisel is preferable to the saw, in that the former leaves a smooth surface to which the flap readily adheres. In removing the long horizontal or ascending spurs, the anterior portion can be removed first, thus allowing a view of the posterior portion and sufficient working space for its removal. It is also of great value in removing spurs with broad bases and those situated at the junction of the septum, and the floor of the nasal fossa. In the latter case a small gouge similar in general shape to the chisel illustrated herewith, is of great value.

The various nasal chisels shown by instrument makers are, as a rule, too thick and clumsy. I have made and used with great satisfaction a chisel like the one illustrated. This is 16 cm. long, and has a cutting edge 6 mm. to 8 mm. wide. The instrument is made quite thin. The shank, directly back of the blade, measures 1 mm. by 3 mm. As this instrument occupies a minimal portion of the nasal cavity, a good view of the field of operation is possible at all times. In operating in narrow nasal cavities, and in those cases in which the spur is situated on the posterior part of the septum, the value of such a thin chisel will be fully appreciated. The cartilage ought to be cut away in layers, and no attempt made to remove the projection in one piece. If the spur extends into the bony portion of the septum, the chisel is advanced by light taps with a mallet.

If in addition to the spur there is considerable deviation, the mucosa of the opposite side is separated from the septum and the whole thickness of cartilage, or bone, removed.

This, called by some, window resection for deviated septum, was described in 1886 by Krieg, who resected both cartilage and mucosa of convex side. Hajek³ retains the mucous membrane and covers the field of operation with it. Healing by first intention is thus secured, and a slow healing by granulations is thus avoided. Freer⁴ recommends 18 or more instruments, most of these being entirely superfluous and unnecessary, as the cartilage can be quickly and neatly removed

covered by normal mucous membrane, and not by scar tissue. 4. Perforation of the septum is a complication that need never occur. The cartilage is removed in small pieces and under the will of the operator. When the spur is removed in one piece with a saw, or crucial incisions are made, as in doing the Asche operation, perforations are at times unavoidable. Another great advantage of the window resection for deviated septum is that the patient is relieved of the discomfort and inconvenience of wearing nasal tubes.

The objections to the operation are perhaps best stated by Hajek.⁷ "The method is complicated, technically difficult, and of long duration, one-half hour to one and a half hours." This statement is greatly exaggerated. We must admit that the method is more complicated than removing the spur and covering by a few strokes of a saw, or correcting a deviation by two cuts of an Asche scissors, but it is not so difficult as to demand more than average operative skill and care. The window resection can generally be done in 25 minutes to 35 minutes, and rarely is the operation prolonged beyond 45 minutes. The difficulties seem greater than they really are. Sometimes the anterior portion of the flap is quite adherent to the cartilage, but with care it can be dissected up and preserved entire. Hemorrhage may also delay the operation, but with the use of adrenalin this is easily controlled.

THE EFFICIENCY OF LOCAL TREATMENT AS A FACTOR IN THE CURE OF LARYNGEAL TUBERCULOSIS.

BY

ROSS HALL SKILLERN, M.D.,

of Philadelphia.

Fig. 4.—Chisel, gouge, knife and flap elevator.

with a pair of Heymann cutting forceps. With a Frankle-Swift speculum, a Sajous knife, a small elevator for flap, a thin chisel, a pair of Heymann cutting forceps and plenty of cotton swabs on toothpicks, spurs can be removed and deviated septums can be corrected.

The flap is held in position against the side of the septum by a spatula, and the nose is lightly packed with iodoform gauze. Twenty-four hours later this is replaced by fresh gauze, and 48 hours after operation the flap will be quite firmly attached to the septum and subsequent packing will not be necessary. The swelling is usually not marked.

The advantages of this method over the usual methods are summed up in the statement that with it primary union is secured. This means: 1. Healing is usually complete in three or four days. If portions of the flap are lost during the operation, the time will be somewhat longer. With care, however, in almost every case the flap can be saved entire. As there is some shrinking, the flap rarely is too large. After the removal of a spur, where no attempt is made to cover the raw area, healing requires a much longer time. Moritz Schmidt⁵ says, "the duration of the healing (viz., after intranasal operations for the removal of spurs from the septum) demands about four weeks in uncomplicated cases; should perforation of the septum have been unavoidable, more time is required;" "healing," quoting Coakley,⁶ "takes place in two and a half to four weeks," etc. "A disagreeable and prolonged scab formation over the cut surface occasionally is seen," etc. 2. Adhesions are impossible, as no raw surfaces are left. 3. Scab formation is not to be feared. The field of operation is

It is not my purpose to enter into detail, or review minutely, either the climatologic or general treatment of this disease, or rather the occasional concomitant symptom of the great disease, pulmonary tuberculosis, but to consider systematically the various forms of laryngeal tuberculosis (due regard being given to the general condition of the patient) and what effect certain forms of treatment have upon the diseased structures. That there may exist cases of primary laryngeal tuberculosis one cannot deny, but they are exceedingly uncommon, and indeed, in many of those reported, foci of infection in the lung have been shown in the autopsy, which were undoubtedly primary to the laryngeal affection. On the other hand, that secondary affection of the larynx is invariably the rule in pulmonary tuberculosis is, of course, never admitted; a large percentage (about 80%) die with no symptom whatever referable to the larynx. It will be remembered that I spoke of this disease as the occasional concomitant symptom of pulmonary tuberculosis. If chronic pulmonary tuberculosis did not exist, it would be almost unnecessary to use the word occasional, as it is fairly constant with the acute type of the disease. However, that it does not exist with the chronic form is fallacy, and these cases nearly always present the same form as the general disease. Under the same conditions, however, a very acute case of laryngeal tuberculosis may occur in chronic pulmonary tuberculosis, but these cases differ from the acute conditions of the larynx found in acute or subacute tuberculous subjects, in that they are more amenable to treatment, thereby proving that the severity of the disease in the lungs is directly bearing on the severity of the disease in the larynx. Whether this is due to the vitiated condi-

tion of the system or to the virulence of those particular bacilli has yet to be determined.

The portions of the larynx first affected depend upon a number of conditions. Usually the disease is first observed in the arytenoids, though in singers and lecturers the cords, or the ventricles of Morgagni are often the first structures attacked. As it is manifestly impossible to note every case at the commencement of the disease, the majority of the following cases were examined at the Rush Hospital either on admittance or as soon as subjective symptoms were observed:

Out of 107 cases, in 38, or about 35%, the disease was first noted in the arytenoid cartilages. In 32 cases, or about 30%, the arytenoid cartilage and cords, including the ventricular bands and the ventricles of Morgagni. In 20 cases, or about 18%, all the portions of the larynx (epiglottis, arytenoids, and cords) were primarily affected. In 7 cases the cords alone were affected, while in 6 cases the first manifestations of the disease were seen in the epiglottis. The cricoid cartilage is reported to have been the primary seat of the disease in 2 cases.

By far the most common form of laryngeal tuberculosis is thickening of the mucous membrane covering the arytenoid cartilage and interarytenoid commissure. Why this part of the larynx is first affected or first shows the disease is well explained by Lennox Browne, who states that these parts bear the strain of extension and vibration during phonation, coughing, etc., and are thereby in action more often than any other portion of the larynx. Shurley contends that the susceptibility of the posterior wall is probably due to its peculiar anatomic formation and the structure of its mucous membrane, made necessary to allow of its folding mobility.

Another theory is that the arytenoids and the posterior third of the cords and ventricular bands being more richly supplied with lymphatics, and the ventricles of Morgagni offering a lodgment for the tubercle bacilli, naturally that portion would be the first affected.

Much depends upon the particular manner of infection, thus, if it occurs through the lymphatics, we would either have tumefaction or thickening of the anemic type, with the formation of small nodules, which later break down and ulcerate. The favorite site of this condition is the arytenoids and commissure.

On the other hand, if there is direct infection from the lungs through an abrasion of the mucous membrane, there would be hyperemia surrounding a superficial ulcer. This type is most often seen on the true or false cords or the posterior surface of the epiglottis.

The anemic type occurs usually in chronic pulmonary tuberculosis, and is apt to run a more chronic course, while the hyperemic is the acute type, and runs a shorter and more severe course, although either type may occur with any form of lung tuberculosis.

General Local Treatment of Tuberculous Laryngitis.—In dealing with this subject, I will review the different treatments advocated during the past 15 years, with reference to the general efficiency and practicability of each.

Before the year 1890 a number of drugs which have been entirely discarded, such as tannin, ethyl iodid, chromic acid, ergot, the salts of zinc and copper, etc., were used, also a number of drugs that are now considered almost indispensable, such as lactic acid, guaiacol, menthol, carbolic acid, iodoform, and a host of others. Counterirritation to the front of the neck, external applications of croton oil, antimonial ointment, and fly-blisters, steam inhalations, sulfurous waters, etc., were also used.

In 1890 a decided departure from the routine treatment was made when Moritz Schmidt used tuberculin (an antituberculous serum discovered by Paquin) hypodermically. He reported 21 cases in which the patients were all greatly relieved by the injection of 1 mg., but adds, "one must be ready to perform tracheotomy, on

account of its giving rise to sudden swelling and asphyxia." This opinion was also shared by Lennox Browne, but later investigations proved that it gave no better results and was far more dangerous than the ordinary local treatment.

In 1891 Koch's tuberculin was introduced, and was at first highly praised, especially by Lennox Browne in his monograph, "Koch's Remedy in Relation Specially to Throat Consumption," but later it proved of less value than the antituberculous serum, and even seemed to do harm.

The first reference to anilin products being used appeared at this time, when Bogroff recommended fuchsin, stating that "when injected into the larynx the superficial cellular elements and intercellular elements and intercellular spaces become infiltrated with particles of the anilin dye, and thus a thin protective film is formed which is impermeable not only by irritating fluids, but by gaseous bodies, and is valuable in cases of laryngeal inflammation from constant irritation from the pulmonary discharge." So far as I know, this has fallen into disuse. Krause modified the lactic acid treatment of Heryng by first cureting then applying the acid. While I believe Krause carried his curetment too far, nevertheless this treatment, using the curet gently, is one of the best in use at the present day in certain cases.

In 1892-93 intralaryngeal injections of a mixture of guaiacol and menthol were popular. Resorcin in 80% to 120% solution was used with some success for ulcers. Stein, of Berlin, in an elaborate paper, strongly urged tracheotomy in the majority of cases.

In 1894, Heryng, the originator of the lactic acid treatment stated that it was useless in cases in which there was hard infiltration without ulceration.

Hunter's modification B of tuberculin was tried in increasing doses from .0025 gm. to .1 gm. The reaction was slight and improvement noted, but no cures were reported.

In 1895, at the International Congress of Physicians at London, Gougenheim strongly urged energetic surgical interference, stating the punch should be used to clear away the diseased arytenoids. In this he was opposed by Lennox Browne. Heryng recommended galvanocautics and electrolysis in cases in which lactic acid was not indicated. Massei and Ruault advocated phenol sulfuricinate (20% to 30% phenol in sodium sulfuricinate). This was of especial value in the form limited to the vocal cords. Tracheotomy at this time found many advocates among whom were Garel, Masucci, Schmidt, Egidi, Macyntire, and others. Carl Von Ruck still recommended antiphthisin finding it less poisonous than tuberculin.

In 1896, Gleitzman contended that the curet, and even the punch forceps should be used in all cases of (1) primary laryngeal tuberculosis, (2) circumscribed infiltrations and ulcerations, (3) dense hard infiltrations and ulcerations of the arytenoid region, the posterior wall of the larynx, the ventricular bands and tumors of the epiglottis, (4) in advanced cases to relieve the dysphagia. Counterindicated in (1) advanced pulmonary disease and hectic type, (2) disseminated disease of the larynx, (3) extensive infiltration producing severe stenosis. Ingals did not coincide with him in this opinion. Spengler used parachlorophenol mixed with an equal volume of glycerin, and reported 40% absolute cures. Lubinski and Seifert, on the other hand, report adverse experiences with this mixture. Harris reported a case in which he used lactic acid, iodoform, and silver nitrate successively after curetment with repeated failure, the patient being subsequently cured by the application of pure ichthyol. Carbolic acid and its derivatives were in great favor at this time. Chappell, with a special syringe, gave intralaryngeal injections of creosote and menthol in castor oil with good results.

In 1897, powders, such as iodoform, aristol, iodol,

etc., were used extensively, and Allan introduced the famous menthol, camphor, and albolin mixture. S. Solis Cohen recommended formaldehyd in solution. Heryng stated that phenol sulfuricinate in 20% to 40% solutions only prolonged discomfort, and was useless in cases in which the epiglottis or ventricular bands were involved, neither was it useful in diffuse inflammation or bleeding surfaces. Murray used enzymol for cleaning off ulcers, with some success. Being a proteolytic digestive ferment it merely digested the dead tissues on the surface of the ulcer which when removed left a clean surface.

In 1898, Chappell reported good results with hypodermic injections of antitubercle horse-serum prepared at the laboratory at Washington.

In 1899, Yonge reported the use of orthoform insufflated into the larynx, which had the advantage over iodoform in that it acted as a decided local anesthetic, and had strong antiseptic qualities. In granular conditions of the vocal cords he found intertracheal injections most efficacious. Gallagher advocated formaldehyd in increasing solutions from 1% in cases in which the disease had not advanced too far. In advanced cases one drop to the ounce of water used in the form of a spray acted as an anesthetic.

In 1900 Schmithuisen reported that he had used the galvanocautery since 1890, and considered it the best form of treatment. Scheppegegrell advocated cupric electrolysis and claimed the following advantages for it: 1. There is no destruction of tissue or lesion of the surface through which pathogenic germs may infect the system. 2. There is no reaction or hemorrhage. 3. It does not require extraordinary skill and is especially easy when direct laryngoscopy can be used. 4. It is applicable in all cases of laryngeal tuberculosis. As the electrodes must remain in position from 5 minutes to 7 minutes, it is unnecessary to give this treatment further consideration, especially when the hypersensitive condition of the tuberculous larynx is remembered. Laverand used a new microbic product which was administered internally and was prepared from Koch's bacillus. I have been unable to procure any statistics regarding this treatment so surmise it is discontinued. Lake still used intertracheal injections, scarification, and cureting with the application of formaldehyd and orthoform.

In 1901 Stanislaus von Stein urged the employment of a solution made up of carbolic acid, 9 parts; salicylic acid, 1 part; lactic acid, 2 parts; menthol, $\frac{1}{5}$ part. After its application dysphagia improved, dry ulcers became clean and the larynx resumed a rosy red color and in cases in which there was ulceration with infiltration, improvement was very rapid. Freudenthal considered the treatment by lactic acid antiquated and barbarous and urged the use of an emulsion of menthol and orthoform with heroin for the cough. Donellan advised the interlaryngeal injection of sodium cinnamate in 1% to 5% solution every three or four days. Lake, in the *Journal of Laryngology* gave a very clear and conservative review of cases amenable to surgical treatment.

In 1902 Freitag and Neuman advanced an entirely new treatment which consisted in absolutely refraining from using the voice, and no local medication. They claim a number of cures under this treatment. Stillman reported an absolute cure in a case in which ulceration and necrosis had set in, by the application of the direct rays of the sun accomplished by means of a hand mirror. Grayson recommended intertracheal injections of a solution of menthol, guaiacol and eucalyptol in olive oil to relieve the cough. Off and Newcomet experimented extensively with the röntgen rays, but the results did not justify their expectations, although there were a number of cases in which improvement was noted.

In 1903 Marmoreck's serum (which the Italians claim to be identical in every respect with Maragliano's) was introduced. While it is too early to pass judgment

upon it, still it appears to be looked on with disfavor. Hallopeau, Championnière, Dieulafoy and LeDentu, reported negative results from its use.

It is a well-established fact that all patients improve temporarily under a new treatment, and this fact has been the cause of many authorities advancing treatments and promising the most brilliant results which ultimately are found to be of no more value than those formerly employed.

It is not my intention to advance anything new in the way of treatment, but rather to consider special procedures which have been found most useful and which are now carried out at the Rush Hospital, Philadelphia.

All patients admitted to the hospital have their throats thoroughly examined as soon as possible. When any throat symptom either subjective or objective is noted they are placed under local treatment.

If the arytenoids are slightly infiltrated with the rest of the larynx normal, and the subjective symptoms consist of a slight huskiness and the voice tiring easily, the larynx is thoroughly cleansed with a normal salt solution, and if the turbinates are congested, which is usually the case, they are reduced by the application of adrenalin chlorid 1 to 10,000. Finally the whole upper respiratory tract is sprayed with the menthol, camphor, albolin solution. In this condition, the old astringent treatment while it temporarily relieves the patient, ultimately does more harm than good by decreasing the elasticity of the tissues and reducing their resisting powers. Steam inhalations have been tried over a period of several years but appear to be of no value beyond the moral effect they exert on the patient.

When the arytenoids and the interarytenoidal space are greatly infiltrated and anemic (the rest of the larynx normal) and the patient complains of partial aphonia, and a feeling as of a foreign body in the throat, etc., the larynx is cleansed as before and the turbinates reduced. A solution of mercuric chlorid 30 cc. (1 oz.) with .65 gm. (10 gr.) of menthol in equal parts of glycerin and water to the strength of 1 to 1,000 is gently swabbed over the affected area. The menthol stimulates the capillary circulation while the mercury acts as an antiseptic and stimulant to the deeper tissues. The nares are sprayed with the menthol, camphor and albolin mixture and the patient is strictly enjoined to use the voice as little as possible. In this form of the disease, some authorities recommend all the way from scarification to the punch forceps, but such procedures appear to me entirely unjustifiable.

In the more advanced condition when the arytenoids are pyriform, the interarytenoidal space obliterated, the aryepiglottic folds and posterior third of the cords and ventricular bands thick and infiltrated, with the whole larynx bathed in a thick tenacious mucus, the patient will complain of dysphagia and a constant desire to clear the throat, there will be severe pains in the larynx and the respiration is short and frequent. The first indication in this type is obviously to cleanse the larynx with the least possible amount of irritation; as a rule it is extremely hypersensitive. This may be accomplished by first shrinking the turbinates and washing out the nasal cavities and choanæ, the patient is then given a 50% solution of hydrogen dioxid and made to gargle the throat several times, this cleanses the walls of the pharynx, tonsils and mouth. The larynx is then partially cocaineized with a 2% solution and swabbed out with dilute Seiler's solution. A preparation of menthol 32 gm. (5 gr.), guaiacol and olive oil of each 15 cc. ($\frac{1}{2}$ oz.) is then applied and the pharynx sprayed with the menthol, camphor, and albolin mixture. The patient is taught to take nourishment using the Wolfenden position (lying down with the head lower than the body) this relieves the dysphagia because food tends to enter the esophagus through the pyriform sinuses on each side of the larynx, and thus avoids contact with the latter. This condition unless checked will

speedily progress with the formation of ulcers over the interarytenoidal space or the arytenoid cartilages and will gradually creep along the cords and ventricular bands until practically the whole larynx is involved. In the treatment of this condition much has been said both for and against lactic acid. I use the acid because nothing better has been found, and because with many others, I firmly believe it is not the acid as much as the rubbing that brings about good results, the real object being to attract the leukocytes with the resulting resolution of the part; therefore the following solution, which is antiseptic and preserves whatever inherent action the lactic acid may possess, is used after thorough cocaineization. Formalin, 7 parts; oil of cloves, 10 parts; lactic acid, 50 parts; and glycerin enough to make 100 parts. Orthoform is then insufflated until all the ulcerated parts are well covered. If the orthoform shows signs of losing its effect aristol is used for a short time with a subsequent return to orthoform. A different type of ulceration often occurs with acute pulmonary tuberculosis in which the whole larynx is red and swollen with numerous ulcers found particularly on the posterior surface of the epiglottis. As the pulmonary trouble usually proves fatal in a few days or weeks, little or nothing can be done beyond the alleviation of suffering.

Regarding surgical treatment in this disease, one must admit that sometimes certain conditions arise in which an operation of more or less severity is demanded, but these are very few.

It is of the utmost importance that the patient's condition will not only warrant the surgical interference, but be able to sustain the system after the operation is completed. Gentle curetment sometimes gives excellent results when there is an excess of granulomas, particularly on the vocal cords, or in ulcerations with an accumulation of debris. Submucous injections and scarification often cause violent reaction and are prone to leave an ulcerating surface which may resist all treatment thereby further provoking the disease.

Occasionally new formations, such as pedunculated tumors are seen which offer more or less obstruction to respiration and give rise to paroxysms of coughing. These obstructions can be readily removed with cutting forceps (such as Lake's) with immediate benefit to the patient.

CONCLUSIONS.

1. Local treatment is always beneficial even if it only relieves the most distressing symptom, *i. e.*, pain.
2. It depends entirely upon the general condition of the patient what form of local treatment is most advisable.
3. While laryngeal tuberculosis in some cases may be entirely cured, there always remains more or less chronic laryngeal catarrh.
4. That extensive surgical procedures in cases in which the lungs are deeply involved except as a palliative treatment are unjustifiable.
5. That extensive curetment should only be employed in those cases in which there is a fair chance of curing the disease and when it is necessary to prolong life a short time.
6. The prognosis depends more on the general systemic condition of the patient than upon the throat lesion. It naturally follows that the more severe the throat lesion the greater the degree of constitutional weakness.
7. If a case is seen at an early stage of its development, the prognosis is good provided of course the concomitant lung disease is responding to treatment.
8. When there is much ulceration and loss of tissue, absolute cure is impossible, but such an amelioration of symptoms may be brought about as to render the patient fairly comfortable for the rest of his existence.
9. The best results are obtained when the tuberculous deposit in the larynx is localized.

 Sharp: Medical Journal, N. Y., February 7, 1903.

University Students in France.—According to *The British Medical Journal*, the total number of students attending the French universities is 30,405. The Arts Faculty has 4,384 students, of whom 3,873 are French. It has 613 women students. Law has 10,972 students, and of these 4,382 belong to the University of Paris and 1,021 to Toulouse. In the Faculty of Science there are 4,765 students, of whom 1,546 attend the Paris Faculty, 552 that of Lyon, and 476 at Nancy. There is a total of 6,686 students of medicine, of whom 6,115 are French. They are distributed as follows: Paris 3,496, Lyon 958, Bordeaux 654, Montpellier 552. There are 571 foreigners attending this Faculty, of whom 197 belong to Persia, 89 to Turkey, 63 to Bulgaria, and 57 to Roumania. To these must be added 202 French women students and 164 women students from abroad, together with 1,558 students who are taking the course of medicine and pharmacy. Beside these there are 3,014 students of pharmacy.

A MODIFICATION OF EXISTING METHODS FOR STAINING FLAGELLA.

BY

O. P. JOHNSTON, A.M.,

Rush Medical College, formerly of Cornell University,

AND

W. B. MACK,

New York State Veterinary College, Cornell University.

The demonstration of flagella on motile bacteria gives all beginners in bacteriology and many experienced workers much difficulty. The methods employed in most laboratories are complicated and involve several steps that are of no advantage. We find, after considerable experimental work conducted in the bacteriologic laboratory at Cornell University, the following technic almost uniformly successful and comparatively simple. It is not claimed to be a new method, but a modification and combination of existing ones. Its efficiency has been demonstrated for members of the colon group of bacteria and for *Pseudomonas pyocyaneus*. It is believed it will prove equally successful with other species. Further, it has given good results in the hands of inexperienced as well as experienced workers.

The essentials for securing uniformly good preparations, free from background, seem to be: 1. Clean cover-glasses. 2. A film that does not contain much organic matter. 3. And most important of all, a film in which the organisms lie with flagella extended so they can be seen when stained. Much less depends on the stains and the method of staining than is commonly believed.

METHOD.

Cleaning Cover-glasses.—Cover-glasses are cleaned in the ordinary way and then boiled in 5% caustic soda about ten minutes, rinsed in water and boiled in dilute 10% hydrochloric acid about an equal time, then rinsed very thoroughly in water, one at a time, taking care not to soil in handling, and transferred to ether alcohol until ready to wipe. Place a piece of cheese-cloth or thin muslin in 5% caustic soda for a few hours, or over night, rinse in water, then for about the same time place in dilute (10%) hydrochloric acid, rinse thoroughly in water and dry. A quicker way is to rinse the cloth in ether for a few minutes, but it is no more effective and is more expensive. Cleanse the hands thoroughly in soap and water, then in ether, before further handling the cover-glasses. This treatment removes the oil from cover-glasses and the muslin and sebum from the hands. Wipe the cover-glasses from ether alcohol with the muslin thus prepared, using care to handle them only by the edges, and put in a clean covered receptacle; a petri dish is very convenient, until ready to use. When thoroughly cleaned and free from oil, a drop of water placed on a cover-glass spreads over a considerable surface in a very thin film without difficulty. This method of cleaning cover-glasses is rather long, and is not claimed by us to be better than other methods carefully used. It is simply the one we have followed with uniformly good results.

Preparation of Films.—Make a culture of the organism to be stained on slant agar and incubate for 18 to 24 hours. Prepare a tube with 6 cc. to 8 cc. of sterile water, and keep in the incubator until it is at incubator temperature. With a sterile platinum loop, scrape away some of the growth from the agar surface, using care not to remove any of the agar, and rinse it off carefully in the tube of water previously prepared for this purpose. There should be enough to impart to the water a faintly perceptible cloudiness. This should be done in a warm room, the incubator room if one is convenient, and with considerable care. Replace this tube in the incubator and the bacilli will distribute themselves quite evenly through the water, but any clumps or masses settle to the bottom. The tube is left in the incubator for from two to three days before preparing the films. However, good results have been obtained at different times up to four weeks. Place a tray of cover-glasses in the incubator to warm; then, still in the warm room, with a platinum loop put a drop or two from the tube on each cover. We have failed of good results when all conditions seemed right, apparently because the room was too cold. Replace the tray in the incubator until the water has evaporated, when the films are ready to stain. The small amount of organic matter in films prepared in this way gives but little background when stained.

Mordants and Stains.—Different mordants and staining solutions have been used in this work. Those of Löffler or Pitfield, prepared as follows, have given the most uniform and satisfactory results:

LÖFFLER'S MORDANT.

Twenty percent aqueous solution tannic acid . . . 10 cc.
Saturated aqueous solution iron sulfate . . . 5 cc.
Saturated alcoholic solution basic fuchsin . . . 1 cc.
Mix, let stand two or more hours, and filter.

Tannic acid solution should be freshly prepared, but the iron sulfate solution is better if it stands until it begins to turn brownish by oxidation, but it should not be too old. If, when this mordant is used it gives a precipitate, filter again. When properly prepared it should have much the same color as a solution of hematoxylin.

ZIEHL'S CARBOL FUCHSIN.

Saturated alcoholic solution basic fuchsin . . . 2.5 cc.
Five percent carbolic acid 20 cc.

If not clear add fuchsin solution drop by drop until it clears; then filter.

PITFIELD'S MORDANT.

Ten percent aqueous solution tannic acid . . . 10 cc.
Saturated aqueous solution mercuric chlorid . . . 5 cc.
Saturated aqueous solution potassium alum . . . 5 cc.
Ziehl's carbol fuchsin 5 cc.

Mix, let stand two or more hours, and decant clear fluid or filter.

PITFIELD'S STAIN.

Saturated aqueous solution potassium alum . . . 10 cc.
Saturated alcoholic solution gentian-violet . . . 2 cc.
Mix, let stand two or more hours, and filter.

Saturated alcoholic solution of methyl-violet, basic fuchsin, or methylene-blue can be substituted for gentian-violet in the above formula with equally good results.

With a pipet apply to a film all of either mordant the cover-glass will hold, allow it to act two or three minutes without heating, rinse thoroughly in clean water, apply any one of the stains in the same manner, stain two or three minutes without heating, rinse well, and examine in water, or dry and mount in balsam.

All these solutions should be freshly prepared. Considerable care in washing after the mordant will be well repaid by insuring a cleaner background.

These films require no fixing, the mordant fixing them sufficiently, and flaming often ruins them. Heating mordant and stain is not only useless, but gives almost invariably a precipitate which is very objectionable. Around the edge of where the drop was applied to the cover-glass a heavy line of bacteria will be found, and if the right amount of culture was added to the water, many will be found scattered within the ring, some of them isolated so they can be easily studied. A little practice with this will enable one to make good preparations altogether free from background and precipitate.

SUMMARY.

Those things which seem to insure a good preparation are: Clean cover-glasses; but little organic matter in the film to stain and give a heavy background; avoiding fixing film in flame, but allowing the mordant to fix it; avoiding heating either mordant or stain on the films, as it tends to produce a precipitate and background. Finally, the all-important prerequisite for staining flagella is to have a film which contains the organisms with flagella extended, and with this one condition fulfilled, no special technic is required other than the use of a mordant. If these conditions are satisfied, no special difficulty will be experienced by anyone in staining the flagella. Failure to stain flagella usually means failure to get them in the film to be stained. In other words, it has been our experience that it is practically as easy to stain the flagella as the organism itself. In general, this much might be said, that conditions which would seem to lower the irritability of the organisms, tend to give the best films for staining. Such conditions are an even temperature, avoiding sudden changes of temperature in preparing the films, avoiding jarring and allowing the organisms to remain in sterile water for several days or weeks before making the films.

Our special thanks are due to Dr. V. A. Moore and the instructors in bacteriology for the courtesies extended, as well as for the direct assistance given in carrying on this work.

SPECIAL ARTICLES

ADDRESS TO THE MEMBERS OF THE PHILADELPHIA PEDIATRIC SOCIETY, AT ITS EIGHTH ANNUAL MEETING, JANUARY 12, 1904.¹

BY

D. J. M. MILLER, M.D.,
of Philadelphia.

The year just completed, the seventh in the life of our young and vigorous society, differs in no wise from its predecessors in the record of instructive and interesting papers and cases presented and well-attended meetings; indeed, in the matter of attendance, we compare very favorably with other medical societies. With a membership of 208, we have had an average attendance of 25, or about 12%. But the actual attendance has, I am sure, been larger, many having failed to register their names on entering the hall; so it can fairly be assumed that fully 30 have usually been present at the meetings. The Pathological Society, with 334 members, has an attendance of 42, or 12.5%; the County Medical, with 900 members, an attendance of 40 to 60, or from 4.4% to 6.6%. Because other societies, however, have about the same attendance as ours is no reason that our meetings should not be larger. Surely it ought to be an easy matter to get 40 or 50 together, once a month, in a society as young and active as this, whose object is the study of a subject as broad and fascinating as pediatrics, a specialty which includes every branch of medicine, and is so catholic as to have been well called the specialty of the general practitioner.

I have often thought that the cases and papers presented at our meetings should be more representative of the society as a whole. In looking over the work of 1903, I find that the 49 cases and papers presented were contributed by 33 members (i. e., 13 contributed papers or cases more than once). This leaves 175 who were unmindful of the injunction of Francis Bacon that "Every man is a debtor to his profession . . . and ought of duty to be a help thereunto." I am sure you will agree with me that there is room for improvement here. I know that some are deterred by modesty, others by the belief that unless a case is especially rare or interesting it would be but boring the society to report it, others again by the claims and opportunities of a busy life, and still others, I fear, by inertia. But none of these excuses seems valid. There is hardly one of us who does not occasionally see cases or has used methods of treatment that would not interest and help his or her fellow members, nor very few who could not snatch a few moments now and then to write a brief report or prepare an elaborate paper.

Another way to add to the attractiveness of our meetings, would be the personal invitation, by presenters of papers and cases, to men especially skilled in the subject they are to report, to take part in the discussion—the discussions being often as valuable and interesting, sometimes more so, than the papers themselves. Members themselves, too, might enter more into the discussions, for we must not forget that one of the chief benefits we derive from this and all medical societies is from the different points of view with which almost every subject is looked at by different minds.

All of us have observed that on the evenings when many patients are shown there is usually a larger attendance than at meetings devoted to papers alone. It has occurred to me that it would be well to act upon this fact, and I would suggest to your Executive Committee the advisability of setting apart one or more evenings in the year exclusively to the exhibition of patients. Such "clinical evenings," as they are called, are a peculiar feature of the Harveian Society of London, and many, if not the majority, of the meetings of the English Society for the Study of Disease in Children seems to be of this character. How attractive and instructive the exhibition of patients can be made is well shown by the meeting in December last, when 4 out of the 5 items on the program were the presentation of patients, 3 of whom were the extremely interesting ones shown by Dr. Griffith.

As an additional means of maintaining the interest in the society's meetings, I would also recommend to the consideration of the Executive Committee the Symposium. I can only recall two such meetings: The one on heart disease and the one on vaccination, both of which were due, I believe, to the indefatigable zeal of the revered and lamented Packard, who was always a firm believer in the value of this form of meetings, and so successful in organizing them.

I do not mean to imply by these remarks that our meetings are not attractive—indeed, they are always extremely so. I merely wish to insist that our attendance is hardly proportionate to our membership, and to point out how we can make the meetings more interesting, and thus draw out a larger attendance.

While dwelling upon the matter of attendance I cannot refrain from expressing the wish that our women members would participate more actively in the proceedings of the society. According to the register, only five women were present at the meetings of the year just closed, and but two presented papers; one in conjunction with another member, and one alone. More, however, I am sure, were present than the register indicated, many having failed to put down their names. Notwithstanding this, I feel that more women should take part in the proceedings of a society devoted to a branch of medicine in which they are, or are supposed to be, particularly interested.

As to the character of the material presented during the past year, while there have been few, if any, papers of eminent scientific nature or showing painstaking and laborious research, the clinical and practical aspect of pediatrics has been most excellently represented. Our proceedings compare very favorably with the recently published third volume of the transactions of the English Society for the Study of Disease in Children. Indeed, although the volume just mentioned contains the records of 70 papers and cases, neither in the manner in which they are presented, nor for practical and clinical value, are they in any way superior to those contributed to this society. For our work, too, we need not apologize when placed alongside that of the American Pediatric Society. Comparisons, I am well aware, are odious, yet I must mention among the papers read during the year as noteworthy and interesting contributions to pediatric knowledge, those on the nature and treatment of recurrent vomiting, on amaurotic family idiocy, on aneurysm of the aorta in early life, and on subphrenic abscess and typhoid perforation in children. But we must not rest complacently upon the excellence of what we have achieved; that which we and our predecessors have done in the past should act only as a stimulus for renewed efforts on our part in the future. We need more carefully prepared papers; not only those displaying painstaking research, but also those of a practical and clinical character, especially such as are devoted to treatment. There has always been a dearth of papers of this character, from the natural diffidence, I suppose, that every one has of expressing views on a subject about which there are always so many and diverse opinions as that of therapeutics. Yet the treatment of disease is the physician's chief *raison d'être*, and is to him ever a topic of perennial interest. I would suggest to the many specialists who are members of this society, that their associates would be very grateful if they would more frequently give to them their experiences in the treatment (and diagnosis, too), of the affections in which they are especially interested. Others, also, might occasionally report to the society methods of treatment in which they have been successful. I have no doubt that there is not one of us, however experienced or skilful, who would not at some time or other learn something useful if papers of this character were more often read.

You will learn this evening from the treasurer's report that this society suffers from an *embarras de richesse*, in that the balances of each year since the organization of the society have accumulated into a handsome surplus. What disposition should be made of this money has for some time agitated the minds of many of us—whether we should expend it in some useful way or permit it to accumulate. If we decide upon the former course (and I see no good reason why we should adhere to the latter), several plans suggest themselves whereby the money

¹Seventh Presidential address.

might be profitably used: One is to establish a pediatric library in the College of Physicians to which all our members might have access; a second is to create an entertainment fund; a third to institute an annual or biannual prize essay on some pediatric subject; and, lastly, to publish our transactions. I confess that the latter appeals most strongly to me. Any one who has examined the handsome and interesting volume of transactions just published by the English Society for the Study of Disease in Children cannot avoid the wish that our proceedings were in an equally attractive and accessible form. And, if only we could afford it, there is no good reason why they should not be. Our material, as I have already shown, is as valuable as that of other societies devoted to pediatrics, and it is desirable from every point of view that this society's influence should be extended, as it surely would be, by a well-edited volume of transactions. The profession would thus learn what we are doing, and our work would be in a form permanently and readily accessible to all interested in the diseases of children. For these reasons, it seems to me, that we could not better use this surplus than by issuing such a volume; either by spending the whole of it, or by using only a portion, or in some other way, to be decided upon, after thorough investigation, by a special committee. To which end I would suggest that a resolution be offered referring the whole matter to the careful consideration of the Executive Committee.

It is an interesting coincidence that it was just seven years ago tonight—on January 12, 1897—that this society held its first meeting; a preliminary meeting, it is true, had been held at the residence of Dr. Griffith early in December, 1896; but the first regular meeting and the first election of officers occurred on the date first mentioned.

I well remember that a prominent clinician spoke to me at the time in a most disparaging way of the undertaking, partly on the ground that there were already too many medical societies, but especially for the reason that there was no place in medicine for a special department limited to children's diseases, the speaker maintaining that the diseases of children differed in no wise from the diseases of adults, and with the exception of infant feeding, which he said could easily be mastered in a short time, there was no sufficient cause for regarding pediatrics as a special branch of medicine. Curiously enough, shortly after this conversation there appeared in a well-known medical journal an editorial with the same purport.

How mistaken the first portion of this criticism was, the seven prosperous years of this society bear convincing witness, and as to the latter part, the need of especial study and experience in diagnosing and treating the diseases of early life will be better appreciated, as soon as it is recognized that while there are very few affections confined to children alone, the manifestations of disease in infancy and childhood differ very materially from those in adult life and old age. This difference is well shown, in the case of one disease, by Dr. Cheadle in his monograph on the manifestations of the rheumatic state in childhood. Those, he says, who, in diagnosing rheumatism in childhood, have in mind the adult type of articular rheumatism, will frequently fail to recognize many of the symptoms, which in early life are undoubtedly due to the rheumatic poison. Another instance is the frequency of abdominal pain in the pneumonias of children, causing the diagnosis of gastritis, gastric fever or appendicitis to be made, when the actual seat of disease is in the lung. In fact, one whose experience is limited to the pathology, symptoms, and prognosis of the pneumonias of mature life will often find himself far astray if he depends upon such knowledge for the recognition of the same disease at an earlier age. Other instances, too numerous to mention, of the specific manner in which disease manifests itself in early life, and which makes the recognition of the ailments of the young so difficult at times, to those not familiar with sick children, will doubtless occur to you all.

But the purpose of this society needs no vindication at my hands. Pediatrics is a well-established and important branch of medicine, although still in its infancy, for the "anatomic and physiologic" peculiarities of infancy and childhood, the pathology and bacteriology of disease at this period, offer numerous wide and inviting fields for especial study, in which, although

there has been much good work, much more remains to be done. Among the many problems awaiting solution may be mentioned the nature of the status lymphaticus, especially in connection with enlarged thymus and sudden death in infants; the cause, prevention and treatment of many of the specific infectious diseases; the nature of the acute and chronic arthritic affections of childhood and their relation to purpura, erythema, tonsillitis, endocarditis, and chorea, besides many important questions connected with the nutrition and feeding of infants, upon which the last word has not yet been spoken.

How much the especial study of pediatrics has led to a more intelligent understanding of the nature and treatment of the diseases of early life will, perhaps, be better appreciated when we compare, for a brief space, our position today with what it was in the past.¹ (And if I refer more especially to infant feeding, it is because of its interest and intimate connection with the development of pediatrics.) In one of the earlier English treatises on the diseases of infants (that of W. Harris, first published in Latin, in 1689²) the author attributes all the symptoms of infants to an all-prevailing acid (a conception due probably to the custom of the age, a custom not yet extinct, of feeding babies from the hour of their birth with bread and other farinaceous foods). Hence the most valuable medicines were antacids and absorbents, such as crab's eyes and claws, oyster shells, coral and pearls; the more expensive, the more efficacious. As the humoral pathology held sway, almost all treatment was of an eliminative nature. Thus puking, purging, blistering and bleeding, even in tender infants, were the accepted forms of practice. A baby of 6 or 10 months with thrush must have found the struggle for existence especially difficult when he was first poked with antimonial wine (12 drops to 20 drops), then purged with 15 gr. of rhubarb or senna, or 6 gr. of calomel; and, if the fever was high, bled to the amount of 3 oz. Yet such was the accepted practice. Dr. Harris, however, protested against some of the therapeutics of his day; for he stated that "bleeding is unnecessary in any disease of infants, except in convulsions, chin-coughs and fevers attended with violent fits of coughing." And again, "opiates are contrary to the nature of children, except in obstinate vomitings, especially if it is joined with dreadful and continued gripings." His views on difficult dentition, even at this late date, claim many followers; for he remarked that "of all the disorders of infants there is none that produces so many grievous symptoms as the laborious breeding of the teeth."

In speaking of prognosis, one author makes two statements which are equally true today: One, that "from the middle of July to the middle of September the epidemic watery gripes are so rife that more children die of the disease in one month than three or four at another time of the year;" the other, that "the cure of disease depends often upon the nurse, whether she is obedient to your instructions or relies upon her own wisdom." Artificial feeding is not referred to, but it sounds familiar to read that many mothers refuse to suckle their offspring, "because of frequent visits, fine clothes, theaters, or the devoting the greater part of the night to their beloved cards." An evidence that human nature was much the same then as it is now.

Dr. George Armstrong, who wrote about 1767,³ believing that most of the complaints of infancy were due "to activity of the glandular secretions and the stagnation of their slimy contents in the stomach and bowels," employed emetics, in the form of antimony, for almost every ill that infantile flesh is heir to. But if parents sometimes objected to such treatment as too harsh, he stated that in one disease (the watery gripes) he had fallen upon a method of treatment that often succeeded well, namely, the use of purgatives followed by anodynes, a practice which we today still find of great value. This pediatricist goes quite fully into the question of dry nursing, and recommends a pap made of bread boiled in water and sweetened with sugar. He recommends mixing with this pap, cows' or asses' milk as often as possible, and, now and then, some of it alone to drink. If the milk sours on the stomach, broth of

¹ In the review that follows only English writers are referred to.

² A Treatise on the Acute Diseases of Infants, Translated into English by John Martyn, London, 1742.

³ An Account of the Diseases Most Incident to Children, New Edition, London, 1783.

either chicken, veal, or mutton is advised in place of the milk. Milk, you will observe, was regarded as a rather dangerous food. Feeding by spoon he preferred to the horn, because the latter "induces loose bowels and compels the use of too thin a food." The horn was the common cow's horn, on to the smaller end of which was fastened "two bits of parchment, shaped like the finger of a glove, and stitched together in such a manner that food poured into the horn could be sucked through the stitches."

Michael Underwood's treatise, written about 1785¹, is really an excellent manual on the diseases of children, and, although his conceptions of the nature of infantile diseases are much the same as those of his predecessors, his treatment is more natural and less harsh. He deprecates the indiscriminate use of antimonial wine, and protests against the universal practice of giving newborn infants bread and like forms of food. For infants deprived of the breast he advises cows' milk with a little jelly of hartshorne shavings (to correct its natural acescency²), diluted with a little water, if very rich. For very young infants he recommends that the milk be boiled.

It is remarkable that 17 years after this, in 1811, a non-medical writer, who styles herself "an American Matron,"³ in a little work entitled "The Maternal Physician," containing much excellent advice, states that "milk is the only proper substitute for the breast," and that "if infants were never suffered to take any other food many of their distressing disorders would be avoided."

In 1825 the first American work devoted to the diseases of children was published by Dr. Dewees of this city⁴. In the descriptions of the symptoms and, occasionally, of the etiology of disease, and in prognosis, this book leaves little to be desired. The treatment by drugs is still harsh and crude, but the directions for the hygienic management of sick and well children are excellent. Cholera infantum, for instance, is attributed to atmospheric heat, dentition and improper food. Change of air is recommended as the best treatment, and regimen more important than medicines. The suggestion to give teaspoonful doses, every 15 minutes, of hot black coffee for the gastric irritability and general prostration, seems to me, to be worthy of imitation. It is interesting to note that scarlet fever and measles are not regarded as contagious, but epidemic in nature, and that he opposes tracheotomy in croup "on the ground that it can do no more than the spontaneous expulsion of the membrane, which is rarely followed by permanent relief." As already stated, the portion of Dewees' treatise devoted to the dietetic and hygienic management of infants and children is so excellent that it would serve well as a reliable nursery guide at the present day. The rules for the artificial feeding of infants show remarkable advances over previous authors. Farinaceous substances are condemned, and a mixture of milk ($\frac{3}{4}$), water ($\frac{1}{4}$) and sugar is strongly recommended. After the eruption of the first one or two teeth, the addition of thin gruels is advised. Food is to be administered in a bottle fitted with a sponge or a prepared heifer's teat. Most explicit are his directions for the cleansing of the bottles, nipple and every utensil employed in the preparation of the food and the care of the milk.

From the time of Dewees down to the appearance of the first editions of the treatises of John F. Meigs and Charles West, in 1848, we note but little advancement in the domain of pediatrics. In Meig's work, however, we remark the first attempt to modify cows' milk so as to make it resemble human milk in the recommendation of his wellknown mixture of cream, milk, and arrow-root or gelatin water, a mixture still occupying a prominent place in the prescribing manual of the Children's Hospital of Philadelphia. To a member of this society, his son, is due the credit of further elaborating this idea and laying the foundations of the modern method of percentage feeding.

From the publication of the works of Meigs and West the progress in pediatrics has been rapid, and since 1880, so mar-

velous and so numerous have been the advances that it would be impossible in a single evening to consider them even partially. It should be a source of congratulation, also, that these onward steps have been more in the direction of the supreme aim of medicine; namely, the prevention of disease and the saving of life, than in almost any other branch of our art, save, perhaps, the brilliant achievements of modern surgery. The discovery of diphtheria antitoxin and intubation, the recognition and proper treatment of congenital pyloric stenosis and the advances in artificial infant feeding may justly be regarded as distinctly life-saving measures.

Indeed, so successful and so safe has the artificial feeding of infants become that I believe it has given rise to a real danger, in that we are apt, in the fascination of calculating percentages and adjusting our mixtures to the ever-varying needs of the infant's nutrition, to forget that the best food for the baby is its mother's milk. Trite as the remark may appear, the proper food for the infant is that fluid which flows from the human breast, and our aim should be not to improve artificial feeding, but to encourage breast feeding, and to discover methods to modify human milk with the same zeal with which we have studied the modification of that of the cow.

Members of the Pediatric Society, we have "a goodly heritage." Let us see to it that this precious thing which we have received does not languish in our hands. Let us press onward in the advancement of our special branch of medicine, charged as it is with a mission so important to the welfare of the race as the strengthening and healing of little children, the fathers and mothers of tomorrow.

THE WORLD'S LATEST LITERATURE

Journal of the American Medical Association.

9. Enormous Mixed Tumor of the Parotid Region Reaching to the Clavicle and Weighing About Seven Pounds: Operation: Recovery. W. W. KEEN.

1.—Cesarean Section for Placenta Prævia.—J. B. Deaver gives the mortality of other methods of treatment as about 11% for the mother and 5% to 10% for the child. In 24 cases of cesarean section collected from literature the mortality was, respectively, 20.8% and 66.6%. In view, therefore, of these figures it is not a method to be unreservedly recommended, but should be confined to those whose cervix is with difficulty dilatable, whose birth canal is rather contracted, when immediate extraction of the fetus is necessary, and when further hemorrhage would almost certainly kill either mother or child, or both. In a private house, without skilled assistance, version and extraction would be the better treatment. Mortality, both for mother and child, has been greater when the operation was undertaken before the fetus was viable, showing that the early stage of pregnancy is more unfavorable for the mother. [H.M.]

2.—Surgical Observations in the Philippines.—J. M. Banister finds that aseptic results will just as surely follow aseptic methods in the Philippines as in the United States. Should infection occur, blame the technic and not the climate. Successful attainment of the object for which operation has been undertaken will follow careful and skilful surgery in the Philippines with the same regularity as at home. Convalescence is rapid and satisfactory. Mortality is not increased by the climate unless the patient is the victim of some other serious disease. [H.M.]

3.—Bacillus Dysenteriae in Boston and Vicinity.—R. W. Hastings reports a study of 28 hospital cases, in which there were found 23 of the Harris variety, 3 of the Shiga, and 2 of both. The local pathologic lesions have proved to be thick-

ened intestinal walls, with prominent, injected, sometimes ulcerated follicles, and a coating of thick glairy mucus. Two patients were breast-fed. In most the food lacked even ordinary care in its method of preparation. Of the severe cases there were 13 deaths, 5 recoveries, and 2 unrelieved, both of the latter dying outside the hospital. The writer can draw no positive conclusion from experience with the serum used. No harm was done. He believes in another year a stronger serum which will then be available, may be more efficient. [H.M.]

4.—The Panama Canal and Oral Hygiene.—E. S. Talbot believes intestinal gingivitis will extensively prevail during work on the Panama Canal. Its pathology and etiology are at bottom the same as scurvy. It is caused by change of climate and food. The excretory organs do not adjust themselves to the new environment, and intestinal fermentation and autointoxication result. The largest number of cases occur between 21 and 30. In the American army mostly young men are enlisted. There is no part of the West in which the disease is so prevalent as in the Northwest. [H.M.]

5.—Detecting and Differentiating Reducing Agents.—W. G. Doern points out the frequent source of error in diagnosis in accepting a positive reaction without confirmation. The objections to Trommer's test for sugar are that if the two solutions are not used in proper proportion a precipitate will form; a large quantity of urine is required; increasing liability of error from uric acid, creatinin and the phosphates precipitated by the KOH. The test is not delicate without boiling and when boiled becomes oversensitive. Fehling's solution is more convenient but less stable. Haines' solution is stable. The copper and bismuth tests are reliable negative tests, but a positive test must be confirmed. With Haines' test a certain technic must be exactly followed. Bismuth solutions are not reduced by the alkaptons and serve to differentiate them from other reducing agents. The fermentation test serves to differentiate lactose, glycuronic acid, hippuric acid, the alkaptons, and the pentoses, which do not ferment, from levulose and dextrose. If the completely fermented urine should still reduce the copper solution it indicates glycuronic acid or alkaptons. Phenylhydrazin test is good but the technic is complicated. Pentoses may be recognized by the orcin test. Alkaptons are recognized by the characteristic organized alkali test. We can differentiate dextrose from levulose by a polariscope examination. [H.M.]

7.—Parasitic Hemoptysis.—A. D. Mackenzie reports a case in which the ova of the distoma were finally found in the sputa; the first observed on this continent in man, though it has been noted in three instances in animals. The reasons for considering that separate species have been described are as yet insufficient. There is every reason to believe the case here reported was infected in Japan. The disease is endemic in Okayama. *Distoma* or *Paragonimus westermanii* is responsible for both pulmonary and cerebral disease. Cysts are the chief anatomic change. Those in the lungs are usually on the upper lobes and near the surface, where they may form brownish or darker projections. Their size is about that of the tip of the little finger. When they contain parasites there is a viscid, brownish-gray fluid, and the lining is rough, ragged or wrinkled. They rarely contain more than a single worm in man. Their firm walls measure a millimeter, and are formed by the tissues of the host. A bronchitis is set up with a mucopurulent hemorrhagic exudation as well as various forms of pneumonia, depending on the stage of the infection and on repeated infection. The nodules forming about the ova are said to simulate chalicosis. [H.M.]

8.—Illegitimacy an Economic Problem.—J. E. Davis uses the term to designate a vice in which is the implication of a child, a mother, a father, the relatives, friends, and community. The statistics in this country are very incomplete. The chief causative factors are insufficient instruction in the phenomena of sexual life, particularly of girls; incontinency on the part of the male, combined with the passive submission of the woman, with mutual passion prevailing; faulty guardianship; seduction under promise of marriage, lack of means to establish a home and other impediments to marriage; the general servility of women and aversion to marriage on the part of males, and a prevailing notion that hard work is disgraceful and that

good clothes are a necessity; the remoter causes of heredity and environment. The preventive measures, educational, moral, and religious, fail for want of direct and specific application. The sexual nature should be plainly outlined by personal interviews, and confidences secured. In answer to questions sent to physicians and philanthropists 75% favor secrecy as to the individuals involved. The best interests of the child should decide the question of secrecy or publicity. Should publicity compel the father to do his duty, secrecy would be an injustice. When the woman's parents are dead or worthless or would cast off their erring child, or when the father of the child is worthless, absolute secrecy should be imperative to avoid disgrace and destruction of incentive to right living, injury to the future of the child and to society. [H.M.]

9.—Enormous Mixed Tumor of the Parotid Region.—W. W. Keen reports a case of interest from the slow and later rapid growth, the enormous size (seven pounds in weight), the age of the patient (65 years), and the fact that he was able to dissect it away from important structures, especially the blood-vessels of the neck, and the very happy recovery of the patient with simply a scar and paralysis of the right seventh nerve. The diagnosis was myxochondrolymphangiendthelioma. [H.M.]

1. Introductory Lecture at University Bellevue Hospital Medical College. BEVERLEY ROBINSON.
2. Resection of Nasal Septum with Report of 15 Cases. LEON E. WHITE.
3. Some Clinical Observations on Care of Septic Wounds. ARTHUR L. CHUTE.

2.—Resection of the Nasal Septum.—Leon E. White reports 15 cases, and describes in detail the operation. The latter consists briefly in cocainizing the convex aspect of the septum and later the concave, making a straight vertical incision in the nasal mucous membrane at the anterior extremity of the convexity, dissecting off the mucous membrane, puncturing through the cartilage, but not through the mucous membrane of the opposite side and biting away in piece-meal the edge of the cartilage thus freed. With another special instrument carried through the opening made in the cartilage, he pushes away the mucous membrane of the opposite side, thus clearing the cartilage so that as much as is necessary may be nipped away in successive pieces by a specially devised forceps. Illustrations of the special instrument accompany the article with directions as to treatment. The advantages of this method are enumerated as follows: (1) There is accuracy, the work being done under the eye of the operator. As every part of the deflected portion can be seen, and then removed, the position of the septum will be uniformly good. In no other operation is there such a certainty as to the result; (2) splints do not have to be worn—these at the best are a great nuisance to both operator and patient; (3) rapidity of recovery—three or four weeks, as against six or eight by other methods; (4) lack of pain due largely to the absence of traumatism; (5) short after-treatment; (6) freedom from sepsis; (7) free respiration 48 hours after the operation; (8) it is available for either bony or cartilaginous deflections; (9) it creates the utmost possible space by not only straightening the septum but by reducing its thickness to that of the two layers of the mucosa; (10) the lumen of the concave side is never lessened. [A.B.C.]

3.—Clinical Observations on the Cure of Septic Wounds.—Arthur L. Chute writes at some length upon this subject, and concludes as follows: Dry sterile gauze dressings are far preferable for the dressing of septic wounds, because they, by their greater power of absorption, most efficiently drain the wound, and by their slight mechanical irritation and comparative dryness make the granulations more active and allow us to take full advantage of nature's reparative power, while moist dressings and antiseptic baths and irrigating fluids have a depressing effect on the granulations; moist dressings are, however, indicated when one cannot obtain sterile dressings or cannot depend on the aseptic skill of the persons who are to apply the dressings. "Antiseptic poultices" are not to be preferred to sterile dressings, and there is at times a danger in

their use; in case irrigating fluids are necessary, when from some unusual reason we are unable to make a wound of such shape that it can be properly dressed, sterile salt solution should be the irrigating fluid used. One should avoid hydrogen peroxid, since in partially closed cavities or loose tissues its gas production may make it a spreader of infection; the use of dry sterile gauze meets the indications in the routine treatment of the great majority of septic wounds better than any other material. [A.B.C.]

5. Hemorrhage after Tonsillotomy: Its General Consideration. H. JARECKY.

1.—Surgery of the Common Ducts of the Liver.—

William J. Mayo says, given an infected gallbladder containing stone which causes mechanical irritation and we have the most favorable condition for bacterial excursions into the common duct, and should this be accompanied by calculi which fail to pass the duodenal orifices we have all the conditions favorable for development of cholangitis, pancreatitis, etc. At least 90% of all the cases of common duct disease upon which we are called to operate arise in this way. If the cystic duct is closed mechanically, either by stone, kink, or stricture, a diseased gallbladder results, which should be removed. The key to the diagnosis of this condition is found in the fact that the gallbladder contains no bile, cholecystectomy is easily performed from below upward, the cystic duct and vessels are caught with forceps while a second forceps on the gallbladder side prevents leakage and enables division of the cystic duct and vessels. The gallbladder can then be readily separated from below upward without hemorrhage or trouble. If the gallbladder contains bile we have an entirely different condition to deal with. Free communication through an open cystic duct means a possible infection of the common duct, and if the infection is at all marked provision must be made for bile drainage to the surface. This is best accomplished by a cholecystostomy, which not only drains the gallbladder, cystic duct or common duct, but the pancreatic duct as well, particularly if a stone be lodged in the ampulla of Vater. Interesting illustrations accompany the article. [A.B.C.]

2.—Appendicitis in Children.—

John W. Brannan reports a case in detail occurring in a boy of 6 years. He then discusses the literature on the subject and calls attention to the relatively few cases which have been reported. When we have the classic symptoms of sudden and severe pain in the right iliac fossa which localized tenderness and vomiting, there is not much doubt with what we have to deal. But all writers agree that these symptoms, with the exception of vomiting, are much less constant in children than in adults, especially the localization of the pain and tenderness at the site of the appendix. According to Deaver, the pain is referred to this region in 54% of all cases, as the attack progresses, though in the beginning it is usually placed in the umbilical or epigastric regions. The location of the tenderness is much more to be depended upon, being an objective rather than a subjective symptom. As stated by Churchill, more importance is to be attached to what children *look* than to what they *say*. In six Bellevue cases in which the history was obtained, there was tenderness in the right iliac fossa in all, whereas pain was referred to that region in only three. When a tumor is present or a resisting mass is felt, or there is rigidity of the right rectus muscle with flexure of the right thigh, there can be no further room for doubt. [A.B.C.]

3.—Uric Acid, Gout, and Lithemia.—

E. Le Fevre says: In order to explain the relation of uric acid to the affections, it is necessary to have more definite knowledge on (1) the conditions which increase endogenous nucleoproteids from increased tissue metabolism; (2) all the forms in which nucleoproteids are introduced with the food; (3) the power of the tissues to decompose the purin bases into uric acid or still further change

them into urea or some form beyond uric acid; (4) the effect of the purin bases or the products intermediate between them and uric acid, on physiologic and pathologic processes; (5) the factors that cause its accumulation in the tissue in the form of urate of sodium, and the production of the gouty condition; (6) the factors that prevent elimination of uric acid in normal amounts; (7) the factors that cause separation of uric acid from the urine in kidney and bladder. In meats the nucleoproteids are the only source of uric acid. The fermented liquors introduce xanthin bases and also produce endogenous uric acid from tissue-change. With an outdoor life and free muscular exercise immense quantities of animal food and even alcohol can be taken without causing a corresponding increase in the uric acid secretion, and this same mode of life is frequently sufficient to remove the symptoms of lithemia. More than 50% of all cases showing these symptoms give a family history of gout. [H.M.]

4.—**Insufficiencia Pylori.**—Mark I. Knapp's remarks are based on an experience with over 50 consecutive cases. Normally, one hour after a Ewald's test-meal, the healthy stomach should yield from 30 cc. to 50 cc. of chyme, the solid part of which should be well pulverized and the fluid part thin. Insufficiencia pylori is the condition in which nothing, or possibly only 1 cc. or 2 cc. of chyme are aspirated an hour after the test-meal, and this is because the pylorus either does not close at any time or does so insufficiently for a shorter period than is normal. If the condition is not attended by too severe complications, prognosis is excellent, no matter how old the patient or how long the disease has existed. In treatment the etiology must be kept in mind, alcoholism and the gulping down of food should be interdicted; mastication must, at all times, be complete; loss of teeth should be supplanted by artificial ones; all cereals and vegetables should be well boiled and eaten in the form of puree; meats should be cut into very small pieces or ground before being eaten. The dietetic treatment is of chief importance. The object is not to introduce any acid food nor food which develops gases. What the patients complain of is due to faulty intestinal digestion. And, usually, the patients do not seek medical advice before the intestinal functions are interfered with. Insufficiencia pylori cannot be diagnosed without a test-meal—possibly, several test-meal examinations, one to follow the other one day after the other. Absence of chyme one hour after the test-breakfast or at most 1 cc. or 2 cc. of coarse particles is the diagnostic criterion. [A.B.C.]

5.—**Hemorrhage after Tonsillotomy.**—H. Jarecky says a review of the past 61 years places the number of reported post-operative hemorrhages after tonsillotomy at 175, with two reported deaths. The causes of the bleeding are (1) hemophilia, (2) fibroid tonsils, (3) laceration of the bloodvessels, (4) anomalous arteries, (5) wounding of the anterior pillars, (6) ulceration. These cases are discussed at length. He reports in detail the history of a girl, aged 27, operated upon under a general anesthesia. There was severe after-bleeding and two days' strings of clot were found hanging in the pharynx. These were removed and again on the sixth and eighth days there was bleeding, which was evidently venous in character. The patient made a good recovery. His conclusions are: (1) That troublesome hemorrhages occur in children; (2) they happen very frequently in adults, in proportion to the number operated upon; (3) in case of bleeding, use a good light and clean the parts to ascertain the cause; (4) anesthetize or use morphin, if necessary, to quiet the patient; (5) never operate without being prepared to cope with a hemorrhage. [A.B.C.]

8. The Soules Hospital Method of Burying the Stumps of the Appendix and Mesosigmoid in Appendicectomy. THOMAS E. SOULES.

1.—Sclerosis and Ossification of Veins.—Carl Beck has made skiagraphic examinations of the thrombi in dilated veins, and says that whenever the röntgen rays show the presence of osseous degeneration, it is obvious that the much favored methods of using laced stockings, elastic bandages, injections into the circumvascular tissues or ignipuncture, are not only futile, but directly dangerous efforts; the only procedure which guarantees recovery being extirpation. The diagnosis of the presence of osseous degeneration cannot be made by palpation, the indurated areas not appearing different from simple fibrous convolutions. Thus the röntgen rays are the only means to secure anatomic evidence before operation. [C.A.O.]

2.—Congenital Hip Dislocation.—The article presented by D. D. Ashley and Frederick Mueller deals exclusively with the treatment following the bloodless reduction of congenital hip dislocation. A part of the after-treatment, the stretching of the flexors which have been rendered too short by the reduction and the extreme abduction, is best performed while the patient is still under the influence of the anesthetic. Immediately following the operation, the child is put to bed and the pelvis is kept elevated by a pillow placed under the hips, since in this position the pressure of the borders of the cast against the abdomen and against the inner condyle of the knee is reduced to insignificance. This latter point calls for special attention, because decubitis is very likely to develop at the knee if the cast is not abundantly padded and its borders very well everted. Some form of opium may be necessary during the first three nights. In some patients, usually where an overextension in primary position was necessary, an edema of the whole lower part of the leg may develop, due to an interference with the venous circulation. This edema may disappear readily if the leg is bandaged with a flannel binder. If the swelling persists, it is well to look to the spica. At first the walking exercises consist in placing the child in the upright position and teaching him to maintain his equilibrium. After two or three days of these exercises, attempts at walking are begun. In a few weeks the child walks around without any aid, and appears only slightly hampered by the cast. [C.A.O.]

3.—Chemistry in Infant Feeding.—H. D. Chapin says that as no absolutely exact constituents are necessary, chemic analyses of food are only of general value in establishing the range of safety in feeding. He says the successful feeder is the one who gets the infant to taking some suitable food and then adjusts the ingredients so that they are in sufficient quantity to carry on the normal chemic changes that take place in the body and allow storage of tissue other than fat, and at the same time produce proper functional development. He does not disparage chemic analysis of food, but shows that food chemistry has limitations in practical feeding; also that the chemic teachings of a few years ago are not the same as those of today. [C.A.O.]

4.—The Treatment of Typhoid Fever.—In discussing the diet in these cases, Morris Manges calls attention to the importance of keeping the mouth moist and the tongue and fauces clean. Large quantities of water should be drunk. The use of quinin has been of decided value in the hands of the author. No immediate effect is noted, but the general course on the following day is distinctly better. When quinin cannot be given by mouth, the subcutaneous use of the quinin and urea bichlorid in eight-grain doses offers a very reliable substitute. Manges does not hesitate to give castor-oil late in the disease, when he is not satisfied that the bowel has been properly cleared by high oil enemata. A method of arresting prolonged temperatures is the administration of large doses of quinin, 20 gr. to 25 gr. every afternoon for 2 or 3 days. The effect of these massive doses is often very prompt. There is no objection to the rational use of salol, the various bismuth salts, etc. He believes, however, that far better results are obtained by simpler means; these include (1) the early use of calomel, one or more times; (2) the systematic use of hydrochloric acid; (3) daily enemata to wash out the lower bowel, and finally, the prevention of undue intestinal distention. He uses alcohol only when it is needed as a stimulant; and when the patellar reflexes are exaggerated in typhoid fever he never uses strychnin. [C.A.O.]

5.—Contagiousness of Pneumonia.—R. N. Willson reports a series of cases of acute croupous pneumonia which

undoubtedly presents an instance of direct contagion. The three cases of identical infection occurred within one week in the same house, and among three intimate associates. Two other cases are reported which strikingly evidence the same probability. The chill in the second case occurred 11 days after that of the first. [C.A.O.]

8.—Appendicectomy.—T. E. Soules gives in detail with illustrations the Soules Hospital method of burying the stumps of the appendix and mesoappendix. The mesoappendix is tied off at or about its center in sections varying from one to four, usually according to length; each succeeding ligature being made to include some fibers of the preceding. The mesoappendix is then cut down to its base, the adherent mesentery is dissected from the appendix and removed, and a circular incision made through the peritoneal envelope, and carefully peeled off throughout its entire length to, or very near, its colonic junction, where a fine silk ligature is thrown around the denuded base of the appendix. Another ligature is applied about a quarter of an inch externally to this, and the cut made between the two; the appendix is then removed. The glove finger of peritoneum is then turned back and slit along the line of former mesenteric attachment, and spread out, making a flat membrane equal in extent to the circumference and length of the excised appendix; this is then made to cover the appendicular stump, together with the bare ends of the mesocecocolic stumps; and with edges turned in. [C.A.O.]

6. The Scope of Physical Economics: An Inquiry into the Possibilities of Enhancing Human Efficiency through Physical Education. J. MADISON TAYLOR.

1.—Bronchopneumonia in Children.—M. Nicoll, Jr., describes this as essentially a disease of the poor and unfortunate. The germ is so omnipresent we must seek an explanation of the affection in the character of the tissues. The causative factors in the so-called primary cases are unhygienic conditions and neglect of disease of the upper air passages. It occurs at all seasons; 70% are under two years of age. There is no disease more irregular in its course and uncertain in its outcome. Diagnosis is based on the acute onset in primary, the aggravation of all symptoms in secondary cases; in primary cases on the changed demeanor of the child and evidence of toxemia; fever continues over 36 hours, with increase of respiration and pulse, disturbance of respiration-pulse ratio; the presence of fine rales and occasionally a change in respiratory sounds. Cough is not an essential. Disturbance of pulse-respiration ratio occurs in several other diseases, but is rarely long-continued in them. Fluid in the chest usually occurs as a complication of pneumonia. Slow respiration differentiates laryngeal stenosis and meningitis. In malaria with bronchitis, blood-examination must be relied on in doubtful cases. [H.M.]

2.—Pathology of Pneumonia in Children.—D. Bovaird, Jr., has found at autopsies bronchopneumonia in 40% and lobar pneumonia in 2% of the cases. The latter is infrequent in the autopsy-room, because rarely fatal. He has never seen the stage of simple congestion, only red or gray hepatization. As a rule a whole lobe or several are involved, but partial consolidation is commoner in children than in adults. Apart from the area involved, appearances are the same. The amount of pleurisy varies greatly. In some cases a yellowish cut surface suggests the caseous pneumonia of adults. True caseous pneumonia is very rare in infancy. Small abscesses or gangrene may occur. The serous membranes, including pericardium, meninges, and peritoneum are often inflamed. Three types or stages of bronchopneumonia exist, bilateral and generally symmetric. In the first, on section, the greater portion of the lung is normal, but

about the smaller bronchi there are rings of deep congestion. The bronchi are full of exudate containing epithelium, bacteria and leukocytes, their walls being infiltrated with the latter, and the contiguous air cells contain fibrin and debris. In the second stage there are areas of consolidation throughout the lung, appreciable to touch. The third stage is known as pseudolobar pneumonia, in which the previously disseminated areas merge, the whole lobe becoming solid. It lacks the granular look of lobar pneumonia, and is generally mottled dark red and gray. Abscesses and gangrene may also occur here. With involvement of the larger part of a lobe there is usually pleurisy. Empyema is more frequently associated with bronchopneumonia than it is with lobar pneumonia or tuberculosis. The pneumococcus is the prevailing organism in both affections. [H.M.]

3.—Treatment of Bronchopneumonia in Children.—

W. P. Northrup advises castor-oil to clear the field; fresh air, cool and flowing, the room temperature being regulated inversely to that of the child; the feet must always be warm and the head cool. There should be plenty of water used inside and out, the temperature being indicated by that of the child. There should be quiet and rest and undisturbed sleep, avoidance of gas by correct feeding, and high, hot salines if necessary. No coaltar products should be given. The heart should be stimulated by fresh air, hot foot-baths, relief of tympanites and crowding whisky and strychnin. To kill the baby put the crib in the corner with a canopy over it, steam kettle, gas stove (leaky tubing), room at 80° F., many gas jets burning, friends in the room, also the dog, chest tightly enveloped in waistcoat poultice, windows blanketed, doors shut. If these do not do, give coaltar antipyretics and wait. [H.M.]

4.—Behavior of the Costal Arch in Diseases of the Abdominal Organs.—

Ellsworth Eliot completes his article in the present number with a report of 23 cases illustrative of the points under discussion and concludes, in part, as follows: (1) That the symptom of costal resistance may always be elicited in the acute and subacute inflammatory processes of the contiguous underlying organs. In chronic inflammation of these same organs it is present irregularly; (2) the degree of resistance is in direct ratio to the intensity of the inflammatory process; (3) the increase of costal resistance is most marked in that segment of the costal arch which is closely situated to the original point of infection; (4) its value as a diagnostic symptom is greatest in pathologic conditions invading the upper half of the abdominal cavity; (5) the presence of asymmetry in the elastic recoil is very much less frequently observed than asymmetric increase in the costal resistance; (6) with subsidence of the inflammatory process, the costal resistance again returns to its normal condition; (7) the presence of this symptom is valuable not only in facilitating accurate diagnosis, but in serving as a useful guide to incision; (8) proper and skilful technic in determining the presence or absence of this symptom may be easily acquired, and therefore, the application of the symptom may be utilized by the general practitioner. [A.B.C.]

5.—Transillumination of the Stomach by Means of

Fluorescent Media.—Robert Coleman concludes an interesting article, as follows: There are certain interesting problems that suggest themselves from this work: 1. The use of a radioactive solution in the fluorescent medium for stomach transillumination, since Morton demonstrates that a radioactive solution increases fluorescence. 2. The radioactive solution in the fluorescent medium might itself give us a picture of the stomach in the dark-room, by use of the fluoroscope alone. 3. The possibilities of thus photographing the stomach either with or without the accessory of the röntgen ray apparatus by using the radioactive solution with fluorescence internally; fluorescein combines well with a normal saline and soda solution. 4. The possible value of the nonirritant fluorescein solution in the bladder, for the purpose of improving the scope of cystoscopy and an investigation as to whether such a solution would enable us to detect minute ulcers, or fissures in the bladder, just as in the cornea. [A.B.C.]

6.—Enhancing Human Efficiency through Physical

Education.—J. Madison Taylor, in an interesting article, states the objects to be obtained are to acquire elasticity of

tissues, and a capacity to relax. To acquire normal attitudes it is absolutely essential that symmetric elasticity of the tissues be first secured. Relaxation being gained, or fully appreciated, he gives directions as to how (1) to acquire normal attitudes; (2) to overcome contractures; (3) to attain full flexibility of the muscles by which alone their competence is established; (4) to acquire accuracy in movements, etc. It is desirable also to secure (5) full capacity for extension, first passive, and later active, by which the tendons are stretched to their uttermost and through this, much improvement is possible; (6) full respiratory capacity; the basis of oxygenation in lungs as well as muscles (7) circulatory capacity, the heart and great veins need development; a long story and attainable through automatic movements repeated to the limit; (8) capacity for muscular endurance, by repetition of automatic simple acts or varied movements; (9) muscle building, and (10) a combination of muscle-building, accuracy, endurance, full muscular competence of limbs and heart from such means as fencing, wrestling, boxing or other dual contests. [A.B.C.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

REVIEW OF LITERATURE

Hemorrhagic Type of Typhoid Fever.—Of this rare form Samohrd¹ reports five cases. The severe hemorrhages are apparently vicarious, and occur in the third or fourth week of the disease. In the first case there was profuse epistaxis. The second seemed almost hemophilic; a great outpouring took place from the ears, nose, and gingival surfaces, to which was soon added hematemesis, hemoptysis enterorrhagia, and bleeding from the urethra. The third case was one of hemic leakage through the urethral mucosa—not severe. In the two remaining cases the hemorrhages were limited to epistaxis and cutaneous leakage. One patient alone died—the fourth. At necropsy were found numerous slight intramuscular hemorrhages; there was a hemorrhagic infiltration of the mesenteric glands, and of the kidneys, bladder, and other viscera. The bacillus of Eberth was recoverable from all these hemorrhagic deposits, but no other morbid microorganism. It seems, then, that this variety of enteric fever is not due to a mixed infection, secondarily, or to an enterogenic septicemia. The author suggests the possibility of a more than commonly virulent species of the bacillus, which seemed to bring about a fatty degeneration of the venules and arterioles, which could predispose to the hemorrhages. [T.H.E.]

Gastrosuccorhea and Tetanic Attacks Occurring with Chronic Ulcer of the Stomach.—J. Kaufmann² regards gastrosuccorhea, or the presence in the fasting stomach of gastric juice, as a symptom instead of a disease. Motor insufficiency is of paramount importance in causing the condition but gastritis may cause and always aggravates it. The symptom-complex known as Reichmann's disease should be regarded as a symptom of gastric ulcer. Whenever a patient suffers from gastric pains that come on regularly after meals and especially at night, with or without vomiting, the presence of acid fluid even in small quantities in the fasting stomach indicates ulcer of that organ. As a rule in cases that develop gastrosuccorhea the ulcer is situated near the pylorus and causes mechanical obstruction, generally by spasm of the pylorus. Treatment of the condition should consist in freeing the stomach of its stagnating contents and at the same time applying methods commonly used in combating gastric ulcer. In cases which do not yield to methodical internal treatment, operative interference should do away with the hindrance at the pylorus. Kaufmann details at length the history of a case that bears out his contention regarding the nature of the condition under discussion. This patient also suffered from attacks of gastric tetany which Kaufmann believes are due to the great loss of fluid by vomiting or lavage; the system is also deprived at the same time of large amounts of chlorides which probably exerts an effect. [A.G.E.]

² American Journal of the Medical Sciences, April, 1901.

GENERAL SURGERY

A. B. CRAIG MARTIN B. TINKER C. A. ORR

REVIEW OF LITERATURE

Hygienic Surgery.—F. K. Etlinger¹ advocates the application of the principles and details of the sanatorium treatment of tuberculosis in the handling of surgical affections. The greatest safeguard against reinfection in any condition is light, well-ventilated rooms that are kept scrupulously clean. For improving the general condition of the patient, air, food, and exercise are to be considered. Etlinger maintains that in both operative and nonoperative surgery very little attention is paid to maintaining and improving the general condition of the body; certainly no attempt has been made to apply the principles of scientific hygiene generally in every surgical case. It is customary to keep hospital wards and private sickrooms quite inadequately ventilated; in the matter of food the tendency is to give too little nourishment, and even that of the invalid kind, when in many cases plenty of solid food is urgently required; the employment of massage or regulated exercises is frequently neglected. Special emphasis is put upon the damaging effect of stuffy operating rooms, where the patient has to breathe the anesthetic and in addition the foul air of a close room containing several other persons. These rooms should be well ventilated, necessary means for keeping the patient warm being supplied. [A.G.E.]

Operation for Gastroenterostomy.—John Rogers² summarizes the literature on the subject, and reported five cases operated upon. Among these there was one death three weeks after operation from an ascending urinary infection. The others resulted entirely satisfactory. They represented cancer, atonic stomach, ulcer, chronic gastritis, and probable ulcer with hepatic cirrhosis, and benign stenosis of the pylorus. This operation is undeniably suited for benign and malignant stenosis of the pylorus and for ulcer and dilation of the stomach. Gastroduodenostomy is physiologically better, and when possible should be given the preference. One of the most frequent of the bad results in gastroenterostomy is contraction of the fistula and recurrence of the symptoms. To prevent this Mayo recommends a pursestring suture about the pylorus. Rogers states that plication by infolding of the anterior stomach wall at this point would be simpler, and should be equally effective. [A.B.C.]

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN FRANK C. HAMMOND

REVIEW OF LITERATURE

Yeast Therapy for Gonorrhea in Women.—Otto Abraham³ states as the result of experiments upon four kinds of microorganisms with yeast, that the vitality of the gonococcus was destroyed in six hours, of streptococcus in 32 hours, and of staphylococcus in 40 hours. Under clinical conditions the result is modified and the time is considerably increased, yet in 27 cases of cervical catarrh put under yeast treatment, a complete cure was secured in 20 cases. Abraham considers it very improbable that the yeast cells can cause an endometritis or increased inflammation since microscopic examination of vaginal secretions after an application of yeast has shown that the yeast cells lose their virulence after a very short period. [W.K.]

Puerperal Eclampsia.—H. H. Arthur⁴ reports a case that presented some unusual phenomena. The patient was a primipara of 23, pregnancy normal until the ninth month. Edema, headache, nausea, and ocular disturbance then appeared, and the urine contained $\frac{1}{2}\%$ of albumin. Under the use of diuretics and exclusion of meat diet, the urine became normal and continued so until labor. Delivery was without incident, but one hour after, convulsions began, and lasted for 12 hours, during which time 18 seizures occurred; during this time the patient was practically comatose. Specimens

of urine obtained every few hours during the attack never showed more albumin than had been present before labor. The urine became normal the day following the convulsions. Severe pain referable to the liver was felt during the latter part of pregnancy, this disappearing about the same time as did the albumin. Arthur believes that the phenomena in this case justify the conclusion that the liver was more affected than were the kidneys, and hence a causative factor in the eclampsia. [A.G.E.]

Exohysteropexy According to Kocher in Enucleation of Myoma and also in Treatment of Prolapse.—J. Lauper¹ advocates Kocher's method of exohysteropexy for the following advantages: 1. The prompt appearance and much easier control of any after hemorrhage in contrast with the method in which the stump is deeply buried. 2. The greater certainty of an aseptic course especially in cases of hematoma or necrosis of the stump. 3. The smaller danger of the entrance of any complication in the return of the menses soon after the operation. 4. The greater ease of the operation and of the control of the hemorrhage. 5. The greater certainty of the procedure and the least mutilation of the aged; important also in the treatment of prolapse is the absolute ease in executing the operation. [W.K.]

TREATMENT

SOLOMON SOLIS COHEN
L. F. APPLEMAN E. LINDAUER

REVIEW OF LITERATURE

Hepatic Extract in Atrophic Cirrhosis of the Liver.—Creguy² reports the case of a man of 58 suffering from symptoms of atrophic cirrhosis of the liver with marked obstructive signs. The heart and kidneys seemed normal. During a period of eight months he was tapped 12 times, and at each tapping from 8 liters to 10 liters of fluid were removed. During this time he was kept on milk diet, and was given potassium iodid, sodium iodid, digitalis, and other diuretics at different times; laxatives also were given without influencing the condition in the least. He then placed the patient on milk diet, potassium nitrate, $\frac{1}{2}$ gm. ($7\frac{1}{2}$ gr.) and hepatic extract 1 gm. (15 gr.). The symptoms soon began to disappear, and shortly the patient was entirely well. [E.L.]

Treatment of Serous Effusions.—James Barr³ reports that in a female suffering from pleural effusion, the cavity was tapped a number of times and varying quantities of fluid were withdrawn; after the fifth tapping he injected a dram of adrenalin chlorid solution, 1 to 1,000, into the cavity, after which there was no further secretion of an annoying character. Since then he has used this treatment in a number of analogous instances, invariably with success. The quantity injected in each case has been 1 dram. He has likewise extended the treatment to ascites. In one instance this fluid was injected after evacuation of fluid due to hepatic cirrhosis, and, while it did not prevent recurrence, it is asserted that the rapidity of recurrence was much diminished. On several occasions he has injected 3 drams of the adrenalin solution into the peritoneal cavity with good effect. He has also injected the fluid into the pericardial sac in a patient suffering from pericarditis with effusions. After tapping the pericardium and withdrawing 20 ounces of fluid, 40 minims of adrenalin solution was injected into the pericardial sac. The patient passed into shock, showing that too great an amount had been injected. Stimulants were used, the patient was aroused, and very little fluid reaccumulated in the sac. [A.B.C.]

A Danger of Adrenalin.—After the addition of adrenalin to solutions used for obtaining local anesthesia, Neugebauer⁴ saw gangrene several times in the infiltrated cutaneous portions; elderly people were especially liable to this. The gangrene was not due to adrenalin diabetes, as none of the patients presented symptoms of this disease. He cautions against the use of adrenalin in old people. [E.L.]

VOL. VII, No. 20.

MAY 14, 1904.

\$5.00 YEARLY.

The demand for reciprocity, so energetic a year or two ago, seems to have become strangely silent. Was the abuse and its reform an imagined one, and if not, why has the profession become so indifferent to the fact that its own members, who have the State licensing in their hands, have done practically nothing to bring about actual reciprocity? There is no question that the States, individually, have the entire power in their hands, and that the Federal Government has no jurisdiction in the matter. And yet there is but one State, Illinois, if we are not in error, which does actually reciprocate. There is absolutely nothing in the Illinois law which empowers the Board to accept a license issued by another Board in place of an examination, and yet for three years the Board, according to resolution has done so, and today stands ready to carry out the practice in the case of applicants from other States which *practically* have the same requirements as the Illinois Board. The just proviso is made that other Boards will recognize the certificates of the Illinois Board. This puts the matter on a just and equitable basis and brings home to the profession the onus of responsibility. If, therefore, you really wish for real reciprocity, you have only to demand its practice by your own State Board. We publish in another column a tabulation of the laws of the different States, compiled by the Illinois Board. Further particulars may be obtained as to the details of licensure from the pamphlet issued by the Board.

Abolish the term "diphtheritic sore throat," at least until it is really demonstrated to be diphtheric. Before the proof has been made, the condition is diphtheria or it is not. The gross appearance of the throat does not determine the nature of the disease, whether it is a simple tonsillitis, etc., or true diphtheria. The differential diagnosis is therefore imperative, and the only way to make it is by the bacteriologic method. And the moment the doubt exists, the sooner the laboratory test is made the better both for patient and doctor. The practitioner may not have either the time or the ability to make these tests, and especially without the least delay. Hence the need of the public or private laboratory and experts to whom the swab may be sent with the greatest expedition. Hence again the utility of the telephone which is now permeating even remote country districts. Do physicians always make prompt use of

express companies, and other means of forwarding the swabs, and of the telephone agencies? Do they always have in their pockets the addresses of laboratories, and have they the plans etc., fixed for ordering fresh antitoxin? That excellent institution, the New Hampshire Board of Health, in its latest Bulletin, cites an illustrative case: There were several cases of mild sore throat in a family in the State. After a few days a physician was called in and pronounced the disease tonsillitis, but finally took a swab and sent it to the State Laboratory of Hygiene. A diagnosis was made by smear, and information telephoned to the physician within an hour that the case was diphtheric. Two hours later the physician telephoned that the child was dead.

Tuberculosis in Street Cleaners.—If the report is true that a third of the street sweepers of New York have contracted tuberculosis during the last five years, it is an added demonstration of the truth of medical theory and practice which should bring conviction to the common mind. It may help to make the work of the anti-tuberculosis workers easier and bring about the reform of present abuses quicker. The sweepers are examined before entering upon their work and declared free from organic disease. If, therefore, within so few years a third of the entire number become infected, it is a striking demonstration of the value of the crusade that has been waged against the sources and carriers of the infection, the spitters, the unclean, the carelessness of the diseased, etc. It may also help to do away with our present stupid and dangerous method of cleaning American streets, which is, in brief, to stir the infectious dust up as thoroughly as possible and make the greatest possible number of people breathe it and rebreathe it. Even if the taxpayers' lives and health are of no value, pity should be taken upon the poor street cleaners.

Poisoning by wood alcohol is increasing. The cheapness of this alcohol is caused by the fact that there is no revenue tax upon it, and it costs only about 50 cents per gallon, instead of \$2.60. This makes the unscrupulous manufacturer use it instead of grain alcohol in flavoring and medicinal extracts. Some essences of Jamaica ginger, peppermint, and lemon contain as much as 75% of wood alcohol. In the last eight years there have been over 50 deaths caused by it, and doubtless this

is only a small part of the total number. Beside the deaths and other injuries, such as gastric disease, etc., from this source, an especially disastrous result is amblyopia, which not seldom ends in absolute blindness; at least 36 cases have been reported within a few years. Eight of these injuries followed the inhalation of wood alcohol fumes while shellacking or painting in vats or closed rooms. It has been found that wood alcohol is only partially oxidized in the body, and that its administration leads to the formation of a highly toxic acid (formic acid), and probably also formaldehyd. This is an interesting illustration of the fact that the body may convert one poison into another, which is far more powerful than the one that was ingested. It is a question if there is any effective way of preventing these calamities except that of putting a revenue tax upon this product equal to that upon grain alcohol.

$E = 0.831 \sqrt[10]{0.831} = 0.831 \times 0.985 = 0.8185 \times 100 = 81.85\%$.—We suspect that these mysterious symbols and figures will have but little significance to many readers, even of *American Medicine*. They may be taken, however, as of serious and scientific import, and, moreover, of medical value. The question of damages for injuries is one that comes up in every court of law, and medical men are called in to estimate the financial ratings which should be made of loss of earning power due to accidents. In the testimonies given great differences of opinions arise. The formulas above represent Dr. E. E. Holt's method of reaching definiteness and scientific accuracy in the estimates. He takes a specific instance, that of a physician, driving over an unsafe bridge, who sustained various injuries, chiefly affecting the eyes, and in holding the town responsible, the aim is to establish the amount of damages. The problem is widened, as stated by Magnus, in his "Visual Economics" (translated by Dr. H. V. Würdeman) and Dr. Holt seeks by similar mathematic methods in extending it to all injuries of the body, with a consequent lessening of the earning capacity, united with computations of the length of remaining life, etc. In the formula cited, E = the doctor's earning capacity. The reader is referred to Dr. Holt's interesting and valuable article published in the *Journal of Medicine and Science*, for April, 1904. Put in a simpler form the illustrative case works itself out thus:

$E = 81.85$ the total remaining earning ability of the doctor, \$40,000 is the sum it was determined the doctor would have earned in the remaining 16 years of his life had he not been injured, and 81.85% of it is \$32,740. Subtracting this from \$40,000 and \$7,260 is obtained, the damage to the doctor's earning ability, carried over a period of 16 years. If this sum is divided by 16, \$453.75 is obtained as a yearly payment for the period of 16 years. But the doctor was laid up four months for which he should at least receive a third of a year's earning, namely, \$833.33, and his other expenses were \$166.67, which added to \$833.33 makes \$1,000, which should be added to the \$5,437.26, making \$6,437.26 that should be paid the doctor by the town for the total damages, loss of time, and expenses in consequence of the injury he received.

The Adulteration of Foods.—The New Hampshire State Board of Health continues its capable work in analyzing the foodstuffs offered to the citizens of the

States. Its latest report thus tabulates the recent results:

Articles examined.	Number found to be of good quality.	Number adulterated or varying from the legal standard.	Total articles examined.	Percentage of adulteration.
Butter.....	3	0	3	0.0
Canned fruits, jellies and jams.....	24	39	63	61.9
Canned goods, miscellaneous products.....	25	5	30	16.7
Chocolate, cocoa and coffee.....	8	0	8	0.0
Honey.....	12	8	20	40.0
Lard.....	2	2	4	50.0
Lemon extract.....	8	21	29	72.4
Maple syrup.....	8	11	19	58.0
Milk.....	11	14	25	56.0
Molasses.....	2	0	2	0.0
Olive oil.....	5	2	7	28.6
Sausage.....	1	8	9	88.8
Spices.....	20	4	24	16.7
Tomato ketchup.....	4	8	12	66.6
Vanilla extracts.....	2	5	7	71.4
Vinegar.....	5	7	12	58.3
Miscellaneous food products.....	11	5	16	31.2
Totals.....	151	139	290	47.9

Of the 290 articles examined, 139 were adulterated, or varied from the legal standard. This is equivalent to an adulteration of 47.9%. It must be remembered, however, that in collecting samples for analysis, care was taken to collect articles of a suspicious character. Therefore, the extent of adulteration of all food products is not shown by this figure, and is represented by a much smaller percentage. Nor must it be overlooked that although so many of the adulterants were perhaps more or less harmless, the fact does not lessen the crime. It is a little disconcerting to know that four-fifths of the maple sugar and syrup sold in the markets is wholly or in part fraudulent. The moral is, Beware of bulk spices, tomato ketchups, "cider vinegar," jellies, jams, etc. The remote effects of saccharin on the system may be bad, and much of the sweetening is by this drug. Another aspect of the question is presented by this excerpt:

A recent addition is a "pie filling," which is sold largely to the baker trade. It is similar to the imitation butters and jams in appearance and composition, and consists of a mixture of apple juice, starch, butter, eggs, glucose, and a small amount of pulp or grated rind of the fruit represented. This product is found on our markets labeled "Lemon Preserves," and is a typical illustration of misrepresentation.

The thoughtlessness of city consultants sometimes causes harm and ill will. A careless word, or gesture—even a silence, may unintentionally reflect upon the distant colleague. And we all know how quick patients or their friends are to perceive the slur and to carry it, perhaps magnify it, to the detriment of the local physician. Such an instance, names not reported to us, has been sent us, which illustrates the point. Our correspondent writes:

It very often happens that a man being in a distant city on business will consult a surgeon or physician there about a patient he is interested in at home. Usually the consultant is honest enough to say he cannot give an opinion on a case he has not seen unless he at least has a history of the case from the physician in charge, and even then he would give it without many conditions; but hardly a month passes in which there do not occur instances such as I have recited. The quacks who treat disease by mail orders are right *sometimes*, but a real doctor ought never to be guilty of such a thing, because even the greatest are most *likely* to be wrong.

Of course, there is the element of doubt as to the patient having correctly reported the consultant, but in this case a letter of protest was sent to the consulting physician, part of which was as follows (we omit the details of the case because of want of space):

Dear Doctor.—Mr. Z. N., of this city, whose wife I operated upon some weeks ago for gallstones, has just told me that he gave you a history of the case, and that you said, "without a moment's hesitation," that there was another stone there (where he did not say). I frankly told him that you had no right in the interest of truth and justice, to give an opinion reflecting upon the opinion of another surgeon, with no more data before you than the history of the case written by a layman. Such an opinion, of course, is worth very little, even in the way of a fee, and I care nothing for it, but hoping it may prevent you thoughtlessly injuring some other innocent doctor in the confidence of his patient, I take the trouble to give you a history of this case. . . . With the case continuously under my care and observation (even when you were being consulted about it), I feel that I am in a better position to give an opinion about the probability of the presence of another stone than you could be at that distance, with a garbled report by a layman before you and giving your opinion "without a moment's hesitation." Such thoughtless or careless actions on the part of our great surgeons not only do great harm to often blameless country surgeons, but often tarnish the reputations for infallibility held by the great surgeons and lessen the confidence of patients in surgery generally. Omitting your name, I am sending a copy of this to *American Medicine*, because I think the subject should be discussed.

Eddyism, Conflagrations, and Insurance Underwriters.—It is the simplest logic that if no disease or matter exists but only the thought of disease and matter, then there can be no Chicago or Baltimore fires. Undoubtedly the reason why the fires at Moscow and Chicago were so terrible was because Mrs. Eddy had not been there to teach the true nature of burning. Not deterred by this a Baltimore eddyite explains why the recent fire in that city was so bad, and why it was not worse. It is a pity that 80 blocks were burned before the eddyites of the nation were sufficiently united and strong in "thought throwing," to prevent the calamity, but when, as one, they all "threw thought" there were saved two large banks "which owe their escape from serious damage" to the "mental protests" of the "condition of mind" hurlers of thought against the fire. The interviewed eddyite says: "Many of the Christian Science doctors throughout the city gathered their pupils around them and instructed them in working against the misfortune. These prayers were continued throughout the fire," thus saving property and preventing loss of life. "Instead of throwing water we threw thought on the fire." Why do not the insurance companies employ the thought-throwing "doctors," and thus save the hundreds of millions of dollars they are losing by such a double, and doubly sad "condition of mind?" Here is a new opening for the financially astute and successful Mother Mary Baker Patterson Glover, etc.

"They shan't cut you up in the hospital," was the promise of the melodramatic wife to her murderer husband. To both the ignominy of the crime of murder was far less than that of being "dissected by the doctors." This old prejudice, as all physicians know, is still intensely alive, and often frustrates the action of the

law and of medical teaching institutions in securing dissection material. Of paupers just dead there rise up "relatives" who were unknown and indifferent before death, but who now are much concerned that their poor cousin shall have "a decent burial," and "shan't be cut up in the hospital." It is a strange evidence of the living on of old superstitions, and of the illogical feeling that respect is due to the dead who were anything but respected in life. In truth, of course, Dr. Wilder's "useful dead" applies to the modern dissection-room material, and there is certainly no less an honorable end there than by means of the worms and roots of trees in ordinary burial.

"How to Have a Male Heir."—The comic papers have had much fun with the shall-it-be-a-girl-or-a-boy question, consequent upon the learned and unlearned investigations of the pseudoscientific. The grocer has been represented as having a large assortment of "sugar and spice and all things nice," but entirely out of "snips and snails and puppy-dogs' tails." It has been left to American ingenuity to devise a method of supplying the latter articles, or of "advice" to replace them, and to turn the mysterious knowledge to money-making uses. The "trained nurse" has found a new role—as medical adviser, in fact, plainly not as grammarian; and a circular sent out to anxious husbands—not to wives, be it noticed—reads as follows:

If you have no son to perpetuate your "name," inherit your estates and fortunes, why not consult Mrs. ————, a "world wide" experienced trained nurse. She is middleaged, has two handsome sons (gentlemen now), it does not take her 20 minutes to convince her "listener" of the surety of having his hopes realized; a "son" born, and leaves the value of this positive secret to the "father's" generosity; and, as it rests entirely with him, she objects to consult with any mother.

Prior to the birth of Mr. Grover Cleveland's third daughter (who he named after me, Marion during his last presidency at the White House), I assured Mr. Grover Cleveland that the expected "new arrival" would also be a girl, and to his annoyance and great vexation, it was; but since he graciously and so willingly accepted my wonderful never-failing experience, two sons have since been born, to his great delight, and he has ceased further reproach to his amiable wife.

A Mr. C. C. Osgood (friend of Ex-mayor VanWyck), hearing of Mrs. ——— skill and wonderful "secret" to Mr. Grover Cleveland, enclosed his check to her of \$1,000; Mrs. Osgood previously had six girls, but has since presented him with four sons.

Of two millionaire brothers, one sometimes dies in an almshouse, the result being the different usage they both give their money or not "knowing how."

Likewise, a gardener does not plant an onion seed and then expect a potato to grow from it.

The race is not in danger of extermination, because all gentlemen will hardly consult Mrs. ———, and the inexorable law of nature will persist in the cases of the foolish nonconsultants. But why the prejudice against onions?

De Profundis.—A correspondent sends the following communication, which, from its mixture of religion and therapeutics seems of interest. An appended note says that the signer of the prayer (written, note well, and sent out to be read, by whom?) is the promoter of

the New York osteotherapy bill introduced at Albany by Mr. Fitzgerald.

A PRAYER (VOICE) FROM THE TOMBS.

O Lord, I thank thee for the steady evolution since the time of thy only son, Jesus Christ, who was crucified for the same thing that mortals are only put in foul prisons now, (namely for the laying on of hands to heal the sick, a science which we call massage, or osteotherapy.)

O Lord we pray thee to give us strength, vitality and intelligence, and above all upright judges, to see that this noble calling is not kept back from the many sufferers, craving for this NOBLE and only harmless treatment. O Lord, we pray thee to forgive our prosecutors, who not satisfied with throwing us in vile, foul, dangers, circulate untruthful stories, going even so far as to lie about our nationality and profession with malicious intent. O Lord, have mercy on our prosecutors for their evil intention, when they call me a Norwegian sailor, something which I am not; though if I were I might be as good a man, and do much good in the healing art, like thy Apostle, the fisherman did without poisoning the human system with drugs, O Lord have mercy on them, awaken them to the fact that the cause of humanity lays deeper than with just dollars and cents, and teach them to do something for humanity sake, teach them O Lord not to rejoice in the Sin they commit by what they think my suffering, as thou O Lord art to great, to let me consider this suffering.

I thank thee O Lord for this well earned rest; and pray thee O Lord to keep me healthy in Body and Mind, so that after this short or long rest as thou wilt it, I may resume the good work for which thou hast chosen me.

Amen.

This prayer was offered up by Dr. C. Conrad (while a prisoner) at the Methodist prison workers meeting on Sunday April the 17th at the 4th floor in the west side courthouse.

C. CONRAD.

[S. W. Abbott, *Boston Med. and Surg. Journal.*]

AMERICAN NEWS AND NOTES

GENERAL.

Could not Accept the Bequest.—The Navy Department recently had occasion to construe article 1166 of the Navy Regulations, which prohibits attendants in naval hospitals accepting gifts and bequests from patients. In the present case, an enlisted man, a patient in a naval hospital, made a will a few days before his death in which he made bequests to two naval hospital apprentices who had been in attendance upon him. The department decided that under the regulations such bequests could not be accepted.

Miscellaneous.—The American Urological Association has issued its preliminary program for the annual meeting which will be held in Atlantic City, June 8 and 9, 1904.—New York: A tablet in memory of the late Dr. Egbert Guernsey was unveiled in the Metropolitan Hospital on Blackwell's Island recently.—Philadelphia: Professor Dr. Albert Hoffa (University of Berlin), the guest of the Alumni Association, will hold an orthopedic clinic at the Jefferson Medical College Hospital, on Thursday, May 26, 1904, at 11 a.m.

Red Cross Reorganization.—The Red Cross investigating committee has prepared a plan for the reorganization of the American National Red Cross, its control by a governing body of 18, of whom the president shall appoint 6, and the auditing of its accounts by the auditor for the War Department. The plan has the approval of Miss Barton, the counsel for the Red Cross, and the lawyers representing the remonstrants. A new charter, prepared by ex-Secretary Foster on the motion of Senator Proctor, and drawn in accord with the views of the remonstrants, will be secured from Congress at the earliest opportunity, and in the meantime it is expected that the affairs of the society will pass under the control of a board of trustees, to be the mutual selection of both parties to the existing controversy.

Do Criminals Reform?—An official connected with a reformatory movement was recently quoted as saying that not more than 3% of criminals were reformed. This statement called forth the comment from a man long identified with the attempt to set discharged prisoners on their feet that anyone who was so hopeless about the possibility of reform, and who took so dark a view of the work was hardly the man to be concerned in it. Further discussion has brought into light the wonderful results obtained by Mrs. Ballington Booth and the Salvation Army. In May, 1896, Mrs. Booth called for the first volunteers, and 26 men were enrolled in Sing Sing under the white banner of the Volunteers' Prisoners' League. The number is now 24,000. Places of refuge, which are appropriately called Hope Halls, are maintained with wideopen doors ready to receive discharged prisoners, where they may stay until they can get the courage and the opportunity to start life anew. The statistics relating to the prisoners are rather remarkable. It appears that 75% of the former convicts have gone to work for a living, abjuring entirely criminal pursuits; 20% are classed as doubtful, while 5% have returned to their former haunts and habits.

Milk Reduced to Powder.—To prepare milk in such a way that microbes cannot breed in it has been the aim of the inventors of a new milk powder. The process removes all the water from milk by the application of heat, and converts it into a light yellow flaky powder, which can instantly be reconverted into something almost indistinguishable from fresh milk by the addition of water. All bacteria are killed in the process. After 400 separate examinations it was possible to say that the powder is absolutely sterile when it comes from the drying machine. Being sterile and dry it will, of course, keep indefinitely, provided that no germs are allowed access to it. The role of the town dairy may be at an end soon, if factories are established which can supply a year's milk supply by post at a moment's notice. As for Arctic explorers, armies in the field, ocean liners, and so forth, I fancy they will not be sorry to have their milk in a form which takes up practically no space, and which keeps indefinitely. There is one serious criticism which the writer makes. The process of boiling or sterilizing milk leads to the destruction of what is called its "antiscorbutic property," and children suffer in consequence. If the dried milk retains this principle, then its success is assured, but the writer does not feel satisfied that this is certain as yet.

Medicolegal.—An exchange commenting on this subject says: In trials for murder the point has sometimes been raised by the defense that death had not resulted from the wound inflicted by the accused, but from the subsequent surgical treatment, and that this should be considered in mitigation of the crime. We have the converse of this view in the case of the woman who stuck a knife into a man's heart and has been in jail awaiting the result of his injuries. By all the laws of probability the man ought to have died. The wound was of a kind generally recognized as fatal. But the surgeons got hold of him and sewed up his heart, and in due time he recovered. Thereupon the woman was discharged from custody, and the

man, in the exuberance of his delight, declares that she shall not be prosecuted. Some curious questions, moral, ethical and legal, are raised by this extraordinary occurrence. How far was the degree of guilt or innocence which attached to the woman's act affected by the degree of perfection which surgery has attained? A few years ago a man so wounded would surely have died, and the person who inflicted the wound would have been convicted of manslaughter at least. Now the surgeons, by a rare chance, save his life, and as nobody is the worse off, no penalty is incurred. Are we to regard science as the handmaid of crime; or, on the contrary, as helping to abolish crime? And suppose the surgeons had failed, who would have been responsible?

EASTERN STATES.

Boston and the Milk Question.—In the new milk regulation, just issued, the Boston Board of Health places the limit on the number of bugs that a person should swallow with a glass of milk at about 100,000,000. Occasionally the milk inspectors will sample the milk in stores, restaurants, bakeries, and shops to count the organisms, and if they find an excess will prosecute for violation of the rules. The new article in the rules provides that no person shall bring into Boston for the purpose of sale any milk which contains more than 500,000 bacteria per cubic centimeter, or which has a temperature higher than 50°. This amount is selected for convenience in examination, and represents about 80,000,000 to 100,000,000 in an ordinary glass of milk. This regulation will have the effect of inducing farmers to keep their stables clean and well ventilated, because if the milk remains warm a long time and foreign substances come into it, the bacteria increase at an enormous rate; kept down at 50° the growth of bacteria is checked. The regulations require, also, that the milk in stores, restaurants, bakeries, and on the market shall be kept in cool inspected refrigerators, no can to be kept on the outside longer than while the sale is being made.—[*Boston Transcript*.]

NEW YORK.

Boston's View of It.—By vetoing the bill to substitute medical examiners for coroners in New York, Mayor McClellan retains an ancient system that Boston long ago decided was out of date. "It is an innovation on a time-honored system," says his honor, "and so far seems mere experiment. It is urged that certain abuses have crept into the present system; but the purpose of the proponents of this measure is not to remedy the abuses, but to destroy the system. An institution which is the growth of a thousand years should not be destroyed unless it is proved that its substitute is more useful and will stand the test of time as well." He fails to mention, however, how much longer trial than a thousand years he thinks an institution of government must have before it is proved, or how many centuries a step forward should have been taken by other cities before New York dare attempt it.—[*Boston Transcript*.]

To Abolish Sweatshops.—The governor of New York State has signed the tenement house law amendments. The articles whose manufacture is prohibited without a license are made to include aprons, pocketbooks, slippers, paper boxes, and bags. Instead of a license being required for the apartments of each individual family in a tenement, the tenement house itself is licensed. This will greatly reduce the number of licenses, and will enable the State Department of Labor to inspect tenement houses to see that work is not going on without a license; to stop work in apartments where there is contagious disease, and to make semi-annual inspections of licensed tenement houses to see that proper sanitary standards are maintained. A house once licensed will stay licensed if kept in a proper condition, even though its ownership should change hands a number of times. All manufacturing is limited to the members of the family residing in each apartment, thus preventing sweatshops in tenements.

Mayor McClellan's Veto of the Coroner Bill.—The better newspapers of New York City, together with the Board of Health, the local fraternity and public-spirited citizens in general, seem to be at one in their condemnation of Mayor McClellan's veto to the coroner bill. The *New York Post*, commenting on this subject editorially, says a difference of opinion about the merits of the bill to abolish coroners is one of the surprising discoveries of Mayor McClellan. So far as we are able to observe, lawyers, physicians, and intelligent citizens unite in favoring the bill, but the coroners naturally hold a different view. Even a coroner, low as he may stand in the official scale, is a human being. He takes no more pleasure in being abolished for the sake of a good cause than the anglerworm in being impaled for the sake of a fisherman's sport. Seriously, however, Mayor McClellan has made a mistake in yielding to the clamor of the coroners and their friends. The agitation for doing away with this absurd office has been carried on for several years. The necessary legislation has been duly proposed in successive sessions, but for one reason or another has failed of passage. Finally, after much effort, the Legislature of 1904 acted, but its good work has been frustrated by an unwise veto.

PHILADELPHIA, PENNSYLVANIA, ETC.

To Fight Pulmonary Tuberculosis.—An investigation of conditions favorable to the spread of pulmonary tuberculosis is to be undertaken by committees appointed by the Pennsylvania Society for the Prevention of Tuberculosis and reports thereon published as a basis for an appeal to the city authorities to abate the evils where they may be within their jurisdiction. Street cars and street cleaning are to be among the first subjects taken up. The president of the society said at the annual meeting recently, that the recommendation to the Department of Public Safety last year that the streets be cleaned only between 1 and 5 o'clock a.m., as is done in European cities, had been referred to the Bureau of Street Cleaning, but nothing further has been heard of it. He said the present method of sweeping the streets, especially if they are not sprinkled, fills the air with pulverized poison that constitutes a never ending danger to health.

Old and Honored Practitioner.—The oldest living graduate of the Jefferson Medical College, of Philadelphia, is Dr. Jacob L. Ziegler, of Mount Joy, Pa., who is 81 years old, and who has practiced medicine for 60 years. In spite of his years, Dr. Ziegler is still in active practice, and makes daily rounds to see his patients, who declare that his medicines are just as potent as ever and his hand as steady. Dr. Ziegler is a member of the Lancaster County Medical Society, and has twice been its president. He also holds membership in the Pathological Society of Philadelphia, the American Medical Association, the Lancaster Historical Society and the Pennsylvania Historical Society. Graduated from Jefferson in 1844 with the degree of M.D., he was honored in 1880 by Lafayette College with the degree of A.M. He is the oldest living member of the Donegal Presbyterian Church, having been affiliated with it since 1840.

Philadelphia Clinics and Demonstrations.—Complimentary to the members of the American Medical Association for the week preceding and the week following the Atlantic City session.

Clinics and Demonstrations at the Jefferson Medical College and Hospital, Tenth and Walnut Streets.

TUESDAY, MAY 31.—Brick, J. Coles, rectal clinic, 9.30 to 10.30 a.m., hospital amphitheater; Roe, W. J., oral clinic, 11 a.m. to 12.30 p.m., hospital amphitheater; Stewart, Francis T., surgical clinic, 2.30 to 4 p.m., hospital amphitheater.

WEDNESDAY, JUNE 1.—Jones, W. S., laryngologic clinic, 10 to 11 a.m., hospital amphitheater; Bland, P. Brooke, pathology of certain pelvic organs with lantern demonstrations, 11 a.m. to 1 p.m., college building; Montgomery, E. E., gynecologic clinic, 1 to 3 p.m., hospital amphitheater; Coplin, W. M., L., insects and lower animals as carriers of contagion, 4 p.m., college lecture-room.

THURSDAY, JUNE 2.—Pathologic and histologic laboratories. Demonstrations by Drs. Ellis and Radasch, 9.30 to 11 a.m., college building; DaCosta, J. C., recent advances in diagnosis by examination of the blood, 11 a.m. to 12 m., hospital amphitheater; Cohen, S. S., clinical lecture illustrating recent advances in medical jurisprudence, 12 to 1 p.m., hospital amphitheater; Horvitz, Orville, genitourinary clinic, 2 to 3.30 p.m., hospital amphitheater; Davis, Edward P., modern obstetric surgery, 4 p.m., maternity building, 224 S. Seventh street.

FRIDAY, JUNE 3.—Bacteriologic laboratory. Demonstrations by Dr. Rosenberger, 9 to 10.30 a.m., college building; Kyle, D. Braden, laryngologic clinic, 10.30 to 11.30 a.m., hospital amphitheater; Brubaker, A. P., demonstrations in physiologic laboratory, 11.30 a.m. to 1 p.m., college building; Spencer, Geo. W., surgical clinic, 1 to 2.30 p.m., hospital amphitheater; Graham, E. E., typhoid fever in infancy and early childhood, 3 to 4 p.m., college building; Hansell, Howard F., ophthalmologic clinic, 4 p.m., hospital amphitheater.

SATURDAY, JUNE 4.—Brubaker, A. P., demonstrations in physiologic laboratory, 9 to 10 a.m., college building; DaCosta, J. C., gynecologic clinic, 10 a.m. to 12 m., hospital amphitheater; Hearn, W. Joseph, surgical clinic, 1.30 to 3.30 p.m., hospital amphitheater; Davis, Edward P., the preventive treatment of eclampsia, 4 p.m., maternity building, 224 S. Seventh street.

MONDAY, JUNE 5.—Wilson, H. A., and Professor Hoffa of Berlin, orthopedic clinic, 9.30 a.m. to 12 m., hospital amphitheater; Keen, W. W., surgical clinic, 1 to 3.30 p.m., hospital amphitheater; Fisher, John M., gynecologic clinic, 4 p.m., hospital amphitheater; Hansell, Howard F., ophthalmologic clinic, 4 p.m., Philadelphia Hospital, Thirty-fourth and Spruce streets.

SATURDAY, JUNE 11.—Fisher, John M., 9 to 10 a.m.; Montgomery, E. E., 10 to 11 a.m.; DaCosta, J. C., 11 a.m. to 12 m., gynecologic clinics, hospital amphitheater.

MONDAY, JUNE 13.—Pathologic and histologic laboratories. Demonstrations by Drs. Ellis and Radasch, 9 to 10 a.m., college building; Rugh, J. T., treatment of ankylosed joints, 10 to 11.30 a.m., hospital amphitheater; Dercum, F. X., neurologic clinic, 12 to 1 p.m., hospital amphitheater; Stelwagon, Henry W., dermatologic clinic, 1 to 2 p.m., college building; Metheny, S. A. S., röntgen ray demonstrations, 3 to 4 p.m., hospital amphitheater; Roe, W. J., oral clinic, 4.30 to 5.30 p.m., hospital amphitheater.

TUESDAY, JUNE 14.—Brubaker, A. P., demonstrations in physiologic laboratory, 9 to 11 a.m., college building; Cohen, S. S., medical clinic, 11 a.m. to 12 m., hospital amphitheater; Brick, J. Coles, rectal clinic, 12 to 1 p.m., hospital amphitheater; Spencer, Geo. W., surgical clinic, 2 to 3 p.m., hospital amphitheater; Stewart, Francis T., surgical clinic, 3 to 4 p.m., hospital amphitheater; Hansell, Howard F., demonstrations of the changes in the fundus of eye in Bright's disease, 4 to 6 p.m., Philadelphia Hospital, Thirty-fourth and Spruce streets.

University of Pennsylvania Clinics and Demonstrations at the University Hospital, Thirty-sixth and Spruce Streets.

FRIDAY, JUNE 3.—Edsall, demonstrations of the methods employed in the analysis of the gastric contents, 11 a.m., medical amphitheater; Steele, diagnosis and treatment of diseases of the stomach, 12 m., medical amphitheater; Russell, exhibition of cases of heart disease with special reference to myocarditis, 1 p.m., medical amphitheater; luncheon, University Hospital, 2 p.m.; Randall, stereopticon demon-

stration of the clinical anatomy of the tympanic cavity, 3 p.m., medical amphitheater.

SATURDAY, JUNE 4.—*Smith, A. J.*, demonstrations of autopsy technic and of pathologic specimens, 10 a.m. to 12 m., medical hall; *Tyson*, medical clinic, 12 m., medical amphitheater; *Anspach*, demonstrations of a series of natural color preparations illustrating the value of routine histologic examination of gynecologic specimens, 1 p.m., gynecologic amphitheater, University Hospital; luncheon, University Hospital, 2 p.m.; *Clark*, gynecologic clinic, 3 p.m., gynecologic amphitheater.

MONDAY, JUNE 6.—*Muller*, pathology of the pancreas, 10 a.m., University Hospital; *Edsall*, diagnosis and treatment of diseases of liver, 11 a.m., medical amphitheater; *Young*, the surgery of paralysis, 12 m., orthopedic amphitheater; *Mills*, some of the newer aspects and methods of cerebral localization, 1 p.m., medical amphitheater; luncheon, University Hospital, 2 p.m.; *Spiller*, tumors of the brain, 3 p.m., surgical amphitheater; *Frazier*, surgery of brain tumors, 4 p.m., surgical amphitheater. NOTE: Subject of lectures by *Drs. Mills, Spiller and Frazier* will be brain tumors. Each lecturer will discuss or demonstrate a different phase of the subject, so that there will be no repetition.

FRIDAY, JUNE 10.—Opening exercises of the new medical laboratories, 4 p.m.

SATURDAY, JUNE 11.—*Altis*, congenital dislocation of the hip. A demonstration on the cadaver, in which both hips will be simultaneously dislocated by a force simulating routine contractions, with brief remarks on the etiology, diagnosis and treatment, 9 to 11 a.m.; *Willard*, treatment of congenital dislocation of the hip, 11 a.m., orthopedic amphitheater. *Professor A. Hoffa* of Berlin, will be in attendance during this hour. Clinics will close in time for those who so desire to take the 1.20 train for Washington to witness the unveiling of the Rush monument.

MONDAY, JUNE 13.—*Evans*, serum diagnosis of typhoid and other infectious fevers, the precipitins and their medicolegal value, 10 a.m., University Hospital; *Sailer*, application of the röntgen ray in the diagnosis of thoracic diseases, 11 a.m., University Hospital; *Stengel*, practical demonstrations of methods used in the diagnosis and treatment of valvular heart disease and arteriosclerosis, 12 m., clinical amphitheater; *Hirst*, plastic and abdominal surgery for complications and consequences of childbirth, 1 p.m., maternity amphitheater; luncheon, University Hospital, 2 p.m.; *deSchweinitz*, ophthalmologic clinic, with special references to ocular traumatism, 3 p.m., gynecologic amphitheater; *Shumway*, lantern demonstration on the embryology of the eye, 4 p.m., University Hospital.

TUESDAY, JUNE 14.—*Stanton*, demonstration and application of the methods of determining blood-pressure, 10 a.m., medical amphitheater; *Griffith*, pediatric clinic, 11 a.m., medical amphitheater; *Musser*, medical clinic, 12 m., surgical amphitheater; *Martin*, surgical clinic, 1 p.m., surgical amphitheater; luncheon, University Hospital, 2 p.m.; *Piersol*, demonstrations of monstrosities, 3 p.m., medical hall; *Pancoast*, the relative results obtained with the röntgen ray and radium in the treatment of carcinoma and other lesions, 4 p.m., surgical amphitheater.

Clinics at the Medico-Chirurgical Hospital, Cherry Street, Seventeenth to Eighteenth Street.

THURSDAY, JUNE 2.—*Mann, James P.*, orthopedic clinic, 11 a.m. to 12 m.; *Christian, H. M.*, genitourinary clinic, 12 m. to 1 p.m.; *Gleason, Edward B.*, otologic clinic, 3 p.m. to 4 p.m.

FRIDAY, JUNE 3.—*Rodman, William L.*, surgical clinic, 10 a.m. to 11 a.m.; *Shoemaker, John V.*, dermatologic clinic, 11 a.m. to 12 m.; *Anders, James M.*, medical clinic, 12 m. to 1 p.m.; *Mann, James P.*, orthopedic clinic, 3 p.m. to 4 p.m.

SATURDAY, JUNE 4.—*Ashton, W. Easterly*, gynecologic clinic, 10 a.m. to 11 a.m.; *La Place, Ernest*, surgical clinic, 11 a.m. to 12 m.; *Boyd, George M.*, obstetric clinic, 12 m. to 1 p.m.; *Rodman, William L.*, surgical clinic, 3 p.m. to 4 p.m.

MONDAY, JUNE 6.—*Pearce, F. Savary*, neurologic clinic, 10 a.m. to 11 a.m.; *Haehnlen, W. Frank*, obstetric clinic, 11 a.m. to 12 m.; *Fox, L. Webster*, ophthalmologic clinic, 12 m. to 1 p.m.; *Daland, Judson*, medical clinic, 3 p.m. to 4 p.m.

SATURDAY, JUNE 11.—*Pearce, F. Savary*, neurologic clinic, 9 a.m. to 10 a.m.; *Ashton, W. Easterly*, gynecologic clinic, 10 a.m. to 11 a.m.; *Anders, James M.*, medical clinic, 11 a.m. to 12 m.

MONDAY, JUNE 13.—*Shoemaker, John V.*, applied therapeutics clinic, 10 a.m. to 11 a.m.; *Haehnlen, W. Frank*, obstetric clinic, 11 a.m. to 12 m.; *Cleveland, Arthur H.*, laryngologic clinic, 12 m. to 1 p.m.; *Daland, Judson*, medical clinic, 3 p.m. to 4 p.m.

TUESDAY, JUNE 14.—*Hollopeter, W. C.*, pediatric clinic, 10 a.m. to 11 a.m.; *La Place, Ernest*, surgical clinic, 11 a.m. to 12 m.; *Fox, L. Webster*, ophthalmologic clinic, 12 m., to 1 p.m.; *Boyd, George M.*, obstetric clinic, 3 p.m. to 4 p.m.

Polyclinic Hospital Clinics, Lombard Street, above Eighteenth.

MONDAY, MAY 30.—*McKee*, pediatrics clinic, 10 a.m.; *Stewart*, surgical clinic, 10 a.m.; *Vansant*, nose and throat clinic, 11 a.m.; *Goepf*, medical clinic, 12 m.; *Schamberg*, dermatology, 12 m.; *Packard*, ear clinic, 1 p.m.; *Watson*, nose and throat clinic, 2 p.m.; *Ashton*, medical clinic, 2 p.m.; *Christian*, genitourinary clinic, 5 p.m.; *Roberts*, surgical clinic, 5 p.m.

TUESDAY, MAY 31.—*Hamill*, pediatrics clinic, 10 a.m.; *Baldy*, gynecologic clinic, 10 a.m.; *Steinbach*, surgical clinic, 11 a.m.; *Gibb*, nose and throat clinic, 11 a.m.; *Eshner*, medical clinic, 12 m.; *Schamberg*, dermatology, 12 m.; *Stout*, ear clinic, 1 p.m.; *Baer*, gynecologic clinic, 2 p.m.; *Young*, orthopedic clinic, 2 p.m.; *Freeman*, nose and throat clinic, 2 p.m.; *Sailer*, diseases of stomach, 2 p.m.; *Makuen*, defects of speech, 2 p.m.; *Slocum*, gynecologic clinic, 5 p.m.; *Riesman*, medical clinic, 5 p.m.

WEDNESDAY, JUNE 1.—*McKee*, pediatrics clinic, 10 a.m.; *Baldy*, gynecologic clinic, 10 a.m.; *Vansant*, nose and throat clinic, 11 a.m.; *Goepf*, medical clinic, 12 m.; *Schamberg*, dermatology, 12 m.; *Packard*, ear clinic, 1 p.m.; *Watson*, nose and throat clinic, 2 p.m.; *Ashton*, medical clinic, 2 p.m.; *Spiller*, neurology, 3 p.m.; *Christian*, genitourinary clinic, 4 p.m.

THURSDAY, JUNE 2.—*Hamill*, pediatrics, 10 a.m.; *Adler*, rectal diseases, 11 a.m.; *Gibb*, nose and throat, 11 a.m.; *Eshner*, medical clinic, 12 m.; *Schamberg*, dermatology, 12 m.; *Stout*, ear clinic, 1 p.m.; *Young*, orthopedic clinic, 2 p.m.; *Sailer*, diseases of stomach, 2 p.m.; *Freeman*, nose and throat, 2 p.m.; *Makuen*, defects of speech, 2 p.m.; *Spiller*, neurology, 3 p.m.; *Riesman*, medical clinic, 5 p.m.

FRIDAY, JUNE 3.—*McKee*, pediatrics, 10 a.m.; *Stewart*, surgical clinic, 10 a.m.; *Vansant*, nose and throat, 11 a.m.; *Goepf*, medical clinic, 12 m.; *Schamberg*, dermatology, 12 m.; *Packard*, ear clinic, 1

p.m.; *Baer*, gynecologic clinic, 2 p.m.; *Watson*, nose and throat clinic, 2 p.m.; *Ashton*, medical clinic, 2 p.m.; *Spiller*, neurology, 3 p.m.; *Christian*, genitourinary, 4 p.m.; *Slocum*, gynecologic clinic, 5 p.m.

SATURDAY, JUNE 4.—*Hamill*, pediatrics, 10 a.m.; *Steinbach*, surgical clinic, 11 a.m.; *Gibb*, nose and throat, 11 a.m.; *Eshner*, medical clinic, 12 m.; *Schamberg*, dermatology, 12 m.; *Stout*, ear clinic, 1 p.m.; *Freeman*, nose and throat, 2 p.m.; *Sailer*, diseases of stomach, 2 p.m.; *Young*, orthopedic clinic, 2 p.m.; *Makuen*, defects of speech, 2 p.m.; *Spiller*, neurology, 3 p.m.; *Riesman*, medical clinic, 5 p.m.

Lectures at the Philadelphia Hospital, Thirty-fourth and Pine Streets.

SATURDAY, JUNE 4.—*Haehnlen, W. F.*, 9 a.m.; *Allyn, H. B.*, 10 a.m.

MONDAY, JUNE 6.—*Stengel, A.*, 10 a.m.; *Cryer, M. H.*, 11 a.m.; *Hansell, H. F.*, 4 p.m.

SATURDAY, JUNE 11.—*Peck, E. L.*, 9 a.m.; *Riesman, David*, 10 a.m.; *Martin, Edward*, 11 a.m.

MONDAY, JUNE 13.—*Spiller, Wm. G.*, 10 a.m.; *Marshall, G. M.*, 11 a.m.; *Potts, C. S.*, 3 p.m.; *Hansell, H. F.*, 4 p.m.

Surgical Clinics at the German Hospital, Girard and Corinthian Avenues.

Deaver, June 1, 2, 4 and 14, 1 to 5 p.m.

Surgical Clinics at the Pennsylvania Hospital, Eighth and Spruce Streets.

Harte, June 4, 6 and 11, 11 a.m.

SOUTHERN STATES.

War against the Mosquito.—According to the New Orleans *Picayune* it appears that Dr. Quitman Kohnke, health officer in New Orleans, has persistently advocated in his home city that another means should be employed to prevent the breeding of mosquitos, holding that the municipality should employ a corps of persons to engage in the warfare, using kerosene on all surface water. It seems that New Orleans failed to hear the advice of Dr. Kohnke until San Antonio, Texas, responded to the call, and in consequence of lectures in that town by Dr. Kohnke, a brigade of school children has been employed to place kerosene in all the pools of stagnant water in the vicinity. New Orleans has now awakened from her lethargy and is following the example of San Antonio.

Baltimore would Prevent Grim Harvest of the "Glorious Fourth."—With figures compiled by a Baltimore physician, relating to Fourth of July casualties in the United States in 1903, a councilman has introduced in the city council of that city an ordinance which prohibits the manufacture, sale or use of fireworks within the boundaries of Baltimore city. According to Dr. Randolph, there were just 4,458 casualties on the last glorious Fourth. The measure provides that "no person shall cast, throw, or fire any squib, rocket, cracker, torpedo, grenade or other explosive preparation within the city limits," and that "every person, for every such offense, shall forfeit and pay a sum not exceeding \$25." A similar penalty is provided for the manufacture of such explosives. According to the physician the casualties last Fourth of July were as follows:

Deaths from wounds.....	60
Deaths from tetanus, resulting from wounds.....	415
Number of persons made totally blind.....	10
Number of persons who lost one eye.....	75
Number of persons who lost hands, arms or legs.....	54
Number of persons who lost one or more fingers.....	174
Number of painful minor accidents.....	3,670
Total.....	4,458

The American loss at Bunker Hill was 449.

WESTERN STATES.

Quarantine of Mexico.—The passenger and freight traffic of the railroads in Mexico which lead to the three border points of Texas is paralyzed as the result of the strict enforcement of the order of Dr. George Tabor, Texas State Health Officer, requiring that all persons who desire to enter the United States via Texas shall remain in quarantine detention at either Nuevo Laredo, Ciudad Porfirio Diaz or Juarez five days, no matter from what place or part in Mexico they come. Under this order the whole of Mexico is classed as infected with yellow fever. The Mexican Government authorities say that Vera Cruz is the only place in that country where the disease exists.

Deathrate in Chicago.—The Bulletin of Chicago's Health Department for the week ended April 30 says: In 1897 the rate was 18.84 per 1,000 of the population; in 1901 it was 14.64, and in 1902 it was 15.83. For the previous 10 years the average annual rate had been 17.31. The 2,486 deaths reported during the month up to the close of office hours April 30 represent an annual rate of 15.68 per 1,000—or 9.4% lower than the average. As has been the case since the first of the year, the reduction of deaths is almost entirely among children under 5 years of age, of whom 225, or nearly 30%, fewer died than in April, 1903. In fact, the first 4 months of 1904 have established a record for low mortality from the contagious diseases of childhood. Diseases of adult life show the following increased mortality as compared with 1903: Apoplexy, 22.6%; Bright's disease, 16%; cancer, 10%; pulmonary tuberculosis, 9.1%; heart disease, 3.3%; pneumonia, 3.7%.

A TABULAR OUTLINE OF THE STATE AND TERRITORIAL LAWS AND REGULATIONS IN FORCE IN MARCH, 1904.

Admit to practise on presentation of a recognized diploma.	Require an examination.		Examine nongraduates in medicine.	Empowered to recognize certificates of other Boards.	Permit the practice of physicians from other States in consultation.	Empowered to issue temporary licenses.	Osteopathy legalized.
	Diploma necessary.	Diploma not necessary.

CANADA.

Contract Medical Practice.—A correspondent from Sherbrooke, Province of Quebec, sends us the copy of an agreement which has been adopted at a meeting of the Sherbrooke City Medical Society and signed by every regular practitioner in Sherbrooke and Lennoxville, on January 15, 1901. *Agreement.*

—We, the undersigned regular medical practitioners of the cities of Sherbrooke and Lennoxville, Quebec, do hereby agree that, in future we shall not accept any position as physician or surgeon to any benevolent, fraternal, or medical aid association. Also, we shall not attend any member of such association at rates less than those allowed by the tariff adopted by the District of St. Francis Medical Association. We further agree to resign any such position or positions which we may now hold, at the earliest possible date. This agreement shall not apply to contracts with railroad or mining corporations, or educational institutions, or to the accepting of the position of medical examiner to any such associations as previously mentioned. In the event of any medical practitioner entering into and retaining such contracts in the city of Sherbrooke or Lennoxville after having received due notice of the above agreement from the Sherbrooke Medical Society, we agree to refuse to hold professional intercourse with the said party so long as he shall retain such contracts.

FOREIGN NEWS AND NOTES

GENERAL.

Miscellaneous.—The French Government in Algeria proposes to establish a woman doctor in every village where the native population is large enough, the native women being prevented by their social customs from consulting men physicians. In Algiers a dispensary has already been opened for women.

Suicide in Germany.—Official figures recently published by the German Statistical Office, in reference to suicides in the German empire, are by no means of a satisfactory nature. They show a steady increase in the number of persons who have made away with themselves since 1900. A little more than 20 persons in every 100,000 inhabitants killed themselves in that year. In 1901 the proportion rose to 20.8, and in 1902 to 21.4. The percentage of suicides was lower in agricultural than in industrial districts. Of every 100,000 persons in Berlin, 31 committed suicide during 1902; in Saxony 33; in Hamburg more than 37. Eighty percent of the total number of suicides was men. A curious and unpleasant feature of the case is the number of young married couples who have destroyed themselves together, especially in Berlin.

Physical Deterioration.—An exchange says that the physical deterioration of the British people still occupies some of the attention of a Parliamentary committee. Many causes have been alleged for this condition, from the use of soap and the cold bath to alcoholic excesses and the consumption of too much meat. The committee now proposes to measure and weigh every person in the land in order to determine in the future whether the tendency has been continuously toward a decline of stature and strength. Also it is proposed to adopt the American system of instruction in the primary schools as to the deleterious effects of alcohol and tobacco on mind and body. That there is still a diversity of opinion among experts as to the effects of alcohol and tobacco (in moderate quantities) on the system has not deterred the Americans from adopting textbooks which made the most positive affirmations on this subject. Many men of science vehemently oppose the doctrines of these public school textbooks. The English will start with the same firm belief that both tobacco and alcohol are every where and always bad. They confidently expect to find that the children of smokers and drinkers fall below the average stature and intelligence of the children of total abstainers. The results of investigation may confirm their opinions, but it is just as well to be prepared for a disappointment.

The Increase of Quackery in Foreign Countries.—An exchange says: Two Berlin girls of the "backfisch" class, seeking to improve their complexion, went to a local "face doctor." "Take the eggs of frogs, dry them, powder them, and dissolve in spring water, drawn when the moon is full," prescribed the "doctor." The girls did so, and applied the fluid to their faces twice a day. Their parents were forced to take them to an oculist, their eyes having become so inflamed by the concoctions as to produce temporary blindness. This is only one of many other instances in which quacks have wrought ruin through their messes, and the German police have begun a systematic campaign against quacks and quack medicines. The police estimate that in ten years the population has increased 58%, regular medical men 76%, and quacks 1,567%. There are more women quacks than men. The most prosperous of these were two washerwomen and one milliner. Nearly 30% of the men cited to appear at the police bureau had been in prison; of the women, 15%. More than 100 samples of quack medicines were analyzed by the police, and over 80% contained elements of absolutely no medicinal value.

Spotted Fever.—Spotted fever, or spotted typhus, is frequently described as famine or war typhus, because the disease has repeatedly developed and spread in times of famine among the starving population, or in time of war among the troops weakened by privations and hardships. In Germany, during the current century, the disease has in an epidemic form especially visited upper Silesia and east Prussia; it has also been observed in other parts of the empire, notably in certain districts of central Germany. The illness runs its course with high fever, and is distinguished by a rash which appears after the first days of sickness and resembles the rash of measles, but is less diffuse and usually spares the face. The consciousness of the patient is nearly always clouded. The fever lasts about two weeks in favorable cases, yet a sixth or a seventh of the persons attacked succumb to the disease. Sometimes complicating diseases subsequently prove fatal. Spotted fever is one of the most communicable diseases. The contagious matter can both be transferred from the sick to the healthy, and be introduced by inanimate objects. The disease is most frequently spread by roving persons, peddlers, beggars, etc. Its dissemination is to be resisted by isolation of patients and disinfection.—[*Public Health and Marine-Hospital Service.*]

OBITUARIES.

Roberts Bartholow, eminent physician and professor emeritus of materia medica in Jefferson Medical College, May 10, at his home in Philadelphia. Dr. Bartholow was born in New Windsor, Carroll county, Md., on November 28, 1831. He was graduated in arts from Calvert College, and received his degree in medicine from the University of Maryland in 1852. In 1857 he entered the regular army as a surgeon and served in that capacity until 1864, when he resigned to become a professor of theory and practice of medicine in the Ohio Medical College, Cincinnati. He was later elected dean of that institution and remained there until 1879, when he resigned to come to Jefferson Medical College, as professor of materia medica and therapeutics. In 1885 Dr. Bartholow was chosen dean of the institution, but he resigned, in 1886, to resume his work as a professor. He continued in that capacity until 1893, when he was made professor emeritus. After that, and until a short time before his death, he practised his profession. He was the author of several medical books, among the best known being "Hypodermic Medication," "Treatise on Therapeutics and Materia Medica," and "Practice of Medicine," which was translated into Japanese at Tokio. He was a member of the American Philosophical Society and an honorary member of the Royal Medical Society of Edinburgh and the Société Médico Pratiques de Paris.

William Barton Hopkins, a wellknown physician of Philadelphia, May 4, after an illness of less than 48 hours. He was surgeon to the Pennsylvania Hospital and to the Orthopedic Hospital and Infirmary of Nervous Diseases, and was for years surgeon to the Episcopal Hospital. He published many valuable articles, and his book on fractures has been widely read. Dr. Hopkins was a member of the Rittenhouse, Country, New York Yacht, Corinthian Yacht and several medical clubs. He was graduated from the University of Pennsylvania in 1874.

Benjamin F. Dodson, at his home in Berlin, Wis., April 12, after a prolonged illness, aged 72; a graduate of the Cincinnati College of Medicine and Surgery in 1853; member of the American Medical Association, Wisconsin State Medical Society, and Green Lake County Medical Society. He was a pioneer practitioner and highly esteemed.

Edward E. Jenkins, from malignant disease, at his home in Palatka, Fla., April 18; a graduate of the Medical College of the State of South Carolina in 1853; a member of the American Medical Association, and one of the most esteemed physicians of Florida.

Orisa W. Gould, well known for her philanthropic and missionary work, especially among the poor on the East side, at her home in New York, May 3, aged 43. She was a graduate of the Woman's Medical College of New York.

Charlotte Blake Brown, of San Francisco, at the Alder Sanato-

rium, in that city, April 19, aged 57; a graduate of the Woman's Medical College of Philadelphia in 1874, and for 30 years a practitioner in San Francisco.

Henry M. Cox, from pneumonia, at his home in New York City, April 25; a graduate of the College of Physicians and Surgeons in 1871, and medical inspector in the Department of Health for the past 20 years.

Thomas John Chew, from apoplexy, at his home in Washington, D. C., May 2, aged 58; a graduate from the University of Princeton, and in medicine from the University of Maryland.

Edward A. Hight, of Kokomo, Ind., at Hope Hospital, Fort Wayne, Ind., April 15, after an operation for gallstone; a graduate of the Eclectic Medical Institute, Cincinnati, in 1898.

Isaac T. Wilson, from pneumonia, at his home in Quincy, Ill., April 24, aged 78; a graduate of New York University in 1851, and the oldest physician in his home city.

Edward L. Trudeau, Jr., from pneumonia, at his home in New York City, May 3, aged 31; a graduate of the College of Physicians and Surgeons, New York City, in 1900.

George E. Talbert, at his home in Beaver Dam, Wis., April 16, aged 75. He was surgeon of the Fourteenth Wisconsin Volunteer Infantry during the Civil war.

Thomas E. Barry, of New York City, in Utica, N. Y., April 26, from septicemia following an autopsy wound; a graduate of the University of New York in 1897.

John J. Smith, from chronic bronchitis, at his home in Yonkers, N. Y., April 20, aged 38; a graduate of the College of Physicians and Surgeons, New York, in 1889.

Fred. Van Akeren, at his home in Elgin, Ill., April 26, supposedly from an overdose of morphin; a graduate of the University of Würzburg, Germany, in 1888.

James L. Perryman, at his home in Belleville, Ill., April 22, aged 73; a graduate of the medical department of the University of Missouri, St. Louis, in 1854.

David D. Thomas, for 50 years a practitioner in Louisville, in Dallas, Texas, April 21, aged 80; a graduate of the University of Louisville in 1849.

John Moore, from pneumonia, at his home in Lakeville, Ind., April 23, aged 67; a member of St. Joseph County (Ind.) Medical Society.

John S. Poole, from influenza, at his home in Pooleville, Md., April 23, aged 40; a graduate of the University of Maryland, Baltimore, in 1887.

Guilford W. McCray, from apoplexy, at his home in Buffalo, N. Y., April 18, aged 73; a graduate of Castleton (Vt.) Medical College in 1857.

J. K. Herman, at his home in Kossuth, Miss., April 16, aged 60; a graduate of Washington University School of Medicine, Baltimore in 1869.

John B. Mahoney, from Bright's disease, at his home in Medford, Mass., April 20, aged 42; a graduate of Harvard Medical School in 1887.

Ernest W. Salter, from pneumonia, of Stronghurst, Ill., at Bayonne, N. J., April 23, aged 34; a graduate of Belleville Medical College in 1892.

E. H. S. Hutchinson, from pneumonia, at his home in New York City, April 13, aged 44; a graduate of Bellevue Medical College in 1881.

Theo. Bange, from diabetes, at his home in Cincinnati, April 18, aged 45; a graduate of Miami Medical College, Cincinnati, in 1881.

Ezra H. Ferris, at his home in Champaign, Ill., April 10, aged 82; a graduate of the Military College of Ohio, Cincinnati, in 1846.

James W. Montgomery, at his home in Paoli, Ind., April 19; a graduate of Hospital College of Medicine, Louisville, in 1884.

Franz Hugo Krebs, at his home in Boston, April 22, aged 80; a graduate of the Harvard University Medical School, in 1850.

Isaac P. Alger, from apoplexy, at his home in Cold Water, Branch county, Mich., aged 83.

A. Vandeventer, by suicide, at Fulton, Mo., April 17, aged 60.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended May 7, 1904:

SMALLPOX—UNITED STATES.		Cases	Deaths
California:	Los Angeles.....Apr. 8-23.....	23	6
Colorado:	Denver.....Feb. 27-Apr. 16.....	5

Changes in the Medical Corps of the U. S. Army for the week ended May 7, 1904:

FOSTER, DOUGLAS E., contract dental surgeon, is granted leave for two months, to take effect June 1.

CHENAY, ARTHUR A., sergeant first class, transport Sheridan, now at San Francisco, Cal., is relieved from further duty aboard that vessel and will report to the medical superintendent, army transport service, San Francisco, for duty in his office, and to relieve Sergeant First Class Nelson A. Hoberg. Sergeant First Class Hoberg will report on the transport Sheridan for duty aboard that vessel.

LOMMEL, NICOLAS, sergeant first class, Columbus Barracks, will report to the commanding officer, Second Battery, Third Infantry, at that post, to accompany that regiment to Alaska, and the headquarters, band, Companies A, B, and C to Fort William H. Seward. Upon arrival at Fort Seward he will report to the commanding officer for duty at that post.

ANDERSON, E. A., contract surgeon, is granted leave for two months, to take effect upon his arrival at his home, Devil's Lake, N. D.

* Week ended April 2, 1904, 42 cases, 3 deaths. Erroneously reported in previous report.

GOSMAN, First Lieutenant GEORGE H. R., assistant surgeon, is granted leave for three months, from about June 1, with permission to go beyond sea.

EBLE, CHARLES F., sergeant first class, Fort Thomas, will report to the commanding officer, Third Infantry, at that post, to accompany that regiment to Alaska. Upon arrival at Alaska, he will report to the commanding officer, Camp Skagway, for duty at that camp.

WOOD, RICHARD A., sergeant first class, Camp Skagway, Alaska, upon expiration of furlough authorized April 5, will report by letter for further orders.

MAUS, Lieutenant-Colonel LOUIS M., deputy surgeon-general, leave granted on surgeon's certificate May 5, is extended one month on surgeon's certificate.

OLIVER, ROBERT T., contract examining and supervising dental surgeon, is relieved from duty in the Philippines Division, to take effect about October 17, and will then proceed to San Francisco, Cal., and report by telegraph for further orders.

LONG, CHARLES J., contract dental surgeon, is relieved from further duty in the Philippines Division, to take effect about September 17, and will then avail himself of the leave granted him December 30.

The following named contract dental surgeons are relieved from duty in the Philippines Division, to take effect on or about the dates set opposite their respective names, and will then report to the commanding general of that division for transportation to San Francisco, Cal., on the first available transport sailing from Manila, and upon arrival at San Francisco will report by telegraph to the military secretary for further orders: S. Davis Boak, July 1, 1904; Clarence E. Lauderdale, July 1; Hugo C. Rietz, July 1; Ralph W. Deddel, July 1; William H. Ware, July 1; Franklin F. Wing, July 1; George L. Mason, August 17; Jean O. Whinnery, August 17; F. Homer Wolven, September 6.

SHELLENBERGER, JAMES E., contract surgeon, will proceed to Leon Springs, Texas, for duty, relieving First Lieutenant William P. Banta, assistant surgeon.

BANTA, First Lieutenant WILLIAM P., assistant surgeon, upon being relieved from duty at the target camp at Leon Springs, Texas, will proceed to Kerrville, Tex., and report at the artillery camp at that place for duty.

STONE, RANDALL C., contract surgeon, leave granted March 23 is extended one month.

APEL, Major AARON H., surgeon, will report to Brigadier-General John F. Weston, commissary general, president of an Army Retiring Board at the War Department, for examination by the Board.

SNARR, SAMUEL S., sergeant first class, is relieved from further duty in the Philippines Division and will proceed to San Francisco, Cal., reporting to the commanding general, department of California, and by letter to the military secretary of the Army for further orders.

DUBES, WARREN E., sergeant first class, Fort McPherson, will proceed to Fort Clark to relieve Sergeant First Class Ernest Jenks. Sergeant First Class Jenks will proceed to Fort McPherson for duty.

Changes in the Medical Corps of the U. S. Navy for the week ended May 6, 1904:

HULL, H. F., assistant surgeon, ordered to the Naval Hospital, Naval Training Station, Newport, R. I.—April 29.

WICKES, G. L., assistant surgeon, ordered to the Naval Hospital, Philadelphia, Pa.—April 29.

BROWN, H. L., assistant surgeon, detached from the Naval Museum of Hygiene and Medical School, Washington, D. C., and ordered to the Lancaster—April 29.

LANGHORNE, C. D., passed assistant surgeon, ordered to continue on duty on the Monongahela at the Naval Station, Guantanamo, Cuba—May 4.

WHEELER, L. H., MAY, H. A., BELKNAP, J. L., and FLINT, J., assistant surgeons, appointed assistant surgeons with the rank of lieutenant junior grade, from April 22, 1904—May 4.

Changes in the Public Health and Marine-Hospital Service for the week ended May 5, 1904:

PETTUS, W. J., assistant surgeon-general, leave of absence for seven days granted by Bureau letter of April 25, 1904, amended so as to be for three days from April 26—April 29, 1904.

SAWTELLE, H. W., surgeon, granted leave of absence for five days from May 6—May 4, 1904.

STONER, G. W., surgeon, five days' leave of absence from April 29, 1904, under paragraph 189 of the regulations.

CARTER, H. R., surgeon, to report at Washington, D. C.—April 29, 1904.

CARMICHAEL, D. A., surgeon, granted leave of absence for fifteen days from May 12—May 4, 1904.

YOUNG, G. B., passed assistant surgeon, two days' leave of absence from April 29, 1904, under paragraph 189 of the regulations.

McMULLEN, JOHN, passed assistant surgeon, granted leave of absence, on account of sickness, for seven days from April 21, 1904, under paragraph 191 of the regulations. Granted extension of leave of absence, on account of sickness, for ten days from April 28—April 29, 1904.

BURKHALTER, J. T., assistant surgeon, granted leave of absence for four days from May 4—May 8, 1904.

BOGGESS, J. S., assistant surgeon, to proceed to Newport News, Va., for special temporary duty—April 2, 1904.

SALMON, T. W., assistant surgeon, relieved from duty at Stapleton, N. Y., and directed to proceed to Philadelphia, Pa., and report to medical officer in command, for duty and assignment to quarters—May 3, 1904.

STILES, C. W., zoologist, to proceed to Missoula, Mont., for special temporary duty—May 2, 1904.

BIERMAN, C. H., pharmacist, granted leave of absence for eight days from May 26—May 4, 1904.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

SORE THROATS WHICH PRESENT SYMPTOMS AND PHYSICAL SIGNS OF DIPHTHERIA.

BY

A. E. BLACKBURN, M.D.,
of Philadelphia.

I know of no condition in which quick and accurate judgment on the part of the physician is more needed than the sore throats which present many of the symptoms and physical signs resembling diphtheria.

We have all frequently seen one or both tonsils covered with a grayish-white tenacious membrane, swollen and red fauces, and large cervical glands, altered voice, and fever. We have also seen patients with all these symptoms, except that there is no membrane present. I have lately had three cases similar to the former description, two were true diphtheria, the other staphylococcic infection.

The more experience one has the more uncertain one becomes when having to decide in a given case. We have all experienced the fallacy of relying at all times on the general symptoms and appearance of the throat.

When in doubt, err on the safe side, even though we may be somewhat compromised in the sight of some of our patients by subjecting them, or some member of their family, to the unnecessary physical inconvenience and expense of using antitoxin in instances in which the culture did not show true diphtheria. Such positions as these are very embarrassing, and we must rely on the culture for a definite diagnosis. If we wait for a report from the Board of Health, much valuable time is lost and the chances of recovery sometimes are decidedly diminished.

Under present circumstances one is exceedingly fortunate to receive from the Board of Health a report under 36 to 48 hours. I think it would be a good plan if the profession could adopt methods whereby a report could be obtained more promptly. With our modern means of communication, the report should be received in from 15 to 20 hours after the culture is taken, and then we could safely wait for this report before giving antitoxin.

This is merely a suggestion, but the following will illustrate the difficulty:

CASE I.—R. P., a lad of 12, after two days' indisposition, developed fever, prostration, and sore throat. When first seen at 8.30 p.m. his temperature was 101°; his throat was greatly swollen, and there was a grayish-yellow exudate on the right tonsil. The following morning his temperature was 101° and the membrane had spread to the other tonsil, practically covering both. The cervical glands beneath the angle of the jaw on both sides were enlarged and hard; there was great difficulty in speaking and breathing, and a very offensive odor. Clinically, this was true diphtheria, and yet repeated cultures showed a pure growth of staphylococci. If I had been compelled to wait for a report from the Board of Health I would surely have injected antitoxin.

CASE II.—The patient, who was a maid in the Presbyterian Hospital, became sick at a time when diphtheria was present among the inmates. She had fever, prostration, and an intensely injected throat; deglutition was very painful, but there was no membrane. Repeated cultures showed diphtheria bacilli present. The cultures became negative some time after the symptoms disappeared.

The next case was so instructive to me that I will give a detailed report:

CASE III.—M. D., a probationer of ten days from the interior of the State, had not passed her physical examination for the training school. A nurse in training, with whom she had been intimately associated, had been sent to the isolation ward two days previously with diphtheria. On May 23, 1901, at 9 a.m., she complained of sore throat and malaise; her temperature was 100°, pulse 100, respirations 24. Examination showed a violently red throat, with a grayish-yellow patch covering the right tonsil.

Owing to the existing circumstances, she was sent to the isolation ward at once, and 2,500 units of antitoxin given. A culture was immediately taken, which showed a pure growth of streptococci, as did a culture on each of the two following days. By the fourth day the membrane had quite disappeared, but as the fever and other general symptoms were worse, she was sent, after an antiseptic bath, to the private floor.

The temperature remained irregularly remittent and intermittent throughout the disease, varying from 96.2° to 105.2°. Accompanying this irregular temperature there occurred series of chills, chilly sensations, and sweats at irregular days and hours, numbering ten in all. Numerous tonsillar abscesses developed, first on one tonsil and then on the other; these had to be freely drained. During this time the patient was very sick, nausea and vomiting were of frequent occurrence, and it was with the greatest difficulty that she was able to take sufficient nourishment. Emaciation and anemia were progressive and marked.

The blood-examination showed four negative reactions (Widal); these were made on the sixth, ninth, twelfth, and sixteenth days of the disease. Repeated examinations for the malarial organism were also negative. On the twelfth day of the disease the blood showed hemoglobin, 52%; red blood-cells, 4,020,000; leukocytes, 14,400. On the twenty-fifth day of the disease, hemoglobin, 43%; red blood-cells, 3,440,000; leukocytes, 8,600. On the thirty-fifth day, hemoglobin, 45%; red blood-cells, 2,500,000; leukocytes, 4,500.

The quantity of urine was always low, varying from 14 oz. to 35 oz. in 24 hours. A few days it was over 40 oz. The specific gravity varied from 1.012 to 1.026. Albumin in moderate amounts was present in 29 consecutive examinations, 7 of these showing granular casts. Whether or not albumin was present before this illness we do not know, for, as before stated, the patient had not yet been admitted to the training school. She finally recovered.

These cases illustrate the difficulty of an early decision between diphtheria and other infections of the throat by clinical means. In numerous instances it is perfectly easy by the symptoms and appearance of the throat to be absolutely certain of the diagnosis, but there are other instances in which it is absolutely impossible to differentiate without the culture. The profession and laity would be relieved of great inconveniences if arrangements were completed whereby cultures sent to the Board of Health were more promptly reported.

THE PROBLEM OF IODIDS, NOT POTASSIUM IODID.

BY

RANDOLPH BRUNSON, M.D.,
of Chicago.

To the Editor of *American Medicine*:—Concerning the internal administration of potassium iodid, I would say that my experience in giving iodids while practising at Hot Springs, led me to stop the administration of potassium iodid several years ago. My reason for doing this was that I frequently noticed what I thought to be an idiosyncrasy for potassium iodid in many patients, so I consulted a professional friend whose experience extended over many years and he suggested that I try sodium iodid and the result would be different. Since that time I have not prescribed potassium iodid, but have given pounds of sodium iodid with markedly few instances of stomach intolerance of the drug. From my deductions it is patent to me that the intolerance was not caused by the iodine but by the potassium salts. The usual minimum dose prescribed is 1.25 cc. (20 m.) of a saturated solution in a glassful of water three times daily, one half hour after meals. This dose can be increased .3 cc. (5 m.) daily up to 24.64 cc. (400 m.) three times daily if desired or to the point of iodism. During the administration of the heroic doses the patient is instructed to drink copiously of water. I believe it essential to give large doses of iodids to obtain the best results, as they are very rapidly eliminated from the system and we cannot get the best effects by giving small doses. In this connection I will say that the administration of some form of mercury is usually necessary in conjunction with the iodids in those old, tertiary manifestations of syphilis, as well as in the secondary period, if we wish to obtain the desired results.

Quarantine Problems.—The officials of the Superior Board of Health of Mexico City say that the quarantine problems lie wholly in the hands of the Texas authorities. Dr. Tabor may send as many inspectors into the Mexican republic as he chooses, and they will be courteously received and will also receive assistance on the part of the Mexican authorities everywhere. These inspectors accomplish quite as much as if they were officially recognized. The quarantine matter has been taken up by the Foreign Relations Department of Mexico and the State Department at Washington.

ORIGINAL ARTICLES

CARCINOMA OF THE ESOPHAGUS.*

BY

W. M. L. COPLIN, M.D.,
of Philadelphia.

Professor of Pathology, Jefferson Medical College.

Tumors of the esophagus are not of common occurrence. Of the benign neoplasms, fibroma is the most frequent; it may be in the submucosa, interstitial or polypoid. Rarely the polypoid or pedunculated fibroma is so situated that it may be vomited or regurgitated into the pharynx and give rise to symptoms of suffocation, relieved by swallowing. Rokitsky¹ reported a smooth, lobulated fibroma 7 in. long and 2½ in. wide. Sarkisoff² reports a fibroma of the esophagus that underwent necrosis and was vomited; the patient recovered. He thinks the tumor was located near the sixth dorsal vertebra. A few cases of myoma, lipoma and adenoma of the esophagus have been recorded. Such tumors, however, are very rare.

Howard³ reports a primary sarcoma of the esophagus with metastases to the cardiac end of stomach. In individuals under 25, sarcoma is more common than cancer. It usually involves the lower third of the organ. Of the 12 reported cases of sarcoma of the esophagus, most were in males; 9 of the 12 were in the lower half of the organ; the tumor usually surrounds the lumen, but in 3 cases it was pedunculated or polypoid.

There were symptoms of obstruction in 11 of the 12 cases; perforation or involvement of respiratory organs occurred in 4. All varieties of sarcoma except angiosarcoma have been reported; 25% are of the round-cell variety. Metastases were present in 5 of the 12 cases and in 2 the metastases were widespread. Sarcoma of the esophagus runs a more rapid course than cancer. Since the publication of Howard's paper, v. Eicken⁴ has reported a spindle-cell sarcoma of the esophagus.

Carcinoma of the esophagus is usually regarded as rare even when compared with cancer of other parts of the body. Of 7,290 cases of cancer collected by Williams, 2,669 were in men and of these 5.3% were primary in the esophagus. Of 4,628 cases of cancer in women, the primary lesion was in the esophagus in 0.7% (35). Kraus⁵ does not think cancer of the esophagus so rare as usually is held; he gives the esophagus about the fifth place among the organs in which carcinoma occurs. Tanchon⁶ in 9,118 cases of cancer, found 13 of the esophagus and 2,303 of the stomach.

Although a disease of advanced life, it is not unknown in the young; Heiman⁷ recorded a case in a patient of 19, Stewart⁸ in a patient of 23, and Harris⁹ in a man aged 21. Most patients have passed 40, and 35% of them are between 50 and 60. The great preponderance of patients is males; of 772 cases of esophageal cancer collated by Kraus, 584 were in males; but 12 of Butlin's¹⁰ 59 patients were women; Rolleston¹¹ states that of 55 cases of carcinoma of the esophagus collected by Wilson from the postmortem books of St. George's Hospital, 8 were in women, and of 510 cases gathered by Newmann, 108 were in women; women are attacked earlier in life (about forty-fourth year) than men (about fifty-fourth year) (Butlin); of Emanuel's 6 cases, 5 were in men between 51 and 55 years and 1 in a woman, aged 33.

The exciting cause of cancer of the esophagus, like cancer in general, is as yet not known. Many predisposing factors have been given more or less importance, some of them clearly more than they deserve. In this article it is not my purpose to include cancer of the esophagus resulting from metastasis or direct extension,

but mention should be made of those rare cases of esophageal carcinoma resulting from involvement of the organ by tumors arising in the pharynx, tongue or stomach. That trauma or irritation of some kind may have something to do with the development of esophageal cancer is indicated by the fact that such growths are most frequent where the organ is most exposed to insults from bodies during their transmission through its lumen. Zenker¹² thinks it may depend on chemie, thermal, or mechanical irritation. All writers lay some stress on alcohol as a possible cause. Körner¹³, Voelcker¹⁴ and Leberts¹⁵ suggest that it is favored by the mechanical irritation resulting from enlarged periesophageal or peribronchial glands. Ritter¹⁶ thinks an esophageal diverticulum may constitute a point from which cancer can arise. Henoch¹⁷, Kraus¹⁸, Deininger and others attribute a certain influence to hot foods or bolting large boluses. Wendland¹⁹, Fritsche²⁰ and others have implicated hot or cold draughts. Ritter²¹ thinks a traction diverticulum may constitute a point of lessened resistance in which carcinoma may arise. It is easy to appreciate that any pouch or "silent area" in which food could lodge or other irritants prolong their action, might be similarly disposed. Leberts found a plum seed in a carcinoma and suggests that such foreign bodies may be causes. Röpke²² reports an esophageal carcinoma developing out of a scar. Wolf²³ reports two cases of carcinoma of the esophagus associated with spondylitis deformans, and briefly records a third case observed by Orth, and states that Schmorl knew of two additional cases.

With regard to location, authorities are not agreed. J. Solis-Cohen²⁴ does not think that any particular division of the esophagus is especially prone to the disease. Recklinghausen taught that cancer of the esophagus was most common where the organ is crossed by the left bronchus. Similar views were held by Virchow²⁵, Harrison Allen²⁶, Zenker²⁷, and Klebs, Rindfleisch, König and some other textbook writers. In 901 cases collated by Kraus 44 involved more than one part of the organ; 397 were in the lower third, 302 in the middle and 158 in the upper third. Von Hacker in 131 cases found 13 in the neck region, 53 in the neighborhood of the bronchial bifurcation, 36 in the hiatus and 29 at the cardia, making the numbers for the various thirds, from above downward, 13, 53 and 65, respectively. Butlin observes that if the esophagus be divided into upper and lower halves the tumors will be fairly equally distributed in the two parts. In Newmann's²⁸ 445 cases, 227 involved the upper part of the esophagus; 120 were situated in the lower and 98 in the middle third. According to Gross²⁹ the most frequent site is behind the larynx; Osler³⁰ says the upper third, and Pepper³¹ in order of frequency, names the region of the cardia, bronchial crossing, and cricoid area; Zenker and v. Ziemssen agree with Kraus and v. Hacker.

With regard to the type of cancer all records show that squamous-cell epithelioma is by far the most frequent; other types of carcinoma of the esophagus are exceedingly rare. Butlin's cases consisted of 54 squamous-cell, 3 scirrhus, 1 medullary and 1 colloid. The colloid spoken of by Butlin, and one observed by Eppinger³² are exceptional. The adenocarcinomas are usually at or near the cardia; they may be extensions from primary growths in the stomach or possibly some of them arise from ectopia of gastric glandular elements abnormally placed in the lower part of the esophagus. Of the origin of esophageal cancer from glands in the mucosa too little is known to justify any sweeping deductions.

Anatomically cancers of the esophagus assume many forms. Papillary growths, irregular projections, polypoid masses that may or may not be lobulated, bossed or fissured, infiltration of the wall of the tube tending to encircle, but rarely doing so, and irregular linear masses which may or may not ulcerate, constitute the most

* From the Laboratories of the Jefferson Medical College Hospital, and the Philadelphia Hospital. Read before the Philadelphia Pathological Society, April 14, 1904.

common forms. Kraus cites cases in which all but a few centimeters of the tube were involved; in other cases, as in the one reported in this paper, large nodular masses develop attached to the esophageal wall by relatively narrow stalks; this type ulcerates slowly. It may give rise to marked obstruction that disappears with the advent of necrosis even before destructive ulceration approaches the esophageal wall. This misleading clinical phenomenon is particularly remarked upon by Arnold.³⁵ Ulceration was absent in but 5 of 54 in Butlin's series and in 3 of the 55 St. George's Hospital cases. Isolated patches of ulceration occur. In types not taking on this polypoid character or having assumed that form and later by necrosis lost the external projection and finally invaded the esophageal wall, stenosis may be brought about by infiltration or, what is more common, the coincident increase in fibrous tissue associated with contraction may narrow the tube. As a result of the obstructive lesion there is commonly an initial hypertrophy of the esophageal musculature sooner or later followed by wasting and dilation. The more or less relaxed organ may assume a spindle form but usually the cavity created by gradual distention is largest just above, but not immediately at, the obstruction and from this point of maximum width progressively narrows to approximately the normal size at the upper limit of the organ. Of course the lower the tumor and, other things being equal, the slower stenosis develops, the more capacious the sac may be. In some instances fluids and solids may accumulate in such quantity that the consequent regurgitation appears, from necessity, to be a true vomiting of gastric contents. Such dilation may occur without demonstrable stenosis at autopsy, but, as Rolleston indicates, the differences between functional obstruction and demonstrable anatomic narrowing may be quite marked.

Some of the complicating anatomic changes are of great clinical interest. Cancer of the esophagus tends to involve the peribronchial and mediastinal lymph-nodes, the gastric glands, the air passages and adjacent blood-vessels and lungs, the thyroid and, less frequently, the pleura, pericardium and heart. When the lung is penetrated Rolleston observes that it is usually the right organ that is involved.

Treves³⁴ reports a case of carcinoma of the lower end of the esophagus involving nearly the whole length of the lesser curvature, the patient surviving a gastrostomy (at which time the diagnosis based on symptoms was verified) for 2 years and 11 months. Fütterer³⁵ reports a case in which cancer of the stomach depended upon transplantation from a growth in the esophagus. He collected six similar cases from literature. Kraske has reported two instances of cancer of the rectum with transplantation below. When the esophagus is perforated by the growth, the trachea may be involved; in Zenker's 120 cases of perforation the air passages were affected in 70; in 26 one bronchus, and in 21 the trachea was entered; in 17 the right lung and in 6 the left lung was affected. In Homan's³⁶ case there was an external opening and also perforation of the trachea.

Adenot and Cadet³⁷ report cancer of the esophagus with esophagotracheal fistula and gaseous distention of the stomach by air, thought to have passed through the trachea into the esophagus, and in that way into the stomach. Gastrostomy was done, at which time the stomach was found distended, and the organ filled and emptied during respiration in such a way as to render the operation more difficult. Three centimeters above the tracheal bifurcation exactly in the median line posteriorly, there was a mammillated projection into the trachea that contained an opening communicating with the esophagus. Sirot³⁸ has been able to collect 68 cases of esophagotracheal fistula. Adenot and Cadet do not state whether these were all cancerous or not and the original paper has not been available for examination. Since the publication of Sirot's thesis a number of cases

has been reported; the complication is not infrequent. In nearly all cases of cancer of the esophagus in which the stomach has been observed, at operation or autopsy, the organ is small, retracted, hidden under the liver, difficult to find, and, at operation, surgeons have opened the colon instead. Adenot and Cadet think that in their case during inspiration, air passed through the fistula into the esophagus, and in expiration it was forced onward into the stomach where it accumulated. They therefore hold that when a tracheoesophageal or bronchoesophageal fistula is suspected, the stomach should be percussed with care, to determine if there is any undue distention of the organ caused by aerophagy. Cade and Revol³⁹ and a few other observers have reported cases in which esophagotracheal fistulas secondary to cancer of the esophagus were entirely latent.

Ross⁴⁰ reports a cancer of the esophagus involving the vertebrae and producing paraplegia.

Bureau⁴¹ reports a cancer of the esophagus, adherent to the left auricle in which was a nodule, the size of a pea, situated just under the endocardium. There was a stenosing growth of the esophagus with ulceration and perforation into the middle lobe of the right lung. The sputum was fetid, and a pleural effusion amounting to 500 cc. was present. The patient had vomited some blood on one occasion. The muscle fibers of the heart were atrophied and infiltrated by cancer cells; the left pulmonary vein and the pneumogastric were compressed by the growth which was an epidermoid cancer. Tachycardia (160) was present.

McKendrick⁴² records an epithelioma of the upper part of the esophagus with involvement of the pneumogastric, and including both recurrent laryngeal nerves; the symptoms—slight dysphagia, dyspnea, stridor, cough, and aphonia—indicated aneurysm of the aorta. Kuckein⁴³ reports two similar cases, both diagnosed as aortic aneurysm and in both expansile shadows by the röntgen ray were produced, due to the pressure of the filling aorta upon the tumor.

Saundby and Hewetson⁴⁴ report an extensive carcinoma of the esophagus occurring in a man aged 50. He had been ill two years. There were enlarged glands in the neck and around the aorta, the latter involving both vagi and the recurrent laryngeal nerves; edema of the lungs, consolidation, and secondary deposits at the base were also present. The upper part of the esophagus for six inches was involved in a sloughing malignant growth, which projected into the lumen and bound the esophagus to the trachea, which at one point was perforated. The growth extended from the first ring of the trachea to two inches below the bifurcation—a distance of six inches. The lumen of the esophagus between these points was three times the normal size; there was no stricture at any point. The growth extended completely around the esophagus and over points involved the whole thickness of the wall. The broncholympathic glands were affected. The trachea was compressed, and a button-like mass extended into the left bronchus. The pneumogastric nerves were involved on each side just behind the bronchi. The growth was a spheroidal-cell carcinoma; cell nests were absent in both primary and secondary growths. The difficulty in swallowing depended not upon stenosis, but involvement of the musculature of the esophagus. Fluid gravitated into the stomach better than solids; hence the appearance of stenosis. The sudden attacks of vomiting appeared to depend upon involvement of the pneumogastric nerves.

The tendency of such tumors, when located in appropriate regions, to involve, usually by inclusion, any adjacent nerves may account for the occurrence of bradycardia or tachycardia, both of which have been observed repeatedly. Compression of a degree sufficient to stimulate the pneumogastric would slow the heart and stimulation of the fibers coming from the inferior cervical sympathetic ganglion would accelerate, and possibly in these facts may be found a satisfactory explanation for

the occasional tachycardia and bradycardia. The latter was present in Arnold's case, the pulse, for two months, ranging between 50 and 60.

Carcinoma of the gullet may be latent; Hödlmoser⁴⁵ reports two such cases. In both dysphagia was absent, and there were no esophageal symptoms. Unilateral paralysis of the recurrent laryngeal nerve was the most marked symptom. Some enlargement of the subclavicular glands was present, and in one case the tumor was attached to a tuberculous gland.

Emanuel⁴⁶ records six cases of cancer of the esophagus without obstruction. In two of his six cases infiltration and perforation of the trachea occurred; in three the left bronchus was perforated; in one case the growth was low and penetrated the lung. Cough or other respiratory disturbance coming on immediately after swallowing should be regarded as a symptom of laryngeal or bronchial involvement.

Dickinson⁴⁷ reports a case in which penetration of the subclavian artery occurred; S. Jones⁴⁸ records an instance of perforation of the intercostal arteries with fatal hemorrhage. Taylor⁴⁹ has been able to collect nine cases of ulceration into the aorta or its branches.

With regard to the life expectancy in these cases, much depends upon the intervention of the surgeon, who may, by gastrostomy, prolong life. Rolleston states that most patients die within a year of the appearance of symptoms, that carcinoma of the upper part of the esophagus is more rapidly fatal than when the lower third is involved, and scirrhous carcinoma progresses less rapidly than the squamous-cell variety. The last statement is not in harmony with our knowledge of the two varieties of cancer when occurring elsewhere. Pepper's observation that metastasis is less frequent than in carcinoma of other organs is correct, if we exclude certain feebly malignant epitheliomas involving the skin.

Diagnosticians will find no little difficulty in differentiating esophageal malignant stenosis from other forms of narrowing, and these difficulties will not be lessened by the findings of Soupault,⁵⁰ who records four cases in which the symptoms resembled stricture of the esophagus, but were due to atrophic retraction of the stomach, small retracted organs being found at autopsy; four similar cases are found in literature. Von Cackovic⁵¹ reports two cases of total contraction or shrinking of the stomach. In such cases the symptoms and even the results of instrumental examination may closely resemble stenosis, and hence carcinoma of the esophagus.

With regard to the treatment little can be said. Radical operative procedures directed to the neoplasm have proved disastrous, but gastrostomy or other palliative undertaking usually is regarded as most valuable. Recently Exner⁵² has treated esophageal cancer by the use of a tube of radium attached to the end of an esophageal bougie; the capsule containing the radium should have the diameter of a No. 16 bougie. He reports three cases, in all of which there was lessened stenosis, but as this may result from sloughing independently of any so-called resorptive action, the observation offers at present no conclusive evidence of specific benefit.

The following is a brief summary of the postmortem findings in a case of carcinoma of the esophagus coming to autopsy in the Philadelphia Hospital. The patient was under the care of Dr. Thomas G. Ashton, who will report the clinical details elsewhere:

H. McG., Men's Medical Ward. Patient, male, white, 63 years, native of Ireland. Admitted August 27, 1903; died January 26, 1904; autopsy held January 26, 1904.

Pathologic Diagnosis.—1. Visceroptosis. 2. Chronic adhesive pleuritis (sinistra). 3. Healed-in pulmonary tuberculosis. 4. Atrophy of heart. 5. Arteriosclerosis. 6. Chronic interstitial nephritis. 7. "Polypus" of esophagus. 8. Catarrhal gastritis. 9. Atrophy of liver. 10. Meckel's diverticulum.

Body is that of an emaciated, aged male; marked atrophy of the muscles; scaphoid abdomen; over acromial end of both scapulas are endosseous nodes irregular and plate-like extending downward along the spines. Subcutaneous fat is scanty, almost wanting. Musculature pale, flabby, wasted.

Abdomen, marked visceroptosis; all of the small intestine lying in the pelvis, transverse colon on brim of pelvis. Duodenum just under umbilicus. Liver also prolapsed. Stomach nearly vertical.

Thoracic cavity. Left pleura uniformly adherent with old firm, fibrous adhesions. Right pleura adherent only at the base posteriorly.

Pericardium contains 100 cc. of clear, straw-colored fluid. Serosa normal. Subepicardial fat is gelatiniform.

Right ventricle contains small quantities of coagulum. Right auricle capacious and distended with clots. Left side empty. Auriculoventricular orifice on right side dilated, admits four fingers and thumb. Valves of right side normal. Marked thickening of mitral leaflets. Atheroma of valve

Squamous-cell carcinoma of the esophagus of the polypoid type. A, cardia of stomach. B to C, cardia of esophagus. C, hiatus esophagi. D to E, area of maximum dilation of the esophagus; from E upward the organ gradually diminishes in size. F, wall of esophagus. G to H, pedicle of tumor by which are attached the projecting bosses of the new growth; at the base there appears to be but slight infiltration beneath the submucosa, although the esophageal wall is slightly thickened. The line F, G, H is near the midline posteriorly from which the tumor has arisen.

bases. Aortic leaflets slightly stiff; no marked valve lesions. Coronary arteries tortuous, typical pipestems at places. Atrium of left coronary artery stenosed. Myocardium brownish, firm, contains small grayish areas. Heart weighs 250 gm. Aorta atheromatous.

Lungs: Both organs show same changes; a few old cretaceous areas 0.25 cm. by 0.5 cm. in diameter. Similar changes in peribronchial glands. Bronchi normal. Larynx and trachea show no gross lesions. Left lung weighs 500 gm.; right lung weighs 520 gm.

Spleen normal in size and color; slightly fibrous; contains numerous cretaceous nodules 2 mm. to 5 mm. in diameter. Parenchyma slightly edematous and somewhat congested. Malpighian bodies rather inconspicuous. Weight, 120 gm.

Left adrenal slightly enlarged; contains many small cretaceous tubercles. Left kidney: Cortex narrow, firm, capsule adherent, surface granular, resists incision, considerably congested, but not small in size.

Pelvis and ureters normal. Right adrenal and kidney in condition similar to the left. Right kidney weighs 150 gm.; left, 160 gm.

Bladder contracted and empty. Middle lobe of prostate slightly enlarged. Internal and external genitals normal.

Duodenum normal. Biliary passages patulous. Gallbladder distended with 250 cc. of rather thick bile, containing considerable biliary sand.

Liver slightly fibrous; capsule thickened; adhesions around gallbladder. Organ rather soft and flabby, but resists incision. Weight, 1,570 gm.

Esophagus: On opening pericardium a fusiform mass is recognized presenting on posterior wall. Pericardial surface smooth and movable over mass. No evidence of pressure on bronchi, though slightly adherent to both trunks; aorta free. On removal of chest viscera the fusiform enlargement of esophagus is better seen. It begins 2.5 cm. above the cardia, attains a maximum width of 4.5 cm. at a point 10 cm. higher. The esophagus incised on its anterior surface. Four centimeters above the cardia is found an irregular polypoid mass made up of numerous bosses, and extending in the axis of the esophagus 9.5 cm. The point of attachment of lower end (pedicle), however, is 5.5 cm. from the cardia, and extends upward 6 cm. This pedicle seems to be about 2.5 cm. in width, its accurate width cannot be determined without mutilation of the specimen. The new growth is composed of bosses varying in size from 4 mm. to 5 mm. in diameter, to larger mass 5 cm. in maximum diameter. (See illustration.) At the upper end is an ovoid, almost free polypoid mass, 2.5 cm. by 1.5 cm., intensely congested, and at one point shows beginning necrosis. The esophagus at the cardia measures 4 cm. in circumference; 2 cm. above this point (hiatus oesophagi) is a slight constriction, measuring 3 cm. in circumference. Just over the mass the esophagus seems to be widest, measuring 9.5 cm. in circumference. Just above mass, 12 cm. from cardia, the esophagus measures 8 cm. in circumference, from which point it gradually narrows to what seems to be normal lumen (4 cm. in circumference) 22 cm. above cardia. The esophageal wall seems fairly thick, but rather irregularly so, 0.25 cm. in thickness at the cardia, 0.4 cm. thick just over the tumor, 0.2 cm. in thickness at the upper end.

Stomach is contracted, particularly at the pyloric end; contains a small quantity of grumous material. Mucosa intensely hyperemic, at points almost necrotic. These changes most marked in the pyloric area. Summits of the rugae pointed and slightly eroded. Mucosa obscured by superimposed mucus.

Intestine: One hundred and eighty centimeters above the ileocecal valve is a bifid Meckel diverticulum. It is 6 cm. in length, arises from free margin of intestine, has a diameter of 1 cm.; 2 cm. from its origin it divides into two small sacs resembling the letter "Y." Its mucosa is normal, overlying serosa is somewhat thickened, otherwise intestine is normal. Large arterial trunks show considerable atheroma.

With the exception of a marked arterial sclerosis, there is no noteworthy lesion of other organs.

Histologic examination of properly prepared sections shows that the growth is a typical epidermoid cancer, a squamous-cell epithelioma with marked keratinization of the cell nests and a richly cellular stroma. A tumor possessing such a structure must be of very low order of malignancy, resembling in its architecture the least malignant of the labial epitheliomas.

IS THE EPILEPTIC ATTACK EXPLOSIVE IN CHARACTER?

BY

J. W. WHERRY, M.D.,

of Clarinda, Iowa.

Assistant Physician Clarinda State Hospital, Clarinda, Iowa.

One feature, that of unconsciousness, has not received the attention it deserves in our considerations of the symptom-complex, known as the epileptic attack. Associated, as it is, with characteristics so much more striking in their manifestations, it has been frequently lost sight of, and, in some instances, entirely forgotten. The convulsion, while only secondary in point of time, is so startling in the manner of its presentation, that it not only challenges the attention of the observer, but usually receives it.

It is true, that in describing the epileptic attack the unconsciousness, the fall, the cry, and the convulsion, are all mentioned as constituent elements, but many textbook writers are seemingly disposed to attach little value to any of these except the convulsion, if, indeed, they do not make all other features completely subservient, and refer to the entire epileptic attack as a *convulsion*.

To speak of the epileptic attack as a convulsion is not objectionable in a general way, if this loose and imperfect manner of expression does not eventually lead to loose and imperfect ideas regarding the real nature of the epileptic attack. That the latter has not only been referred to as a convulsion, but that it has been believed in many instances to be nothing *but* a convulsion is, I fear, too true. Our attention has been directed exclusively to the convulsion; investigation and research have been along the line of determining, if possible, the nature and origin of the convulsion; and treatment has been restricted to those drugs best calculated to prevent the convulsion, until we are almost ready to believe that epilepsy is only a synonym for convulsion, and that the epileptic attack is merely a series of incoordinated movements.

Epilepsy is not simply a matter of muscular contractions. The epileptic attack is a complete and harmonious entity, but it is an entity made up of two separate and distinct elements, viz., unconsciousness, and convulsive movements; each existing as the result of a mutual cause, and neither bearing a more intimate relation to the other than that of fever to the chill which it follows. The chill of malaria does not cause the subsequent fever, nor does the fever precipitate or initiate the chill. The same infection that causes the chill causes the fever, and it produces each at its proper time and in its regular order; and, likewise, the causative factor back of the epileptic attack produces the unconsciousness and the convulsion, and it produces them each at its proper time and in its regular order.

The importance of this condition of unconsciousness preceding the convulsion has not always been fully realized. Our knowledge of its existence, even, is some-

what wavering and uncertain. We know that at some time during the attack unconsciousness supervenes, but statements vary regarding the time of its beginning. Landon Carter Gray says: "The typical attack of epilepsy consists of a sharp cry, an *instantaneous* loss of consciousness, in which the patient falls heavily, and the rapid supervention of tonic and then of clonic convulsions." This would lead us to believe that the loss of consciousness was not only instantaneous, but that it occurred subsequent to the cry, thus placing it after the beginning of the convulsion, so far as position in time is concerned, if, as some believe, the cry is caused by the forcible ejection of air from the lungs by the tonic convulsion.

Most definitions of epilepsy refer to the loss of consciousness as being very sudden or instantaneous, but I believe this error arises from the fact that it is difficult to detect the loss of consciousness until it is complete. When the patient falls the evidence of unconsciousness is unmistakable, and this being the first, and, possibly, only intimation of its presence, it is very naturally regarded as having occurred instantaneously. The cry, or the fall, is practically the beginning of an attack so far as the observer is concerned. But because these are the first things to attract our attention are we to conclude that nothing has gone before? Shall we say that because the fall was the first evidence of loss of consciousness, that therefore this loss of consciousness could not have been slow and progressive, but must necessarily have been as sudden and precipitous as the fall itself? On the contrary, I have every reason to believe that the onset of unconsciousness is usually much slower than we think, and that the beginning of the loss of consciousness antedates considerably the beginning of the convulsion. The difficulty is to prove this. The very nature of the situation precludes extensive demonstration. Watching a patient continuously hour after hour, while hoping and praying that an attack may occur, so that preconvulsive observations may be made, is a tedious and wearying process, and one not likely to be indulged in to any great extent. Consequently, it is only by the merest chance that light is shed upon these obscure points, and so impossible is it to obtain it except by accident, that its existence, even in a limited degree, is not to be ignored.

Not long since I had my attention called to this matter. A patient had an epileptic attack while writing a letter, and the beginning and gradual loss of consciousness can be easily traced in the writing.

This patient, a female, aged 26, has had epilepsy 14 years. She was well-formed, of good muscular development, bright and intelligent at one time, but there is considerable dementia now present. She had written one page of her letter and the illustration given herewith is from the top of the second page. Her writing on the first page is uniform with the first three or four sentences in the illustration.

The point to which I wish to call attention is the length of time which evidently elapsed between the first noticeable indication of mental confusion, and the supervention of total unconsciousness. It is interesting also to note how gradually and progressively the unconsciousness deepened, and yet the nurse sitting beside her holding the bottle of ink did not notice anything particularly unusual about her until she fell from the chair. The attack was a typical one, as all this patient's attacks were, and the fall, the cry, and the convulsion, occurred in their regular order and with the degree of severity usually observed in her case. She was subject to attacks about every third day, and since this letter was written I have been present at the beginning of attacks a number of times but have never been able to notice anything unusual in her behavior until she fell.

This letter has been preserved as it fell from her hands.

Since my attention has been called to the matter, however, I have observed indications of mental confusion deepening into unconsciousness in several epileptics just prior to the convulsion. One patient picks away aimlessly at her clothing; another unbuttons and buttons her dress; another attempts to unlace her shoes; another claps her hands; while another, not now in the hospital, would run the length of the hall, upsetting

everything and everybody in her way, thus furnishing a good illustration of the *epilepsia cursiva* of Bootius.

Gowers¹ says: "I have known a patient always to turn around and retrace his steps, and another would spring up and jump about the room a few seconds immediately before an attack." Many such instances have been noticed by various observers, but why say these coordinated, but meaningless, movements occur before

I have to say this is a nice day, I have to say
the birds are singing. I have to say I hope
you go to chapel every Sunday and hear about
Jesus. I have to say we went out walking today,
we went out walking today, out walking today,
outside went outside we I have to say we
walking outside walking I have to say
say I have to say we walked
we walked we walked we walked
we walked we walked we walked we walked

the attack? Are they not more properly a part of the attack? Do they not indicate, obviously, the gradual loss of consciousness, which is doubtless present in all cases of epilepsy, even though, as in the case illustrated, there is no visible evidence except as secured by accident?

This initial stage of gradually increasing loss of consciousness gives rise to peculiar and confused sensations, to which the name aura has been given. This aura is probably present in practically every case of true epilepsy, though it is impossible to know the real facts in the case, but authors, in describing this phenomenon, base its presence or absence, not on the real facts of its existence, but on whether or not the patient has any recollection of it after the attack. If the sensations experienced during this period are remembered, and the patient gives expression to them after the seizure, they are referred to as an aura, but it is readily seen that, in other cases, the complete obliteration, during the period of total unconsciousness, of all power to recall these sensations subsequently does not necessarily preclude their existence.

I append another illustration to show that the epileptic attack is not explosive in character, and that the phenomenon of unconsciousness exists previously to, and independently of, the convulsion. If the unconsciousness is due solely to the explosive character of the convulsion, then there could be no loss of consciousness until after the convulsion had been initiated. If, in other words, the epileptic attack is due to the explosion of motor nerve-cells alone what, then, causes the unconsciousness? Or, if all the phenomena attending the epileptic attack be due to this motor cell explosion, how could there be any evidences of mental confusion, or approaching unconsciousness, or, indeed, of any loss of consciousness until after the cry? To build up a theory of epilepsy on the evidence of motor cells alone is to build neither wisely nor well, for the truth remains that unconsciousness occurs in advance of the convulsion, and this fact means much more than appears on the surface.

The following is taken from the *Journal of Insanity*, Vol. xxx :

A young printer employed in this city is an epileptic, and frequently has a fit while composing, which results in making "pi" of what he has in his "stick." A short time since he had one of his attacks, but fortunately the matter was preserved, and a proof taken as follows:

The annual meeting of the County Convention of Young

Men's'n's Chri Ctiisrshian years days associations, was asholcia-cation, afforited for the fter cas chere choredess:—

For the purpose of comparison, I append the sentence as it should have been set up, and as it finally appeared in the paper:

The annual meeting of the County Convention of Young Men's Christian Associations, was held at Westborough, yesterday. Officers for the ensuing year were chosen as follows:

This is interesting as showing the time that elapsed, and especially the number of movements that were executed between the beginning of the disturbance and the entire loss of consciousness.

Anyone who is at all familiar with the process of setting type will recognize that the placing of the individual letters composing the above extract in the "stick," and afterward justifying them, as was apparently done in this case, would require some time under the most favorable circumstances. Taking into consideration the fact that the gradually increasing mental condition would necessarily diminish the speed, we can get a fair idea of the length of time involved. Notice also that while setting the words, "The annual meeting of the County Convention of Young Men's," his mind appears to have been clear and his ideas connected, and even from this point on there is a continuous thread of fact running through all his confusion, as may be seen by comparison with the paragraph as it should be, though the thread dwindles to the merest filament as it approaches complete unconsciousness.

The disposition to look upon the fall, or the "initial cry," or, in the absence of either, the tonic convulsion, as the real beginning of the attack, has led us to regard the explosive theory of epilepsy with more or less favor. In fact, the convulsion itself has, by its very nature, riveted the attention until it has succeeded in attaching to itself a degree of importance out of all proportion to its weight and position in this symptom-complex. It has been regarded as the one original and primal symptom of the epileptic condition, all other symptoms being merely incidental thereto, or, at best, holding only the subservient relation of offspring to parent. The narrowing of the glottis at the moment when air is expelled from the chest by the tonic convulsion is said to produce the epileptic cry; but when this principle is carried further, and it is said that the convulsive contraction of the muscles of the extremities causes the fall, and the explosion of motor energy in the brain, at the beginning of the convulsion, produces the unconsciousness, then it becomes evident that the convulsion has been unduly exalted to the position of a prime cause, instead of being regarded as a later manifestation of the same original cause which produces the unconsciousness.

The condition of unconsciousness and the convulsion bear no closer relation to each other than that they are both the result of an identical elemental cause, each representing a stage in the epileptic attack. That the unconsciousness precedes the convulsion must, I believe, be conceded. Both the convulsion and the loss of consciousness must occur to produce the true and, as I hold, the only epileptic attack. Consequently, investigations prosecuted for the purpose of discovering the prime cause of epilepsy must ever keep this fact in view. The investigator who looks only for the source of the unconsciousness will fall far short of the end he seeks, and he who singles his eye exclusively to the origin of the convulsion will be doomed to disappointment; while he who believes that the unconsciousness and the convulsion are identical, that they are the same thing, one and indissoluble, that they may occur at one time in the form of unconsciousness, and at another time in the semblance of a convulsion, or, indeed, if he believes that the diagnosis of an epileptic attack can be safely based upon the existence of either, neither, or both of these conditions, then is he indeed entangled.

If this be true, then it must be allowed that in a typical epileptic attack the original cause must be of such a nature as not only to produce unconsciousness, but also to occasion a convulsion. Anesthetics, alcohol, opium, and other toxic drugs may cause unconsciousness

without convulsive movements. Irritation of the cortex will produce convulsive movements, but these are not necessarily accompanied by unconsciousness. Hence the cause of the epileptic attack need not be looked for in these or similar sources. The production, or the occurrence of a convulsion, without partial or complete loss of consciousness, would not be an epileptic attack, any more than the involuntary muscular contraction of a malarial chill, or the convulsive shivering due to exposure to cold, or the muscular spasm of tetany, or any other spasmodic contraction of the muscles would be epilepsy. Nor, on the other hand, would unconsciousness, even though accompanied by a cry, a fall, and possibly, biting of the tongue, be properly called epilepsy in the absence of any convulsion.

It is true that we are frequently asked to consider epilepsy as a momentary loss of consciousness; as a loss of consciousness in varying degrees without convulsion; as a convulsion in varying degrees without loss of consciousness; as a maniacal manifestation without loss of consciousness and without convulsion; and all of the foregoing in an unlimited number of varieties, but the wisdom of so doing may be seriously doubted. Most diseases, when well understood, present a pretty definite picture, and I am of the opinion that the numerous and, apparently, contradictory forms of epilepsy as now given are only an evidence of our lack of knowledge on the subject, and the establishment of so many varieties may be regarded as merely an indication of the manner in which we are reaching out for the truth.

The treatment of epilepsy must ever remain unsatisfactory so long as it is directed exclusively toward the convulsion, or, for that matter, exclusively toward the unconsciousness, or exclusively toward any other single symptom of the epileptic condition. Antispasmodics may be effective when used simply for the purpose of counteracting purely convulsive causes. Bromids may act very satisfactorily when used as a sedative in the presence of cortical irritation alone, but in epilepsy cortical irritation does not stand alone; it is only half the story. It is not a simple convulsive cause that we wish to attack. If this were all, its accomplishment would be a matter of comparative ease. It is a cause that produces a convulsion, but that is not all; it is a cause that produces unconsciousness and a convulsion. Here is the key to the situation: Keeping in mind the fact that the onset of the epileptic attack is not dynamic or explosive, and that the prime cause of epilepsy is an element, toxic, infectious, or what you will, possessing a double characteristic: (1) to produce unconsciousness; (2) to cause convulsions; and then remembering that treatment, to be effective, must be directed toward those causes only which possess within themselves these two qualities.

A large number of drugs will cause convulsions, when administered in toxic doses, and, likewise, many poisons will produce unconsciousness; but there seems to be very few which cause both unconsciousness and convulsions, especially with the unconsciousness preceding the convulsion. Camphor, belladonna, strychnin, digitalin, aconitin, physostigma, codein, picrotoxin and cocain, all induce convulsions when given in large doses, but there is no unconsciousness. Morphin, nitroglycerin, chloral, chloroform and ether, produce unconsciousness, but no convulsion follows, while the administration of hydrocyanic acid, or carbonic oxid, gives rise to both unconsciousness and convulsions.

It is more than likely that the drugs or toxins causing convulsions do so as a rule by direct and irritating action upon the nerve cells; while those drugs or toxins producing a condition of unconsciousness do so by interference with the oxidizing processes in the blood, or with the supply of blood itself. Camphor, belladonna, strychnin, digitalin, aconitin, physostigma, codein, picrotoxin, cocain, and other purely convulsive drugs produce no known changes in the blood, merely using it

as a vehicle; but, on the contrary, the drugs causing unconsciousness, such as morphin, nitroglycerin, chloral, hydrocyanic acid, and carbonic oxid, all produce noticeable blood alterations.

In Brunton's *Materia Medica* I find this statement: "I found that after the exhibition of opium the vessels of the submaxillary gland no longer dilated, but on the contrary contracted, on stimulation of the chorda tympani, and that the blood which issued from the gland was not of a bright arterial hue, but was very dark, and flowed drop by drop." Also this: "Hydrocyanic acid appears also to form a compound with hemoglobin, which is much less stable than that of carbonic oxid." This hydrocyanic acid compound, while less stable than that of CO hemoglobin, is shown to be much more stable than that of methemoglobin, and appears to occupy a position between these two. Like CO hemoglobin it is sufficiently stable to resist the action of any reducing substances originating during the asphyxial convulsion which follows the administration of this drug, and is consequently very deadly in its nature. Brunton says of nitroglycerin: "It diminishes the oxidizing power of the blood and communicates to it a chocolate color," and the production of unconsciousness is doubtless due to this diminished oxygenation.

Chloral has a similar effect upon the blood and its chief value as a hypnotic depends upon its power to lessen oxidation in the brain. Indeed, one important symptom in poisoning by chloral is that the bodily temperature falls steadily and rapidly, and this, too, "when the animal is wrapped in cotton wool, or is put in a warm place."

Carbonic oxid locks up the oxygen in oxyhemoglobin and forms CO hemoglobin, which is a stable compound. Animals poisoned by CO therefore die of asphyxia, the internal respiration being arrested, and the blood remains for a long time of a florid color. "Reducing substances accumulate rapidly during the process of asphyxia but CO hemoglobin, being a stable compound, remains unaffected by these."

There is little doubt that all cases of unconsciousness, except those resulting from trauma or injury, may with safety be regarded as the result of an insufficient supply of oxygen in the brain, either as the result of vasomotor disturbances, as in syncope; from the loss of blood, as in hemorrhage; or from the changes which affect the supply, or the serviceableness, of the oxygen in the blood, occasioned by the introduction of poisonous drugs or toxins into that fluid. If this be true it must follow then that if a toxin does cause the epileptic attack, it must be a toxin possessing both narcotic and convulsive qualities, as neither of these alone would suffice. In other words, it must have an irritating effect on the motor nerves and also produce the necessary blood changes, if, indeed, these changes in the blood are not in themselves sufficient to produce both the unconsciousness and the convulsion.

Bartholow, in his "*Materia Medica*," says, while speaking of the physiologic action of pulsatilla: "Dilated pupils, hebetude of mind, stupor, coma, and convulsions are cerebral symptoms which occur after a lethal dose has been administered. These cerebral effects may be due to a primary action of pulsatilla on the brain, or to the carbonic acid poisoning and the anemia. When the action of the heart and the respiration are very feeble, carbonic acid accumulates in the blood, and an extreme degree of cerebral anemia ensues. Coma, convulsions, and insensibility, are natural effects of these causes." The active element in the production of coma, and convulsions, however, is not so much the accumulation of carbonic acid and the cerebral anemia in themselves, as it is the absence of oxygen, which the accumulation of carbonic acid and the anemia so clearly indicate.

Just how many causes possess these two qualities of producing unconsciousness and convulsion I do not

know, but the one internal cause which in itself will precipitate an ideal epileptic attack, so far as the loss of consciousness, the fall, the cry, and the convulsions are concerned, is the sudden and complete absence of oxygen in the brain, and this, too, no matter how this sudden and complete absence may occur. In my earlier studies I was under the impression that this absence of oxygen in the brain might occur by reason of a vasomotor spasm preventing the flow of blood to the brain. I was led to this conclusion more particularly because I had noticed that a vasomotor spasm did occur at the beginning of the tonic convulsion, and I had not then learned that the unconsciousness and the convulsion were not so nearly simultaneous in point of time as they appeared.

Later investigation has led me to conclude that the vasomotor spasm I had observed was probably a portion of the general tonic convulsion, in which practically every muscle of the body is at least momentarily involved. Further research continues, however, to fortify the theory of asphyxia and to demonstrate the possibility, at least, that the epileptic attack is caused by a loss of oxygen in the brain, and that this loss of oxygen may not be due to vasomotor spasm, but to the destruction of oxygen in the blood cells, or what is still more probable, to the locking up of the oxygen in the form of methemoglobin, thus making it practically unavailable, and producing a condition of complete asphyxia.

The oxygen in oxyhemoglobin can be readily replaced by other gases, or it may be altered in various ways by the introduction of drugs. Carbonic oxid forms with oxyhemoglobin CO hemoglobin, a stable compound, which neither takes up oxygen from the lungs nor gives off oxygen to the tissues. Those poisoned by CO, therefore, die of asphyxia, with attending convulsions. Hydrocyanic acid also forms a compound with hemoglobin, but this is much less stable than that of carbonic oxid.

Methemoglobin is a condition of the blood whereby the oxygen is locked up, or associated so intimately with the hemoglobin as to render it useless for purposes of internal respiration. This compound is not so stable, however, as CO hemoglobin, and the distinguishing peculiarity of methemoglobin is that, while it produces convulsions, it is itself reduced during the asphyxial convulsion and is again converted into oxyhemoglobin upon the reestablishment of respiration. Brunton says: "As the oxygen in methemoglobin is more firmly combined than in oxyhemoglobin the former, when at all pronounced, will cause symptoms of asphyxia; but its action differs from that of CO hemoglobin in one very important particular, viz., that it is altered by asphyxia, while that of carbonic oxid is not. Reducing substances are constantly present in the blood and tissues, and these accumulate to a greater extent during the process of asphyxia. Carbonic oxid hemoglobin, being a stable compound, remains unaffected by these, and the blood continues to circulate unchanged. But methemoglobin becomes reduced by these substances and forms the normal reduced hemoglobin ordinarily present in venous blood. When this reaches the lungs it again takes up oxygen, forming arterial blood, by which the internal respiration is again restored."

Theoretically, this subject of methemoglobin is intensely interesting, for under no other circumstances would we find the whole situation so favorable to the production of just such a condition as exists during the epileptic attack. If the toxin eliminated at this time, which may be referred to as the "cause" of epilepsy, were such as actually to destroy the oxygen then in the blood, the epileptic attack, by its very nature, would only tend to increase the difficulty by preventing respiration, and restoration, if, indeed, it occurred at all, would be a long, slow, and tedious process. If this epileptic toxin, however, simply converts oxyhemoglobin into methemoglobin, not by destroying the oxygen, but by destroying its usefulness only, until by virtue of a

physiologic process, represented by a condition of unconsciousness and a convulsion, this oxygen is again restored to its original integrity, the outlook is very different; especially when the methemoglobinic condition in itself works out its own salvation by precipitating the asphyxial convulsion, by virtue of which the oxygen is released from its bondage and the blood cell resumes its normal condition, until such time as the whole process is to be repeated.

Given a toxin that will convert the oxyhemoglobin in the blood into methemoglobin, and the problem is solved, for from that moment the process of reconstruction is identical with that of the epileptic attack. The methemoglobinic condition renders the oxygen useless, and the result is asphyxia. This asphyxia is introduced by more or less sudden unconsciousness, followed by convulsions. The result of these convulsions is the production of a largely increased amount of reducing substances in the blood and tissues. The effect of these reducing substances is to convert the methemoglobin into reduced hemoglobin, and in this process the locked-up oxygen is released. The situation is thus relieved, and respiration is gradually reestablished. The reduced hemoglobin as it reaches the lungs again takes up all the available oxygen, and this process, if complete and thorough, necessarily restores the patient to his usual condition between attacks.

If, however, the process is not thorough, the restoration will be incomplete; or if the epileptic toxin persists, and each reconstructive period is met by a fresh supply of the poison, the process will be repeated over and over again until the vital processes are exhausted and death ensues. Brunton, in speaking of methemoglobin and the manner of its reduction by means of the asphyxial convulsion, says: "Thus, unless new supplies of the poison are constantly added to the blood, the asphyxia occasioned quickly passes away." He further says:

"Certain drugs when administered to animals or taken by man produce convulsions. The muscular actions which occur in these convulsive movements may be produced by irritation of the motor centers in the spinal cord, the motor centers in the medulla oblongata and pons varolii, or cerebral cortex. These centers may be irritated directly by the action of the drug upon them, or they may be stimulated indirectly by the drug causing the blood in them to become venous through its action on the respiratory or circulatory organs, (or by changes in the blood itself). Convulsions of this sort, although caused by the administration of a poison, are really asphyxial, and are similar in character to those produced by suffocation. * * * Experiments to ascertain whether convulsions are asphyxial or not may be conveniently made upon fowls, for the venous or arterial condition of the blood is readily ascertained by the color of the comb. Thus, in fowls killed by cobra poison, the convulsions come on at the moment the comb becomes livid, and when artificial respiration is begun the convulsions disappear as the comb again regains its normal color."

It has been demonstrated in several instances that this methemoglobinic condition can be produced by the use of drugs, but the question of most interest to us is, whether or not there is any possibility of such a causative element being generated within the body. Is it possible that some active poison, or some half-formed product of metabolism is generated, which is able to convert oxyhemoglobin into methemoglobin and thus precipitate the epileptic attack?

In all nervous disorders heredity must be reckoned with, and this is true in epilepsy. Whether or not heredity plays so important a role as has been ascribed to it by its most valiant supporters is an open question. True it is that heredity can transmit a predisposition to nervous instability, and in this way facilitate the occurrence of convulsive movements, but convulsive movements are only a portion of the epileptic attack. The

convulsion is preceded by unconsciousness, and if unconsciousness precedes the convulsion it must necessarily find its origin elsewhere than in the convulsion. Consequently, while heredity may hand down nervous characteristics which predispose toward the convulsion, it would be difficult to believe that heredity could hand down characteristics predisposing toward unconsciousness, the first symptomatic step in the epileptic attack. If the condition of unconsciousness requires a definite cause, aside from any heredity, for its manifestation, is it unreasonable to believe that the convulsion, the second step in the attack, might also be the result of a definite cause acting independently of heredity? If hereditary influences are present at all is it not more than likely that they manifest themselves along the line of certain perverted functions which give rise to this possible epileptic toxin? Personally I am led to believe that back of the epileptic attack is a toxic condition which, if present in some individuals, not epileptics, would give rise to a symptom-complex identical with that found in epilepsy; and that heredity is indicated in the functional perversion which leads to the production of the prime cause, rather than in the resultant unconsciousness and convulsion.

Investigation, then, for the future should not be devoted exclusively to the convulsive feature of the epileptic attack, as it has been in the past, for when the discovery of the cause of the unconsciousness has been successfully accomplished, the cause of the convulsion will, in all probability, be found to be identical.

A CONTRIBUTION TO THE PHYSIOLOGIC STUDY OF THE NORMOBLASTS.

BY

JULIO F. ARTEAGA, M.D.,
of Havana, Cuba.

From the Laboratory of "Las Animas" Hospital, Havana, Cuba.

Hematologists have studied pretty thoroughly all the elements of the blood, but they have drawn their conclusions in the majority of instances from the study of abnormal blood. It is my purpose to devote some time and thought to the elucidation of the origin and fate of an element of the blood from the standpoint of physiology.

It has been stated repeatedly that nucleated red cells are, when present, abnormal constituents of circulating blood of mammals except the camel.¹ Furthermore, it has been asserted, that only in diseased conditions do we find erythroblasts in the blood-forming organs of the body. Of course, we are all acquainted with the presence of normoblasts and megaloblasts in diseases attended with impoverishment of blood, as in leukemia, chlorosis, pernicious anemias, etc.; but for the same reason that there is such a reaction in the activity of the blood-forming organs, in order to replace the loss of blood-elements, is it not proper to suppose that similar phenomena are going on physiologically, to replace the loss of cellular elements of the blood? That there is such a loss is beyond dispute, first because the blood is a tissue—"a fluid tissue"—and as such, subject to katabolic changes; and second, because all the pigments of the body have their origin in the hemoglobin of the red blood cells. Therefore, if we admit that there is a constant loss of red cells, we must conclude that there is a corresponding building up of new red cells in order to replace those destroyed.

Where and how are the red cells built? Are they originated as such, or are they the descendants of other cells?

It is an accepted theory among many physiologists that the normal red cells of the blood have had, like all other cells of the body, at some time of their individual existence, a nucleus. Some authorities claim that there

are certain organs of the body, which produce normoblasts, and others, nonnucleated red cells; that the spleen is an example of the former, and the liver of the latter. Again, it is claimed,¹ that many red cells which seem to be nonnucleated do have a nucleus, but that on account of the highly colored stroma of the cell it can not be made out, because its index of refraction is almost identical with that of other parts of the cells, and one must have either a well-trained eye to see it unstained, or else resort to staining. It is remarkable that an investigator like Virchow² should deny the cellular nature of the red cell, because of the absence of a nucleus. This is evidently unfair, especially so, when he himself admits that all cells are subject to modifications, even the loss of their nuclei. Indeed, he cites as an example of this the superficial cells of the epidermis, which, on losing the nucleus, die and by desquamation become separated from the body. In other words denucleation may be considered a transitional stage between life and death, and if this is true of the dermal epithelium it should not be less true of the normoblasts.

There are reasons that lead one to believe that the normoblasts are the ancestors of the nonnucleated red cells, although their presence in the normal circulating blood is difficult and unlikely to be made out, as will be explained later on, but this does not alter the fact that they are in the body, at least for weeks and months after birth.

The fact that fetal blood contains both kinds of red cells (nucleated and nonnucleated), seems to confirm this belief.

By actual experiments, I have been able to observe a preponderance of nucleated red cells, over the nonnucleated ones, during the earlier months of intrauterine life, and this preponderance progressively diminishes in the course of embryonic development. Likewise, in the blood of the newborn, there is an abundance of the nucleated variety (but less than in intrauterine life), and as the newborn becomes older, day by day one notices a numerical diminution of normoblasts and a corresponding increase in the number of nonnucleated red cells. If one considers that the liver is an organ whose function during intrauterine life is limited to the production of normoblasts, and that in extrauterine life its hematopoietic function ceases, and it then becomes engaged in the destruction of nonnucleated red cells, and other functions, we may be able to solve this problem.

The newborn needs biliary secretion, which is not available previous to birth; the biliary salts are the results of hepatic functions, and many authors claim that the chemic combination of the salts with certain elements of the blood, brings about the destruction of the red cells, and then by oxidation converts the hemoglobin into hematin and hematin, which is convertible into bilirubin and other pigments. In other words, until the liver has reached its complete development, it can not perform its physiologic functions, but during that period it is a blood-forming organ, whose activity in this respect diminishes directly in proportion to its development. Hence, I believe that the liver in the newborn is not only a nonproducer of normoblasts, and of the nonnucleated red cells, but that it is just the opposite, a destroyer of all those elements.

My experience in regard to the spleen as a blood-forming organ has been rather limited, but my results added to those of others go far in backing my belief, that the spleen is at all ages a hematopoietic organ. The constant presence (in my experiments) of normoblasts in the splenic blood of different animals (dogs, cats, rats, and human beings), is my chief argument for this assertion. Furthermore, splenectomies have shown that the spleen is an important organ in the regeneration of the blood. In Deriouginsky's case,³ for instance, the red cells diminished permanently from 4,700,000 to 4,500,000, but the hemoglobin, although falling at first to 70%, at

the end of a year, it rose again to 98%, probably because other organs compensated for the loss of coloring matter.

It is needless to attempt to show that bone marrow originates normoblasts at any age of the individual, for it has been proved repeatedly.

The claim for the lymphatic glands, so far as hematopoiesis of red cells is concerned, lacks confirmation.

The normoblastic crisis in the blood of anemic patients means a regenerative activity of the blood, and as the patient improves, the normoblasts decrease in number. Really what happens is, that the organism becomes aware of the deficiency of red cells, and sets to work to repair the loss by producing normoblasts, and as the normal number of red cells is obtained, ceases to produce so many normoblasts. But the production goes on, though in smaller degree, in order to replace the nonnucleated red cells, which are constantly destroyed by the liver in its production of bile pigments.

From the foregoing statements I feel justified in saying, that the spleen and the bone marrow are constantly producing normoblasts, but to the human eye this is made evident only when there is considerable loss of red cells, as in anemic conditions.

Naturally, the next question that presents itself is in regard to the denucleation of the normoblast previous to its advent as a normal nonnucleated red cell. I must confess, that in my experiments I have not gone deeply into this matter, and consequently I am unable to state whether karyolysis or karyorrhexis takes place, or whether Ehrlich⁴ is right in saying that the normoblast expels its nucleus, while the megaloblast gets rid of it by degeneration. Cabot⁵ says that at times the nucleus may be seen during expulsion, and may be lobulated, rounded, star-shaped, or in karyokinesis. In some of my preparations (Tables I and III) I have observed similar changes.

My opinion is, that the nucleus during extrauterine life is less resistant, more short-lived, than during embryonic life. Also, that before the red cell leaves the bone marrow or the spleen, it loses the nucleus, and that is why we do not see it in the general circulation, except in very active hematopoiesis, when a few of them escape—the so-called "normoblastic or blood crisis."

A few words as to the technic I have employed in my experiments: By glancing over the tables it will be noticed that I have limited my experiments to dogs, cats, and human beings. Williams⁶ has already experimented with oxen and hogs, and I thought it would be interesting to study the blood of some other mammals in the same manner. I have followed Williams' technic with slight modifications, but was more fortunate, because the autopsies on my animals were made either immediately or shortly after their deaths. As soon as the viscera (liver and spleen) were taken from the body I carefully washed them in running water, avoiding all contamination. Then I cut a piece from each and passed the cut surface over several slides, allowing the preparations to dry, and then proceeded to fix them for one or two minutes with the following formula (Williams'):

Mercuric chlorid.....	78 gm.
Sodium chlorid.....	28 gm.
Distilled water.....	80 cc.
Dissolve and filter.	

At first, I tried alcohol and ether fixation, also heat, but the foregoing method seems to me the best.

The preparations were colored either with Plascencia's* or Romanowsky's stain, but my preference was for a 5% aqueous solution of "hämalaun" (dry) for 30 minutes or less. This was followed by a thorough washing in distilled water, and counterstained with eosin 3% for 2 minutes. Lastly, a final washing and drying.

No coverslide was necessary in examining the preparations by this last method, and in using the immersion lens no damage was done the preparations by coming in contact with the oil.

*Plascencia's stain consists of a saturated aqueous solution of toluidin and eosin 1%.

The objects of all these steps are evident to those acquainted with hematologic examinations. Alterations in the shape, size and color of the cellular constituents of the blood, and all sources of errors are less liable to occur with the foregoing technic. Besides, this

alterations have reference to the spreading of the blood, its fixation, its staining and its microscopic examination. All these points must be borne in mind, lest we mistake certain cells and foreign bodies for nucleated red cells. And again, as Cabot³ has shown, there are normoblasts

stain has the advantage of coloring the nucleus permanently.

The alterations referred to may be natural or artificial; the former may be due to physical or chemic agencies, such as temperature, moisture, presence of some chemic substance on the slide, etc.; the artificial

and megaloblasts, which may be fixed and stained abnormally, and thus assume different shapes and colors.

It must be remembered that the histologic elements of the blood in recently born animals, are so sensitive, that as Hayem⁷ says, they may become altered on coming in contact with the air, etc.

The size and position of the nucleus in relation to that of the cell, does not help us much in determining whether we are looking at a normoblast or not. The nucleus is usually centrally situated, and it is 4 to 5 microns or over half the size of the cell itself. I have found some of them however, in various stages of karyokinesis, and occupying any portion of the cell. A comparison of the stroma of the supposed nucleated red cell, with the nonnucleated, is perhaps, the only positive test. An identity in the color warrants us in considering it normoblast.

As a rule, the nucleus stains rather deeply, on account of a condensation of the nuclear chromatin.

A summary of my experiments is given in the accompanying tables.

My results, therefore, agree with some of the authorities quoted, and seem to support the views I have expressed in this work, as to the origin and fate of the normoblast, and its relation to the spleen and the liver.*

Further research is necessary, however, before we can say positively that the normoblasts are normally present in splenic blood of adult mammals and absent in hepatic blood of the same animals.

My thanks are due to Drs. Guiteras and Lebreto, and Messrs. Taylor and Gros, of this hospital, for valuable aid in the preparation of this work.

THE PUERPERA: HER CARE AND COMFORT DURING CONVALESCENCE, PARTICULARLY THE PREVENTION OF VISCERAL PROLAPSE.†

BY

A. ERNEST GALLANT, M.D.,

of New York City.

Professor of Gynecology, New York School of Clinical Medicine; Assistant Gynecologist, Roosevelt Hospital, Out-patient Department, etc.

As parturition is, or should be the climax of a woman's life, how comes it that the sequels thereof so often leave her in a state of semiinvalidism, for the relief of which she must apply to the gastrologist, gynecologist, or other specialist?

Assuming that we have conducted the labor on strictly "aseptic" principles,¹ and have delivered the child with proper care, with minimum damage to the parturient canal; or, repaired unavoidable damage, administered ergot, nourishment, secured sleep, adjusted the binder, douchaged the breasts, zealously watched the lochia, bandaged intelligently, noted the fundus descend into the pelvis, and permitted the patient to get up the ninth to the fourteenth day; after all this care and solicitation, have we, as obstetricians, done all that can be done to render the puerperium a period of rest and recuperation from which the woman will arise a stronger and happier being, thoroughly capable of nourishing and caring for the infant so recently committed to her care? Or is it owing to our "sins of omission" that the "gynecologist reaps what the obstetrician has sown," and the dread of childbearing arises, which so many women offer as an excuse for their sin of prevention and abortion?

As a rule, when the attending physician has directed the care of the mother in carrying out the foregoing details, unless something unusual intervenes, he will

* Since the foregoing was written, I have found one or two normoblasts in the splenic blood of an adult rat, having failed to find them in its hepatic blood.

† Read before the Medical Association of the Greater City of New York, December 14, 1903.

permit her to get out of bed on or soon after the ninth day, and too often tell her, without examination, that she is all right, and leave her to find out later what having a baby can do, or rather undo, so far as her general health is concerned as compared with her condition before labor.

Why does the woman on first getting out of bed suffer from vertigo, muscular soreness and weakness, inability to walk, and why does she remain a semi-invalid for weeks and months after getting out of bed? Later on, why does she suffer backache, sacral pain, inability to walk or exercise, and fail to enjoy life as was her former habit?

A thoughtful consideration of these symptoms and examination of the patient will demonstrate that she is suffering from (1) actual muscular weakness (atrophy) due to nonuse while confined to bed; (2) well-marked abdominal distention with ptosis of several of the viscera; and (3) uterine displacement with or without a torn or lax perineal floor.

It is to these three points in the care of the puerpera that I wish especially to direct attention.

Posture Postpartum and Uterine Displacement.—After labor the uterus and its ligaments undergo retrogressive changes which eventually reduce it to natural size and position. Unfortunately this does not always take place, for we often find the uterus displaced; later causing backache, dysmenorrhea, menorrhagia, metrorrhagia, miscarriage, etc. How does displacement occur and in what way can we prevent such a distressing result?

To my mind the chief, if not the only factor in the production of postpartum displacement is the faulty position of the woman during her stay in bed. When in the dorsal posture, the heavy uterus falls backward to one or other side of the promontory, and as that organ diminishes in size, of its own weight it is carried downward along the anterior sacral wall (compare Figs. 1, 2, 3); at the same time the ligaments (broad, round, and uterosacral) are shortening, not as they ought to be in order to hold the uterus forward on the bladder, but in such a way as to accommodate their length to the faulty position of the uterus and thus support it in a faulty way.

Postpartum Tamponade.—For the prevention of this undesirable result it is our custom to insist that the puerperal woman must lie, not upon her back, but always upon the right or left side or upon the abdomen, in order to throw the fundus forward against the anterior pelvic wall and thereby compel it to involute in its normal position, that the ligaments may shorten to correspond and afford proper support when the woman gets about again. In most cases we have deemed it necessary after the uterus has descended to the level of the pelvic brim, to elevate the cervix by tamponing the vagina with sterile gauze tampons, changed every 24 or 48 hours, until the uterus has returned to its normal size and maintains its natural position. If the patient suffered from displacement previous to pregnancy, this plan can be put into practice as the best means of preventing

Fig. 1.

Figs. 1, 2, 3.—Postpartum posture in the production of uterine displacements.

Fig. 1.—When erect, the uterus falls forward toward the symphysis and involutes with fundus on the bladder, normal relation.

a recurrence, but it will be advisable after using the gauze tampons for two or three weeks to insert a well-fitting pessary² to be worn for three to six months or longer.

Muscular Soreness After Labor.—If a man, unaccustomed to laborious effort, were called upon to exert himself to the extent involved in bringing forth a child, we would not question his truthfulness if he complained of being sore and tired for a few days after, and would no doubt, prescribe rest and massage for his relief. Yet,

Fig. 2.—When reclining or sitting, the uterus as it enters the pelvis is forced backward against the sacrum, retroversion.

how few women, postpartum receive the same consideration and care.

Muscular Weakness.—It is a well-recognized fact that if a healthy individual be kept in bed for three or more days she will rapidly lose muscular tone and strength, which will require twice as long to regain; yet how few obstetricians and operators look at this matter from this standpoint, and endeavor to get their patients out of bed at an early date. It is a pleasure to learn that so prom-

Fig. 3.—When lying on the back, the uterus of its own weight drops against the sacrum, and contracts in retroversion. N. B.—When the woman lies upon her abdomen or on the right or left side, the uterus falls forward with its fundus over the bladder, as in Fig. 1, involution takes place in normal anteversion.

inent a surgeon as Kocher is a firm believer in the quick restoration to general, guarded activity as a means of local recovery after aseptic surgical work. It will doubtless excite wonderment among the long-term surgeons to learn that Kocher, almost without exception, sends his patients home on the seventh day after operations for hernia and goiter.³ When I was an interne at the Sloane Maternity Hospital, we noted by daily abdominal palpation the height of the fundus uteri, and

whenever that organ had contracted well within the pelvis, whether on the fifth, sixth or seventh days, or later, the patient was permitted to get out of bed; and up to the time of leaving the hospital no ill effects

Fig. 4.

Fig. 6.

Contour of anterior abdominal wall: Normal vs. visceral ptoses. Case 2.—Actual lead-tape outlines. Fig. 4.—Normal, standing, without clothes. Fig. 5.—Abnormal, standing, without clothes. Fig. 6.—Abnormal, standing, with waistband tied. X, shows point of greatest flattening. Z, shows point of greatest protrusion.

were noted, rather the contrary, the earlier out of bed the less weakness and the sooner would the woman regain her former strength.

Abdominal Distention.—The overdistention of the abdominal cavity by the pregnant uterus stretches its muscular and fibrous structures to such an extent that after the uterus has emptied itself the abdominal wall is left very lax and must undergo a process of involution not unlike the uterus, but handicapped, in that its structures do not shorten as readily, and that the intraabdominal pressure strongly tends to prevent its return to its former capacity. Among the every-day manifestations of subinvolution we find a bulging or protrusion of the abdomen from the symphysis to the umbilicus (Figs. 4, 5, 6, 8, Z), and wellmarked epigastric flattening from the latter point up to the xiphoid extremity of the sternum (Figs. 5, 6, 7, X). This abdominal relaxation if neglected will, within a few months, result in a stretching of the visceral attachments with prolapse of the abdominal organs first described by Glénard under the term "enteroptosis;" it involves most commonly the stomach, large and small intestines, and kidneys, but rarely the liver and spleen. Glénard advised the examiner to stand behind the patient, clasp his hands across the abdomen, just above the pubis; exert pressure in an upward and backward direction, thereby lifting the lax abdomen and its contents, and by this means convey to the patient a grateful sense of support and comfort; and at the same time establish the

Fig. 7

Fig. 7.—Lying on back, viscera gravitate upward, abdomen flattened below umbilicus, more prominent above umbilicus, and bulging sidewise.

diagnosis of enteroptosis. This condition, as a sequel to childbed, will induce a state of chronic invalidism pitiful to behold; and the institution of vigorous measures for its prevention is one of our most solemn duties.

Prophylactic Treatment: Massage and Exercises.—During the past five years it has been my custom in obstetric cases to secure the services of a skilled masseuse, or instruct the nurse in charge how to carry out the following prophylactic measures: (a) Beginning the same evening, or shortly after the initial sleep, the body and limbs are thoroughly massaged for half an hour; this is followed by a weak, alcohol-water bath. This removes muscular soreness, stimulates hemic and lymphatic circulation, and quiets a nervous patient to such an extent that she often falls asleep while the operator is still at work. The general massage is repeated, once daily, on the second and third days. On the fourth, fifth, and sixth days, in addition to the massage, the patient is treated to passive motions of all the extremities, and enjoys it thoroughly. As the uterus diminishes in size, especial attention is given to kneading of the abdomen, with the object of promoting contraction and stimulating peristalsis and digestion. On the seventh day and thereafter active, resistant exercises

are begun, and the patient directed to raise the trunk to the vertical plane, unaided by the elbows; next to lift the legs in the same direction; then turn over upon the abdomen and alternately raise the shoulders and legs;

Fig. 8.—Transverse outline, between anterior superior spines (standing).

all with the idea of strengthening the abdominal and dorsal muscles, and reducing the abdominal cavity to its former dimensions. At all times, other than when exercising, the abdomen must be tightly held by a strong muslin binder (Fig. 9, photo), secured in place by perineal straps. If this binder is properly applied and kept in place, it will prevent the accumulation of gas and overdistention of the intestines. If this plan has been faithfully carried out, about the seventh day the patient is measured for one of my specially designed corsets, the measuring, fitting and putting on being accomplished while she is lying upon her back (Fig. 10).

The dorsal posture causes the viscera to gravitate toward the diaphragm, and when the corset is put on while in the semiopisthotonos position, the viscera are held in place and cannot descend, abdominal relaxation and prolapse are prevented, and owing to the peculiar construction of the corset, the stomach and kidneys are supported in their normal relation. Movable kidney cannot occur, and if prolapsed before pregnancy, the wearing of the corset will support it and prevent a recurrence of symptoms referable thereto.

Culisthenics.—As soon as the patient is feeling strong, usually by the seventh day she is instructed in light exercises, such as swinging the arms and legs; when out of bed she swings, sways and flexes the whole body at the hips. It is not necessary to enumerate details of a long series of cases, but for illustration I will outline two which show what can be accomplished by proper care of the puerperal woman and later in life.

CASE I.—Mrs. K., a physician's wife, II-para. Labor began 8 a.m., November 13, 1902, and pains recurred every two minutes, full and strong. At 9 a.m., head in brim, transversely, unflexed, occiput to the left. Digital pressure on forehead caused the occiput to engage and head to flex. With the next pain the head dropped down to the perineum, and was delivered between pains, with slight splitting of the seat of a former laceration. The girl weighed 7 pounds. Labor was completed within two hours after the first pain. After a liberal drink of whisky and 1 dr. of ergot the patient slept soundly. On awakening, a tight abdominal binder was applied and worn continuously while in bed and the two weeks following. Milk and soft diet was given every three hours. On the evening of November 15, she was given:

Extract of hydrastis.....	8.75 cc. (1 dr.)
Fluid extract of cascara.....	8.75 cc. (1 dr.)
Aromatic syrup of rhubarb sufficient to make 15 cc. (½ oz.)	

and the bowels moved nicely the next day. Shortly after the initial sleep she was massaged from head to foot, especial attention being paid to the lumbar region; this relieved the muscular soreness and proved very refreshing. This was repeated daily, and after the third day active and passive motions were carried out. From the eighth day she was drilled in the calisthenic exercises as outlined, and she thoroughly enjoyed them, so much so that she willingly continued to practise daily after getting out of bed. The uterus was reduced to within the pelvis by the seventh day and the vagina packed with sterile gauze, changed every other day for two weeks, when her husband reported the uterus in good position, and that his wife had gotten out of bed in remarkably good condition, was doing splendidly, and for this reason she had neglected to secure the special corset, which on account of previous abdominal laxness I had advised her to put on; but she delayed doing so until six weeks after confinement and was then very much surprised at the marked degree of support and comfort it afforded her. Six months later she informed me that she cannot wear any other style of corset and is free from backache and abdominal weight.

CASE II.—Glénard's Disease in Multipara. Mrs. E. H., aged 50, has had five children, the youngest aged 20; had one miscarriage 13 years ago; menopause, April, 1902. She is a thin, frail woman, much under weight, and complains of pain in the abdomen and back, especially on walking, and inability to do her housework, however light. She is very nervous, easily exhausted, appetite good, bowels move daily.

Examination of abdomen shows outlines (Figs. 5 and 6). Palpation discloses right kidney below the waist line. On percussion, the lower border of the stomach lies near the pelvic brim, with absence of gastric note above the umbilicus. A diagnosis was made of Glénard's disease, due to abdominal relaxation.

Treatment.—April 5, 1903, she was fitted with the special corset.

December 1. She has worn the same corset continuously, and ever since putting it on has been improving in health and strength; can walk, wash, iron, and do her housework without fatigue. Has gained nine pounds, and her whole appearance, especially her face, indicates a decided improvement. She has ordered a new corset, which was fitted by me December 11.

Results.—From the standpoint of an up-to-date obstetrician, it is the duty of all engaged in this line of work to devote more time and careful attention to the local and general condition of the puerperal woman, in order that she may arise from the puerperal bed in every respect a healthy individual, and not a subject for repair at the hands of the gynecologist or other specialist.

In order to accomplish this laudable purpose, it is necessary that following labor, she secure proper rest and

Fig. 9.—Obstetric Binder, as applied at the Sloane Maternity Hospital, New York.

food; that the bowels act freely; that by insisting on the lateral or abdominal posture, avoiding the dorsal position, we encourage the uterus to contract in its normal relation to the bladder; and after the first week by the use of tampons, overcome any tendency to uterine displacement, or prevent its recurrence, if present before pregnancy; and continue the good effect by inserting a pessary, to be worn until assured that the uterus will remain in its proper position.

For the relief of soreness, stiffness, and after-weakness, loss of muscular tone and strength while confined in bed, the prevention of abdominal laxness and subsequent visceral prolapse, the patient must receive general massage for the first three days, massage with passive and active motions the fourth, fifth, and sixth days, and be taught suitable exercises for strengthening the muscles

of the abdomen, back, and extremities during the succeeding days in bed, and practise daily after she is permitted to get out of bed.

The relaxed condition of the abdominal wall demands the constant wearing of a snugly fitting abdominal binder, held in position by perineal straps, as long as confined in bed; to be followed when out of bed by a specially fitted corset, put on while in the dorsal position, and worn continuously when not lying down.

After practising the foregoing plan for several years, it gives me pleasure to assure my confreres that by these

Fig. 10.—Semiprithotonos posture; woman lying on bed, hips raised, causing viscera to gravitate toward the diaphragm, when fastening corset, for the prevention of visceral ptosis after confinement.

means the puerperal period can be converted into a period of pleasant rest and recuperation; uterine involution takes place more quickly, more completely, and in a normal position within the pelvis; abdominal relaxation, visceral ptoses, and pendulous abdomen can be prevented; the patient can get up out of bed without vertigo, distressing weakness and helplessness, can walk about in comfort and without assistance; and with a properly fitting pessary and a properly constructed corset will have good health, nurse her child with good healthy breast milk, and most important of all, will look back on the labor and puerperal period with pleasure and pride, and anticipate future pregnancy without the horror and anguish with which her women friends have so earnestly endeavored to imbue her mind.

FURTHER EXPERIENCES WITH INTRATRACHEAL MEDICATION.*

BY

P. S. DONNELLAN, M.D.,
of Philadelphia.

Laryngologist to St. Agnes' Hospital.

Intratracheal medication is by no means a novel procedure in the treatment of diseases of the respiratory organs, and has occupied the attention of those who have made a special study of these affections during the past 50 years. In 1855 we find that Dr. Horace Green, of New York,¹ injected a solution of silver nitrate into the larynx by means of a rubber tube, a proceeding which was unanimously condemned by the New York Academy of Medicine at the time. Nothing further was heard of this therapeutic measure until two years later,

when Bennett, of Edinburgh,² reported encouraging results in a series of cases of pulmonary tuberculosis in which he used intratracheal medication—the temperature was reduced and a general gain in health was reported in each instance.

Jarrige³ has recorded favorable results from intratracheal medication in cases of pulmonary disease, especially when complicated with fetid and copious expectoration. Similar observations are reported by Stewart,⁴ Clerc,⁵ Botey,⁶ Anderson,⁷ Brancaccio,⁸ Desroches,⁹ and Thompson,¹⁰ for the details of which I refer you to their original articles. Campbell¹¹ has given intratracheal medication an exhaustive trial in a series of cases comprising asthma, bronchitis, bronchorrhea, pulmonary tuberculosis, hemoptysis, and abscess of the lungs. He injected medications into the trachea over 4,000 times with almost invariably beneficial results, even in the inevitably fatal cases of pulmonary tuberculosis; relief from cough, pain, and expectoration was experienced.

McKinney¹² reports uniformly satisfactory results from intratracheal medication in a series of cases ranging from simple bronchitis to early pulmonary tuberculosis.

I have been interested in the subject of intratracheal medication for several years, and reported in a paper read before the Section of Otology and Laryngology of the College of Physicians, of Philadelphia, December 18, 1901, a series of cases of acute and chronic respiratory diseases in which treatment by this method was followed. It seemed to me a much more rational and satisfactory way of dealing with this class of cases than the usual plan of medication by the stomach, which only too frequently disordered the digestion without relieving the pulmonary condition. This is especially true of pulmonary tuberculosis, in which it is of the utmost importance that the strength of the patient be maintained by perfect digestion and assimilation.

In my earlier experiences with intratracheal medication, I used the Muir syringe, but I found that the wide barrel of this instrument obscured the line of vision and that the canula could not be guided into the trachea with certainty. After a series of experiments, I found that an annealed glass syringe with a barrel of two drams capacity, and fitted with an asbestos plunger, was the most practical instrument. The piston of the syringe has a glass ring for the thumb, and to the barrel is attached a revolving metal collar with rings for the insertion of the middle and index fingers of the right hand—a device of much value in steadying the instrument during its use. To the syringe is attached by a screw-thread, a canula of nickel-plated metal; it is bent at a right angle, and has an olive-pointed closed tip, with four fine lateral openings near the end—an advantage over the open tip, which discharged the injection too freely, producing paroxysmal coughing. The entire instrument can be readily sterilized by boiling (see Fig.).

In giving an intratracheal injection the technic I have employed is as follows: The larynx is first anesthetized with a 4% solution of cocain; the syringe is then charged

* Presented at the annual meeting of the Eastern Section of the American Laryngological, Rhinological, and Otological Society, Fall River, Mass., January 30, 1904.

with the selected medication, previously heated to about 102° F., two drams being the amount employed. The patient is instructed to protrude the tongue and to hold its tip in a napkin, while the operator, guided by the laryngeal mirror, inserts the tip of the canula between the vocal cords and, while the patient takes a deep inspiration, the injection is slowly discharged into the trachea. Care must be taken that the fluid does not enter the esophagus instead of the trachea; that the injection is given during inspiration only, and that the tip of the canula is not allowed to touch the fauces, the base of the tongue or the epiglottis.

If these details are faithfully carried out the patient does not experience any unpleasant after-effects, but on the contrary, is impressed with the beneficial results obtained by the injection, which can be felt for several hours over the entire pulmonary area. In many instances I have detected the odor of the medication in the patient's breath 12 hours after the injection was given and have been able to demonstrate to the satisfaction of the patient and the attending physician the presence of the injected fluid in a pulmonary cavity of a tuberculous patient.

In suitable cases the expectoration is diminished, not only in quantity but in viscosity—the latter result being very marked—the heavy, nummular masses of mucopus being replaced by frothy mucus in which the tubercle bacilli are less numerous and are occasionally absent. The injections are given at first daily and then at lengthening intervals as the patient improves.

The vehicles I have found most satisfactory for the injections are any of the fluid petroleum oils. Pure olive oil or distilled glycerin is also excellent for the purpose. Added to these, the medications found most serviceable are creasote, menthol, guaiacol, camphor or chloretone, in 1% to 4% solutions either singly or in combination—the medicament being varied to suit the individual case and other drugs added according to the indications present; thus, when irritable cough was a prominent symptom 8 mg. ($\frac{1}{2}$ gr.) of codein or morphin was added with advantage. Or, when fetid bronchitis was present, 32 mg. ($\frac{1}{2}$ gr.) of iodoform or of potassium permanganate was found to be a useful addition to each injection.

The following brief notes from my case records will indicate a few of the types of cases in which I have found intratracheal medication of service.

CASE I.—H. R., aged 49, male; consulted me in October, 1900, giving a history of constant cough with mucopurulent expectoration, and gradual loss of flesh and strength for about a year previously. His family history was negative as regards tuberculosis. Physical examination revealed abundant moist rales in the larger tubes with prolonged expiration over the entire pulmonary area, but no impaired resonance. His laryngeal mucous membrane was intensely hyperemic and somewhat swollen and his vocal cords were congested. Tubercle bacilli were found in his sputum in large numbers by different competent observers. He had a daily evening rise of temperature about 101°, and a morning subnormal remission. A diagnosis of diffuse pulmonary tuberculosis was made and, as the patient was a man of ample means and abundant common sense, he was frankly told of his condition so as to insure his cooperation in the proposed treatment. He was placed in the best possible hygienic environment, living an open-air life in the suburbs of Philadelphia, and his strength was maintained by generous diet and tonics. He was given a daily intratracheal injection of 7.5 cc. (2 dr.) of a 1% solution of creasote with 2% of menthol in olive oil. At the end of two weeks he began to notice that his cough was decidedly less, that his expectoration had diminished and that his evening temperature rarely exceeded 99.4°. The injections were then given on alternate days for a month and later at weekly intervals for three months. The patient steadily improved in every way and after his return in September, 1901, from a Mediterranean trip, careful examination showed his chest free from rales and his respiratory murmur normal. His expectoration consisted of a frothy mucus from which tubercle bacilli were absent. This patient has continued to improve steadily and is today practically well because of his excellent care of himself. He has not needed any intratracheal treatment for the past three years.

Careful physical examination of his chest in January of this year shows no abnormal conditions. His sputum continues free from tubercle bacilli.

CASE II.—A male, aged 32. Seen in September, 1903, with Dr. John H. Musser, of Philadelphia, who has kindly given me permission to report the case. This patient was far advanced in pulmonary tuberculosis with a large cavity at each apex and extensive tuberculous involvement of his larynx. He expectorated large quantities of mucopus after violent paroxysms of coughing. The prognosis was extremely grave, but it was decided to try the effect of intratracheal medication with the object of making his expectoration less tenacious and of easing his cough. A daily intratracheal injection of 4% creasote-menthol in olive oil was given; to each injection was added .065 gm. (1 gr.) of orthoform. An interesting point in this case was that the presence of the injection in the cavity could be felt by the patient immediately after it was given. Its effect on the character of the expectoration and on the violence of the cough was most gratifying. In a few days his cough disappeared and the expectoration changed from heavy, nummular masses of mucopus to a thin, frothy, mucus-like saliva. This was all we could expect in such a hopeless case.

CASE III.—W. D., male, aged 14. Three years previous to my seeing him in March, 1901, he had measles, complicated by catarrhal bronchitis, which gradually became chronic, with persistent cough and profuse fetid, yellowish expectoration, which resisted all forms of medication by the stomach.

He was given a daily intratracheal injection of 7.5 cc. (2 dr.) of a 2% menthol olive-oil solution, to which was added .13 gm. (2 gr.) of iodoform. At the end of two weeks marked improvement was noticed. The injections were then given every third day for a month and resulted in complete recovery. The cough and expectoration disappeared and a gain of 15 lbs. in weight was noted. I examined this boy in December last and found him in perfect health.

CASE IV.—M. B., female, aged 32. The patient was kindly referred to me by Dr. Joseph O'Malley, of Philadelphia, in September, 1901, with a history of having had paroxysmal attacks of asthma for the previous 18 years. The attacks occurred on an average about six times each year and each lasted about two weeks, although one attack just previous to the first time I saw her lasted about six weeks and was very severe. As no reflex cause of asthma could be discovered in her nose, heart or kidneys, and as there was no history of uterine or ovarian disorder, I considered the case one of true bronchial asthma, with a distinct hereditary history—her mother, her maternal uncle and one brother having suffered from the disease. She was given a daily intratracheal injection of 2% menthol in olive oil. After the second injection, the paroxysms became less violent and in two weeks they ceased altogether. I have kept this patient under observation during the past 2½ years. She has had only two slight paroxysms of asthma in that time, and each was promptly cut short by an intratracheal injection.

CASE V.—M. T., aged 43, female, for many years has been troubled with a hacking cough, which is always worse in cold weather, and has resisted all forms of internal medication. When seen by me for the first time in February, 1901, I found she had a subglottic laryngitis, the hyperemia extending down the trachea as far as could be seen with the laryngeal mirror. Physical examination of her chest revealed nothing abnormal except some moist rales in the larger tubes. Her expectoration, which was slight, consisted of frothy mucus from which tubercle bacilli were absent. I considered the case one of chronic catarrhal cough resulting from subglottic laryngitis and tracheitis. She was given a daily intratracheal injection of 2% menthol in olive oil for a week. Immediate improvement resulted, and the injections were then given every third day for two weeks, at the end of which time it was noticed that the cough had entirely disappeared. She had a slight return of the cough six months later, but it was promptly controlled by an intratracheal injection, and it has not troubled her since that time.

CASE VI.—H. L., aged 70, kindly referred to me in October, 1902, by Dr. John H. Musser, of Philadelphia, with the following history: For the past three years he has had cough with bronchitis and severe paroxysms of asthma which at first occurred on an average of one a month, but now are of almost daily occurrence. He had no family history of asthma. Dr. Musser found extensive emphysema of both lungs with some diffused bronchitis. A daily intratracheal injection of 4% menthol in olive oil was given with gratifying results. The asthmatic attacks were promptly controlled, and the patient expressed himself free from any discomfort in breathing.

He left for his home in the West one month later, and three months afterward he reported to me by mail that he had had no recurrence of the asthmatic attacks.

THE CORRECT TECHNIC FOR PACKING THE URETHRA, IN GONORRHEA, GLEET AND STRICTURE; TWO NEW INSTRUMENTS.

BY

S. T. RUCKER, M.D.,

of Chattanooga, Tenn.

About 15 months ago, I announced to the profession, my method of treating gonorrhea, gleet and stricture, by packing the urethra with a medicated dressing. Since that time I have been more firmly convinced of the virtue of this method of treatment. Besides the uniform good results I have obtained in my own practice, I have been much gratified by receiving many favorable comments from physicians who are equally successful.

It is my purpose in this paper (1) to state as clearly as possible the procedure usually followed in my own practice, and which has proved the most satisfactory; (2) to describe an improved instrument for applying the treatment; (3) to describe a new urethral sound, that I believe to be superior to the ordinary steel sound.

When a patient presents himself for treatment, he is carefully examined to ascertain whether the case is acute or chronic, anterior or posterior gonorrhea, and what complications, if any, exist. This being determined, the patient is made to void the urine, then the urethra is irrigated with a hot solution of potassium permanganate, about 1 to 4,000, (plain water as hot as can be borne may do as well). To lubricate the packer it is dipped in a bottle of the solution used on the dressing, after which the penis is grasped with the fingers of one hand and the packer slowly and carefully introduced into the urethra with the other hand, the patient standing. It is passed back about 4 inches in anterior gonorrhea and back into the prostate gland in posterior gonorrhea and prostatic troubles. Force is never used in introducing the packer. The urethra is then lightly packed with a soft spun cotton cord, saturated with the following solution:

Ichthyol	} of each	3 gm. (40 gr.)
Resorcin		
Balsam Peru	15 cc. (4 dr.)
Sufficient quantity of castor-oil to make	120 cc. (4 oz.)

The instrument is gradually withdrawn from the urethra as the dressing is fed through (see Fig. 1), and when it emerges from the meatus the dressing is clipped with scissors, leaving about a quarter inch on the outside of the meatus. A small piece of lint is placed over the head of the penis, and treatment is complete.

The patient is instructed to go as long as possible before urinating, when the dressing is removed by ballooning the urethra with urine, which floats it out, or it may be removed by taking it between the fingers and making gentle traction. The average patient will go 5 to 8 hours before urinating, without much discomfort. The urethra may be packed at 8 p.m. or 9 p.m., and the patient will retain the dressing all night. Ordinarily I pack the urethra once a day until the discharge ceases, then every other day for 10 days or 2 weeks. In some aggravated cases it is best to pack morning and evening until the discharge ceases. In acute gonorrhea the discharge will stop in 2 to 5 days. Singularly enough, old obstinate, chronic cases yield more promptly than the acute form. In fact, brilliant results are sometimes obtained in this class of cases, the morning drop often disappearing after 1 or 2 applications of the dressing. I have not yet ascertained how soon treatment may be discontinued after cessation of discharge. It is a safe routine to continue treatment every 2 to 3 days for 2 weeks, to keep in touch with the patients and see there is no return of the trouble. In chronic gonorrhea and gleet it is better to pass a sound 2 or 3 times a week prior to packing the urethra. In treating stricture the urethra must first be dilated or divulsed before introducing the dressing. The dressing will allay irritation

following instrumentation, keep the stricture relaxed and overcome the tendency to contract. The physician who is not accustomed to manipulating the urethra and not familiar with the working of the packer may be disappointed in his first attempts at urethral packing. Much less should he expect good results if his technic is so faulty as to cause the urethra to bleed, give excessive pain to the patient, or if the urethra is packed too tight, or instruments are left lying on dusty tables without even being cleaned.

A packer should be selected that can be easily inserted in any part of the urethra, without injury to the mucous membrane. It must first be oiled and then introduced slowly and gently. The dressing must be well saturated with the oil solution and placed lightly in the urethra, when it will cause no discomfort and practically no irritation. The instrument must be washed in soap and water and sterilized after using.

In hospital practice or a large genitourinary practice, in which many patients pass before the physicians at one sitting, great care is necessary to prevent reinfecting a patient, in whom the discharge has ceased, by using a soiled instrument which has just been withdrawn from the penis of a patient with recent gonorrhea taking his first treatments.

With a correct diagnosis and a careful technic in applying this method of treatment, I see no reason why a physician should fail to relieve promptly almost any case of gonorrhea or gleet. The treatment is based on a simple and rational principle. It keeps the walls of the urethra separated, provides for drainage, if any, and

keeps a medicated dressing in constant contact with the affected surface.

The cuts (Nos. 2 to 5) illustrate the improvement I have made in two instruments for urethral work. One of them is a urethral packer, the other a urethral sound. Both are made of glass. The packer, however, is made in different sizes and lengths and can be used as a general gauze carrier, in packing any cavity of the body. Being made of glass, these instruments possess none of the objectionable features of the steel instruments. They can be quickly cleaned and sterilized; they are always smooth, are easily inserted and not liable to injure the mucous surface. Then glass does not look so formidable to patients as the steel instrument and they will submit quicker to its use. The efficiency and durability of both packer and sound will depend largely on the kind of glass they are made of, which should be of the toughest flint glass and without flaw. Both packer and sound can be made with graduated scale to measure depth of insertion. I will not give a detailed description of the packer, as the profession is already familiar with the mechanism of the common gauze carrier and my special design for urethral work; the mechanism of the glass instrument is the same. Fig. 2 shows the glass packer made for use in the urethra or uterus. It is 9 inches long, 7 inches from finger groove to point, size 21 Fr. The barrel is made straight, with point of distal end round and smooth, which facilitates introduction. Two inches from proximal end is a groove for index and second finger.

The piston or feeder is made of steel with forked

point. I have found that a curve to a urethral packer is absolutely useless. A straight instrument can be readily passed into the prostate gland as far back as is necessary to pack the urethra—hence the curve is left off.

Fig. 3 is 6 in. long, 4 in. from finger-groove to point, size 18 Fr. It is for packing the nares, gunshot or stab wounds, and very small urethras.

Fig. 4 is 6 in. long, 4 in. from finger-groove to point, $\frac{1}{2}$ in. in diameter, and is for packing the rectum and vagina. Either sterile gauze strips or a soft spun cotton cord may be used in the packer. The cotton cord is better for urethral work. Fig. 4 will carry gauze 6 in. to 10 in. wide. One of the chief features of the glass

packer is that it can be manipulated with ease in any cavity, and the packing will not clog or hang in the barrel. This is a distinct advantage over any other instrument of the kind.

Fig. 5 shows the urethral sound made of glass, after the pattern of the ordinary steel sound. The sizes run from a 15 to a 32 Fr. scale, and the instrument is straight or curved.

At first thought one may think it dangerous to introduce a glass instrument in the urethra, for fear of being broken off, but if the instrument is made of the toughest glass, without flaw, and reasonable care be exercised in using, the danger of breaking will be extremely small.

Marines Contract Malarial Fever.—Malarial fever has appeared to such an extent in the battalion of marines stationed at the Guantanamo naval base that the Navy Department has ordered that the battalion be removed to the League Island Navy Yard. None of the cases is serious, the naval officers say, but it was deemed wise to take the marines away before the Cuban summer begins. The lack of proper quarters and modern sanitary arrangements is regarded as the cause of the sickness. When these have been installed another battalion will be sent to Guantanamo. Reports to marine headquarters show that the 450 marines on the Isthmus of Panama are in first-class shape. Only 12 men are on the sick list and their complaints are of a minor character.

SPECIAL ARTICLES

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.

Proceedings Reported by the Secretary.

BY

WILLIAM J. GIES, PH.D.,
of New York.

The sixth regular meeting of the Society for Experimental Biology and Medicine was held on the evening of April 20, in the bacteriologic laboratory of the department of pathology of Columbia University, at the College of Physicians and Surgeons. Dr. S. J. Meltzer presided,

MEMBERS PRESENT.—Burton-Opitz, Calkins, Gies, Hiss, Hunt, Jackson, Lee, Levene, Lush, Meltzer, Murlin, Norris, Park, Richards, Wadsworth, Wallace, Wilson, Yatsu.

MEMBERS ELECTED.—J. J. Abel, E. G. Conklin, A. R. Cushny, C. B. Davenport, W. H. Howell, L. B. Mendel, T. H. Morgan, F. G. Novy, W. T. Porter, L. B. Stookey, W. H. Welch.

CONSTITUTIONAL AMENDMENT.—The following amendment was added to the constitution by unanimous vote: "Each nonresident member shall be required to present in person, at least once every two years, a communication containing the results of an experimental investigation, or to send to the president within that time, such a communication for presentation at a regular meeting of the society."

ELIGIBILITY TO MEMBERSHIP.—Many inquiries regarding admission to membership in the society have recently been addressed to the secretary. It seems desirable to state publicly that only *active investigators* in biology or medicine are eligible to membership. The constitution of the society provides for *automatic forfeiture of membership* by any who may cease to be "active investigators, *by experimental methods*, in biology or medicine." Visitors are welcomed to the meetings.

The following reports were made:

ABSTRACTS¹ OF REPORTS ON ORIGINAL INVESTIGATIONS.

"On the secretion of human bile:" P. A. LEVENE, MELVIN, MICHAILEWSKI.

The bile was obtained from a patient with a biliary fistula. The patient had been operated upon for gallstones, and was in comparatively good health at the time of the experiment.

Attention was directed to (1) the influence of diet on the quantity of bile secreted in 24 hours, (2) the permeability of the biliary ducts for certain substances like methylene-blue and sodium salicylate, (3) the influence of these substances and of some salts and acids on the secretion, and (4) on the nature of so-called "bile mucin."

The quantities of bile secreted under different conditions, together with other data, are briefly summarized below:

Diet and dosage.	Volume—24 hours. Centimeters.	Total solids. Percent.	Organic matter. Percent.	Ash. Percent.
Mixed diet	780	1.57	0.76	0.82
Animal diet.....	785	1.88	0.60	1.08
Milk diet.....	845	1.61	0.56	1.05
Vegetable diet.....	835	1.64	0.80	0.84
Sodium carbonate.....	461	1.62	0.71	0.92
Hydrochloric acid.....	461	1.53	1.08	0.45
Calcium chlorid.....	687	1.63	0.56	1.08
Sodium salicylate.....	642	1.40	0.42	0.98
Methylene-blue.....	864	1.53	0.52	1.04

For methylene-blue and sodium salicylate the bile ducts proved less permeable than the kidneys. There was observed a marked increase in secretion after subcutaneous injections of methylene-blue. The "mucin" was found to be a phosphorized proteid, but no purin bases could be detected in its molecule.

"Experiments with certain nitriles and their antidotes:" REID HUNT.

Experiments (carried out in the laboratory of Professor

¹The authors of the reports have furnished the abstracts. The secretary has made only a few abbreviations and minor alterations in them.

Ehrlich) on the toxicity of a number of nitriles, and the antidotal action of certain sulfur compounds toward them, were described. Most of the nitriles studied are poisonous in virtue of the HCN which is split off in the body; in the case of some of the nitriles of the aromatic series and of certain amino nitriles, the molecules themselves seem to be poisonous. Although each of nearly all of the compound studied is capable of splitting off one molecule of HCN, it was found that the toxicity of the various compounds differed greatly. The toxicity depends in general upon the ease with which the HCN is split off; in some cases this seems to bear a relation to the ease with which the residue united to the CN group is oxidized in the body. Benzonitrile, containing the group C_6H_5 , which is oxidized with difficulty in the body, is scarcely more poisonous than phenol. Acetonitrile, also containing a group, CH_3 , which is oxidized with difficulty, is also but slightly toxic. Propionitrile and formaldehydcyanhydrin, which contain easily oxidizable groups, C_2H_5 and CH_2OH , are very poisonous.

The toxicity of the molecules of a few nitriles is greater than that of HCN itself, although the latter was the only toxic agent involved. Thus the molecule of chloralcyanhydrin, $CCl_3CH(OH)CN$, is nearly twice as toxic as that of HCN. The probable explanation of this is that the chloral residue with which the CN is in combination causes the compound to be distributed especially to the central nervous system; the HCN is thus split off in greater concentration in these important organs than is the case after the administration of a compound which is distributed more uniformly to important and unimportant organs. Through the application of this principle it may be possible to modify the distribution in the body of a remedial agent, so that the active principle may be present in especially great concentration in the organs which it is desired to affect. It was suggested that the powerful action of nitroglycerin upon the blood-vessels may be explained on a similar hypothesis. The view of Hay, that the dilation of the bloodvessels caused by nitroglycerin is due to the formation in the body of nitrites from this body, has been generally accepted (although the objection has been made that it requires 200 times as much sodium nitrite to produce a given effect as of nitroglycerin). This criticism may be met by the hypothesis that the glycerin residue of the nitroglycerin causes this compound to be distributed especially to the arterial walls, and that the nitrite will be formed in greatest concentration at the point where it exerts its action.

The work of Heymans and Masdin on the antagonistic action of sodium thiosulfate toward certain nitriles was extended to many new cyanogen compounds. In addition to the thiosulfate, several other compounds, containing a sulfur atom which is easily split off, were tested (the sulfur unites in the body to form a little poisonous sulfocyanate). The most efficient of these new sulfur compounds were thialdin, carbo-thialdin, and potassium xanthogenate. Great differences in the extent of the antidotal action of these bodies toward the various nitriles were noted. Thus thialdin protected against nitriles toward which potassium xanthogenate was without action; toward other nitriles potassium xanthogenate was the more efficacious. Many of these differences can be easily explained on the hypothesis that the various nitriles and sulfur compounds are differently distributed in the body. Unless both the sulfur compound and the nitrile reach the same cells, and unless the conditions in these cells are favorable for the formation of the sulfocyanate, no neutralization will take place.

Especially interesting are the experiments on the antidotal action of alcohol toward certain nitriles. It was found that small doses of alcohol protected an animal against three to five times the fatal dose of acetonitrile and formaldehydcyanhydrin, and that after otherwise fatal doses of these substances, the animal recovered if small doses of alcohol were given. It was suggested that the explanation for this action may be that, because it is easily oxidized, alcohol consumed the oxygen usually available for the oxidation of the CH_3 and CH_2OH groups of these compounds, and for the consequent liberation of the HCN. Support for this hypothesis was found in the fact that dextrose (another easily oxidizable substance) also protects against acetonitrile.

This seems to be the first case in which alcohol has been clearly shown to have an antidotal action toward a poison. It

was suggested that alcohol may have an analogous action in certain pathologic conditions, in which physicians have long claimed a beneficial result from its use. Toward HCN itself, and several other nitriles, alcohol has no antidotal action; in fact, in some cases the toxicity of the nitrile was increased by it.

"Toxicity of certain quinin derivatives:" REID HUNT.

In one of the side chains of the quinin molecule there is, according to the commonly accepted view, a vinyl group— $CH=CH_2$. As the toxicity of many compounds (e. g., neurin and allyl alcohol), is chiefly due to the presence of such a group, experiments were made (in Professor Ehrlich's laboratory) to determine whether this is the case with quinin. A number of derivatives in which the vinyl union was broken by the addition of H (Hydroquinin), or of O and OH (Oxyhydroquinin), or of H and Cl (Hydrochlorquinin), were tested as to their toxicity upon various mammals and certain infusoria. The experiments showed that the presence of the vinyl group in quinin is without special significance as far as toxicity is concerned, the first two of the new compounds being about as poisonous as quinin itself. The results of the experiments with hydrochlorquinin are of special interest; these showed that the addition of H and Cl decreases the toxicity for mammals, while increasing it for infusoria. Thus the amount of hydrochlorquinin required to kill mice was two and a half times as much as that of quinin, while the former substance is distinctly more poisonous to certain infusoria than the latter. It is possible that hydrochlorquinin (or similar compounds) will be found to be more effective in the treatment of malaria than is quinin, and further work along these lines may result in the discovery of quinin derivatives which will be of value in certain diseases, caused by protozoa, in which quinin is of little value. Further experiments are in progress.

"Report on the metabolism of a case of diabetes mellitus:"

A. R. MANDEL and GRAHAM LUSK.

The case was a young man, whose urine contained no albumin, little ammonia, only a small amount of acetone, and no β -oxybutyric acid. All these symptoms are said to justify a favorable prognosis. The patient was put on three different diets for three successive periods: Diet I.—Rich cream, oatmeal, meat, eggs, butter. Diet II.—Same as I, with 100 grams of levulose. Diet III.—Rich cream, meat, and eggs. The oatmeal was used on account of the favorable results obtained by von Noorden.

Diet III was practically a meat-fat diet. Upon this diet the polyuria decreased and the sugar fell from 8% to 4%, both of which phenomena would be favorably interpreted by the clinician. But on calculating the ratio between sugar and nitrogen in the urine (after deducting the sugar bed in the cream), the relation between the two was found to be 3.65 gm. of dextrose to 1 gm. of nitrogen, as follows:

1904.	Dextrose, grams.	Nitrogen, grams.	D. N.
March 2.....	82.7	23.0	3.60:1
March 3.....	87.1	23.8	3.65:1
March 4.....	100.7	27.5	3.66:1

It will be noticed that the sugar and nitrogen rise and fall together. The amount of fat fed varied, but did not affect the ratio. The sugar production is therefore parallel to the proteid metabolism. Since 1 gm. of urinary nitrogen represents the destruction of 6.25 gr. of proteid we can calculate the sugar production from proteid. This D:N ratio is the same as that obtained in our laboratory in phlorhizinized dogs. It has also been obtained by others in the human subject, but has been falsely interpreted as indicating the production of sugar from fat. It represents the maximum output of sugar from proteid and a complete intolerance for carbohydrates. It is probably the most grievous prognostic sign in diabetes.

A calculation shows that the carbohydrates in the oatmeal and levulose were nearly quantitatively eliminated in the urine when the patient was under the influence of Diets I and II.

The patient rapidly lost in weight and died in coma five weeks after the completion of the above investigation.

"Antihemolytic properties of the serum of nephrectomized rabbits." S. J. MELTZER and WILLIAM SALANT.

In studying the properties of the blood of nephrectomized rabbits it was found that bullock's serum, which is distinctly hemolytic for normal rabbit's serum, was less so for the red cells of nephrectomized rabbits. It was found, further, that the serum of nephrectomized rabbits contains a distinct antihemolytic element which is destroyed by heating for an hour at 58° C. On the other hand the "washed" red cells of nephrectomized rabbit's blood are at least no more resistant to the hemolytic influence of bullock's serum than the red cells of normal rabbit's blood.

"On the influence of suprarenal extract upon absorption and elimination, with demonstration." S. J. MELTZER and JOHN AUER.

In a series of experiments it was found that a previous intravenous injection of adrenalin will make a rabbit resistant to a surely fatal dose of strychnin. (Such an experiment was demonstrated to the society.) In experiments with subcutaneous injections of fluorescein it was also found that in the animal which had previously received injections of adrenalin, the greenish-yellow color of the conjunctiva, mucous membranes, and skin appeared much later than in the control animal. Both results might be due to delayed absorption or delayed transudation, or to both. In further studies with subcutaneous injections of fluorescein it was found that the color entered the blood later and in diminished quantity in the adrenalin animal than in the control. Among other observations, it was noted that the kidneys of the control animal were more intensely colored than those of the adrenalin animal. The same difference was found when equal quantities of the stain were injected directly into the blood stream. The lesser coloration of the kidney is therefore due to the diminished elimination by the kidneys in the adrenalin animal. Other related problems are still under consideration. But the reported series of experiments already justify the conclusions that suprarenal extract delays absorption as well as elimination.

The starting point for the investigation was the hypothesis, stated by Dr. Meltzer in another publication, that since capillary endotheliums possess irritability and contractility, their pores are surrounded by rings of contractile protoplasm which act like sphincters upon them, thus increasing and decreasing the permeability of the endotheliums. The explanation for the observed facts is now offered that suprarenal extract, which causes contraction of the smooth muscle-fibers of the arterioles, causes also an increase of the contractility of the endotheliums, diminishing thereby their permeability, and thus reducing their powers of absorption and elimination.

REVIEW.

"Mendel's law." E. B. WILSON. A review of the more important facts in Mendel's observations, together with a statement of some of the deductions to be drawn from them.

Chance for All.—A correspondent sends us a letter from a so-called college in Detroit, which is self explanatory.

Doctor, Being Fin. Sec. of above, from March 1st I desire to inform you we are just now Issuing Honay Degrees to some of our best U. S. &c. Prof. and men up in standing. Knowing of your medical standing and profession if you are of the Desire and looking for LL. D., in Harness, write me Early when I will send you a "Rekord of data" for filling out for the board to pass on, the only exence \$10 for Issue of Same. Waiting a kind reply

I am Dear Doctor

Yours Very Respectfully

E. M. LL. D.

Fin Sec.,

Tramps and Smallpox.—An exchange states that sooner or later legislation will have to settle the question of vagrancy, if only in relation to its malign influence in the spread of communicable diseases. That particular danger has been shown over and over again to exist in the case of smallpox, a disease which, as a rule, can be readily tracked to its original lair. An important contribution to the literature of the subject has recently been made by Dr. Armstrong, the well known Medical Officer of Health for Newcastle-on-Tyne. His communication takes the form of a report based on inquiries addressed to local authorities throughout the kingdom. The answers show that out of 111 districts invaded by smallpox, the disease was introduced in more than 50% by the agency of tramps.

2. A Case of Circular Insanity Studied from Clinical, Differential and Forensic Standpoints. (Concluded.) RICHARD DEWEY.
3. Some Graphic Observations on Ankle-clonus. AUGUSTUS A. ESHNER.
4. Medical Education and Preliminary Requirements. GEORGE H. SIMMONS.
5. Multiple Loose Bodies in the Knee-joint. JOHN PRENTISS LORD.
6. What Should Be the Physician's Position in the Body Politic? H. BERT ELLIS.

1.—Laboratory Aids in Clinical Diagnosis.—C. E. Ruth and A. S. Rider list a long number of diseases in which the laboratory frequently affords a means of exact diagnosis, and yet it is not employed by the average general practitioner. He is too busy; thinks it won't pay, or lacks the taste or opportunity to become skilled in technic. The solution of the problem lies in cooperation. One member of the community can fit a laboratory and become proficient in technic. His neighbors can either share the expense and go there to make their examinations, or what is better perhaps for both, have one with time and taste, do the work for all. The State may eventually place laboratories at the disposal of the general profession outside of cities, but meanwhile the latter must depend on their own efforts to obtain laboratory aid. [H.M.]

2.—Circular Insanity.—R. Dewey reports a case at great length. It is a psychosis with alternating periods of exaltation and depression with normal intervals between. The only question in this case is whether the various cycles could be merely phases associated with paresis. The cases of general paralysis are few in which complete manic depressive cycles occur for three or four years with strict regularity to the number of four or five; in which mental power and brilliancy are retained with accurate memory for recent and remote events with logical cogency, sharp discernment, concentration, and sustained attention. It is of its very essence that a blurring of perceptions and conceptions is present, the will is weak, the delusions inconsistent. In the depressive state there is more confusion and stupidity and hypochondria, less retardation, anxiety, and discomfort. The moral deterioration of this case, change in disposition, and increased irritability might be common to either. The characteristic symptoms of general paralysis were lacking—fibrillary tremors of facial muscles and tongue, speech defects, immobile pupils, implication of cranial nerves, convulsive, spasmodic, or paralytic phenomena, heightened deep reflexes. Evidence of syphilis was lacking. [H.M.]

3.—Graphic Observations of Ankle-clonus.—A. A. Eshner presents a number of observations showing a not inconsiderable variation in the frequency of the movement obtained under different conditions, between 5.8 and 8 to the second. In a healthy person it was from 7 to 7.6 in the second; in a case of hemiplegia it averaged 6.9, in myelitis 6.4 to 8, another case 6 to 8; in compression myelitis 6.2 to 6.7; lateral sclerosis 5.8 to 6.9; and in a case of probable porencephaly 7 to 7.3. In some cases reenforcement was distinctly evident, being appreciable to the examining hand and indicated in the tracings. The failure to demonstrate this with greater constancy might be due to the check by the examining hand or the elastic band used. Ankle-clonus cannot be induced in the usual manner in the healthy, and the movement excited by supporting the weight of the body on the ball of the foot requires in some degree the consent, if not the cooperation of the individual. It is therefore wanting in the significance of true clonus. [H.M.]

4.—Medical Education and Preliminary Requirements.—G. H. Simmons gives statistics showing overcrowding in the profession and the lack of uniformity in the curriculums of medical colleges and in the time and preliminary requirements. After July 1, 1905, the 68 colleges holding membership in the Association of American Medical Colleges must either withdraw or demand as a minimum requirement for matriculation either a diploma from a four-year high or normal school, a bachelor's degree from an approved college or university, or an examination in branches which are specified. Many schools are

not living up to what they claim. In all countries except this, qualifications are passed on by those not connected with the teaching institution. The high school does not provide sufficient mastery of the sciences, while the four years' college course is excessive. The ideal preliminary education is the high school course, followed by two years of electives in a college of liberal arts, devoted to work more or less bearing on, but not necessarily fundamental to, the medical course. This will be demanded by all progressive schools in a few years. [H.M.]

5.—Loose Bodies in the Knee-joint.—J. P. Lord reports a case in which an incision was made as for Volkmann resection. The patella was sawed transversely, the lateral and crucial ligaments divided. Much effort was required to dislodge some of the bodies behind the crucial ligaments, curved scissors being used. Others required scissors on account of pediculated villous attachments. No precedent for this procedure could be found in literature. It has the disadvantage of precluding early resort to manipulation so necessary in restoring function, without the result of separating the delicate union before it is sufficiently strong to withstand forced flexion, but it facilitates extraction, insuring the success of the operation. The loose bodies were evidently developed from hypertrophied villi. [H.M.]

6.—The Physician's Position in the Body Politic.—H. B. Ellis thinks for a physician to neglect personal attention to civic and political problems is selfish and unjustifiable. He should endeavor to raise the standard of health, education, art, and honesty in the region in which he resides. His membership on school boards is an undoubted advantage to the public. The medical inspector should be directly under the school board and not under the Board of Health as the latter reports only about one-seventh of the cases of contagious disease. Every school, college, and university should have competent teachers for a carefully developed course in hygiene. Except in a few States it is impossible for health officers to obtain any preparation for their work except such as they themselves elect. Dealing with disease is more complicated than dealing with crime; 50% of theologic and 20% of law students have an academic degree, while this is the case with only 7% of medical students. The more thorough the doctor's training the better fitted will he be to assume civic obligations. The general average of education has increased faster than the standard in our own profession. Organization is another essential to proper advancement and political recognition. [H.M.]

1. Herter Lectures. Lecture I: Mutual Relations between Toxin and Antitoxin. Abstract. Lecture II: Physical Chemistry vs. Biology in Doctrines of Immunity. Abstract. Lecture III: Cytotoxins and Cytotoxic Immunity. Abstract. PROF. PAUL EHRLICH.
2. Treatment of Prostatic Hypertrophy. Surgical Anatomy of Prostate, L. R. G. CRANDON; Gross Pathology and Mechanism of Prostatic Obstruction, ARTHUR L. CHUTE; Choice of Operation for Prostatic Hypertrophy, F. S. WATSON; Results of Operations upon Prostate, Massachusetts General Hospital, from January 1, 1892, to July 1, 1893, HUGH CABOT; Use of Cystoscope in Determining what Operation is Advisable in Prostatic Hypertrophy, F. C. BALCH; A Brief Review of Present Status of Treatment of Enlarged Prostate, ARTHUR TRACY CABOT; Prostatectomy, Spinal Anesthesia, F. B. LUND.

1.—Herter Lectures.—Mutual Relation between Toxin and Antitoxin.—In lecture I Ehrlich's conclusions are substantially that the immunization industry which has for its aim the production of serums of highest potency, has made marked progress. Serums of much higher antitoxic value than have hitherto been obtained will be the result. The knowledge that the immunity reaction is reduced by too highly toxic treatment of the animals is spreading. An effort is being made to restrict this immune reaction to tissues of slight vital importance (connective tissue) and to protect vital organs from injury. In this direction are the methods of immunization with toxin and antitoxin injected separately or after admixture. Thus an apparently neutralized toxin may cause antitoxin production. This is due to the presence of ultratoxoids. Progress in the production of curative serums is to be expected only when it becomes possible to obtain antitoxins of greater avidity than those now procured. **Physical Chemistry vs.**

Biology in the Doctrine of Immunity.—In lecture II Ehrlich deals with the physicochemic investigations of Arrhenius and Madsen concerning the application of physical chemistry to the study of toxins and antitoxins. Their belief that tetanolyisin is a uniform substance possessing only a weak affinity to its antitoxin and that its neutralization occurs in accordance with the law of Guldberg and Waage. He protests against the attempt of these authors to claim exclusive priority in the development of these questions. The path of biologic investigation—the method of partial neutralization of toxins—followed by them was first opened and by long years of work developed by Ehrlich. **Cytotoxins and Cytotoxic Immunity.**—In lecture III Ehrlich deals with: 1. The controversy over alexins. These, formerly supposed to be simple units, correspond to a very great number of different agglutinins and amboceptors. These normal substances, destructive to the cell, may arise homologically (for example, the collysins), or heterologously (cholera amboceptors in the goat; trypanosomacides of human serum). An aim of therapeutics should be the obtaining in serum not only of complements but especially of the powerfully curative amboceptors of normal organs. 2. Alterations in the receptor apparatus of the blood-corpuscles and their relations to the isolymins. R. Koch's studies of isolymins in coast fever. 3. Determination of philogenetic relationship. Uhlenhuth's and Wassermann's blood test. 4. Relationship between the virulence of bacteria, the receptor apparatus, and the development of immunity (Welch, Walker, Hamburger, Pfeiffer, Wassermann). 5. Practical results from the production of bactericidal serums. [A.B.C.]

2.—Treatment of Prostatic Hypertrophy.—In this symposium papers were presented by L. R. G. Crandon, Arthur L. Chute, F. S. Watson, Hugh Cabot, F. C. Balch, Arthur Tracy Cabot, and F. B. Lund. That by Watson is of special interest, since it deals with the different methods of procedure for the relief of prostatic obstruction and presents results. In 2,678 cases collected from literature wherein some means of relief had to be afforded to the patient, there was a total mortality of 247. In 530 cases of perineal prostatectomy there was an operative mortality of 33, or 6.2%; in 243 suprapubic operations the operative mortality was 22, or 11.3%; and in 1,164 Bottini operations the same was 69, or 6.3%. The following are the contraindications to the employment of the Bottini operation: (1) Inability to obtain a good cystoscopic view of the bladder beforehand; (2) contracted thick-walled bladder; (3) large middle lobe extending far up into the bladder; (4) inability to enter the bladder with the instrument. There is but one obstacle to the performance of the perineal operations. It is the same as 3 under the Bottini operation. That operation is to be preferred which accomplishes the object with the least destruction of tissues, and with the greatest safety to the patient. These ends are best attained by the perineal operations, when done in accordance with their best technic. This is not to say that it is the only operation which should be used. On the contrary, both the suprapubic and the Bottini have a well-defined place. The former is the operation to be preferred in cases in which a very large middle lobe makes the perineal operations especially difficult. The Bottini operation is to be preferred to either of the others if the patient's condition is such as to expose him to the danger of shock or postoperative pulmonary complications. [A.B.C.]

7. The Syrian Climates. HANNA MIKAIL RAHMI.

1.—Part Played by the Tubes in Menstruation.—J. R. Goffe says the dominant factor in menstruation is the ovary and ovulation. From the ovary, or its sympathetic nerve

ganglions in the pelvis and abdomen, there springs the impulse for the reproduction of the species. Menstruation is a retrograde process, the result of a failure of fertilization of the ovum, and the tubal mucous membrane, as well as the endometrium, participates in the process. In support of the view that the tubal mucous membrane participates in the process of menstruation he cites two cases, in the first of which, after the removal of the uterus with one tube and ovary, the left tube and ovary being left in situ, the patient experienced the usual phenomena of menstruation with a slight blood-stained discharge from the vagina lasting for a day or two. Subsequent investigation proved that the discharge came from the tube, the proximal end of which had been drawn down by the gauze in its extraction and had become incarcerated in the vaginal scar. Fearing the possibility of tubal pregnancy he applied stick caustic deep in the opening of the tube until he induced granulation and closure. The second case was similar except that the tube projected fully a quarter of an inch into the vagina and he actually saw the drops of blood issue from the tube, convincing proof that the tube performed the function of menstruation. As in the other case the vaginal opening of the tube was permanently closed through applications of caustic. [W.K.]

2.—Gallstone in the Common Duct.—A. H. Cordier discusses this subject in relation to the tendency of stone to lodge in the common duct, the inflammatory phenomena attending this condition, and the infectious process arising. In regard to operation, he states that he has seen half a pint of muddy-looking bile-stained fluid escape from the common duct into the peritoneal cavity at the time of the operation, but in no case has there been evidence of peritonitis. He relies upon gauze drainage to conduct the escaping bile to outside dressings. Bacteriologic examinations have revealed the colon bacillus in most of the cases at the time of operation. Many cases with latent common duct stones are diagnosed as gastric ulcer, gastralgia, or cancer of pylorus. The injury to the pancreas from gallstones is often of such a character as to retard recovery after the cause has been removed. Interstitial pancreatitis of the duodenal end of the pancreas and pancreatic stone formation and cancer are the most frequent changes induced in this organ. [A.B.O.]

3.—Dentigerous Cysts.—Charles G. Cumston reports several cases, and entering into the pathology of this condition states that Magitot considered every cystic production lined with a membrane and situated in the interior of the jaws as a maxillary cyst. These cysts usually contain a fluid contents varying in nature from one case to another; they may be thin and fluid, or on the other hand, quite thick and pasty. Every cystic production arising spontaneously in the maxilla usually originates from a tooth. Cysts developing spontaneously he termed progenous cysts, and in contrast to these, those developing around a foreign body he termed perigenous cysts. To these two forms which develop in the bone substance he adds a third type, to which he applied the name of neogenous cysts, which develop outside the osseous tissue. Most of the textbooks on surgery are very deficient in explaining the pathology of these cysts, and even commit gruesome errors in their statements. It is an unimpeachable fact that one tissue can only reproduce itself, and consequently epithelium can only be derived from epithelium, and it is also well known that the lining membrane of these cysts is always epithelial and never composed of granulation tissue. [A.B.C.]

4.—Recurring Membranous Stomatitis with Erythema Exudativum Multiforme.—L. E. Blair reports a case of hebra coming primarily or in a freak manner on the mucous membrane of the mouth and contiguous parts followed in severe attacks by the skin eruption. He brings together the different views of writers to show the confusion which exists in the etiology and clinical picture of this disease. In his case the stomatitis existed from four to 10 days before the skin disturbance. Cases which show desquamation are exceedingly rare. In this case the peeling was severe especially on face, hands, feet and abdomen. Eight months later coppery discoloration and scars marked the site of eruptions. Red blotches of new skin are also apparent on violent exercise. [H.M.]

2. Actinic Sunlight in the Treatment of Pulmonary Tuberculosis. J. W. KIME.
3. Epigastric Hernia. CHARLES GREENE CUMSTON.
4. A Plea for the Earlier Diagnosis of Uterine Cancer. F. H. MAIER.
5. Professional Relations, Mutual and Public: A Presidential Address. JOHN H. NEAL.
6. The Hopkins-Folin Method for the Determination of Uric Acid in Urine. W. E. DREYFUS.

2.—Actinic sunlight in the treatment of pulmonary tuberculosis is the subject discussed by J. W. Kime. He believes that the best source of light for use in the treatment of disease. In the treatment of lupus, superficial ulcers, and other chronic skin affections, he uses a lens 15 cm. (6 in.) in diameter, hollow, and backed with blue glass, all so mounted that it may be adjusted to any position. Application of the light is made for an hour or more each day, depending upon the nature of the case. He says the results are such that he does not wish for instruments more complex or complicated or more costly. With a beam of sunshine one foot square falling into the office the instrument is ready for use. In the treatment of pulmonary tuberculosis the light is obtained in the following manner: A concave reflector, three feet in diameter, overlaid with blue glass, focuses a strong blue light upon the surface of the chest, made bare, for two hours each day. Patients thus treated, using, of course, in addition all other adjuvants of known value in the treatment of tuberculosis, respond more quickly. Kime says he is convinced that but few cases in their earlier stages may not be permanently arrested, and that cases, even far advanced, almost immediately begin to show improvement. [C.A.O.]

3.—Epigastric Hernia.—C. G. Cumston reports several cases in detail. Two cases were without doubt the result of a subperitoneal lipoma; two are good illustrations of a preformed defect in the fibrous tissue of the linea alba, one the result of traumatism, and another the result of pregnancy. Cumston says from the cases reported in literature, as well as of those which have come under his personal observation, it would appear fair to assume that the prognosis of epigastric hernia is quite favorable if the disease is discovered in time, and if proper treatment is immediately instituted. The use of the truss is of little value, although by this means suffering may be averted to a certain extent. As in all hernias, the proper way to deal with the epigastric variety is by radical operation. [C.A.O.]

4.—Uterine Cancer.—F. H. Maier says the statistics of the representative gynecologic clinics show that the mortality from carcinoma of the uterus has undergone, and is still undergoing, a relative reduction. This reduction is chiefly the result of the increasing number of cases that are brought to timely operation, and is influenced largely by two highly important factors: (a) The physician; (b) the patient. 1. The earlier a positive diagnosis is made, the better the opportunity for timely operative intervention. The presence or absence of any one of the classic subjective symptoms pointing to carcinoma of the uterus should be utterly disregarded, and the diagnosis based upon objective examinations only. The patient should be impressed with the risk she runs, wherever there is suspicion of malignant disease, in failing to submit to the necessary pelvic examination, as well as with the grave nature of some cases of rapidly advancing carcinoma, which occur in the absence of symptoms indicative to the patient of such a condition. The popular fallacies that "pain" is the most significant symptom, and that pudendal hemorrhage is always physiologic, especially when associated with the menopause, must be dispelled. 2. In the present state of our knowledge of the predisposing and contributing causes of carcinoma of the uterus, we can conservatively accept, in the absence of a more tangible explanation, the view that trauma is often responsible for at least the propagation if not the cause of the disease. 3. The fact that women suffering from the so-called condition of "cancerophobia," are comparatively free from the disease should be regarded not altogether in the light of a coincidence, but rather the relation between this immunity and the constant medical surveillance which the patient is under, should

be considered. 4. In as far as the healthy uterus is less liable to undergo progressive malignant changes, a highly important element in prophylaxis should be to keep the uterine mucosa in as normal condition as possible, and under no circumstances to neglect lacerations, inflammation, and erosions, especially during the menopause. [C.A.O.]

Medical News.

May 7, 1904. [Vol. 84, No. 19.]

1. The Diastolic Murmur in Diagnosis. AUSTIN W. HOLLIS.
2. The Influence of Bovine Tuberculosis on Human Health. MAZYCK P. RAVENEL.
3. Clinical Aspect of Chronic Myocarditis. JOHN W. BELL.
4. Acute Appendicitis and Its Medical Treatment. G. N. BEST.
5. Summary of an Experimental Research Into the Use of Alcohol, Nitroglycerin and Amyl Nitrite in Shock and Collapse, with Illustrative Protocols. GEORGE CRILE.

1.—**Diastolic Murmur in Diagnosis.**—A. W. Hollis discusses in detail the murmurs produced by aortic and pulmonary insufficiency, persistent ductus arteriosus, aneurysms, mitral stenosis, cardiorespiratory influences, pericardial and pleuro-pericardial. The study of the diastolic presents more difficulties than of the systolic murmur. In its usual form it is simple and clear and its mere time and quality reveal the diagnosis, but no murmur can be more elusive in its site and intensity while the possibilities of its character are so numerous that they defy description as well as diagnosis. He records a number of cases illustrating some of the difficulties. [H.M.]

2.—**Influence of Bovine Tuberculosis on Human Health.**—M. P. Ravenel believes in the intercommunicability of human and bovine tuberculosis. The pathogenic action of bovine bacilli in man is shown in laboratory and postmortem inoculations. These prove that the bovine bacillus grows in the human body under the most unfavorable circumstances, producing typical lesions, and that its pathogenic power is as great as the human bacillus under identical circumstances. If we required the same strict methods of examination as to human as we do as to bovine sources of infection in man we would find that the belief that sputum is the general infecting material is supported by very little experimental and no exact clinical evidence. Koch has set up a standard of accuracy which he does not honor himself. Infection through the alimentary canal is not only by way of the intestines, but through the tonsils and upper digestive tract. It has been demonstrated that tubercle bacilli can easily penetrate healthy mucous membrane without leaving any trace. Infected chyle is thrown into the circulation very near the heart, from which it passes at once to the lungs, and disease in the latter from it might seem primary. Numerous observations prove the tonsils may be a port of entry. A commission doing its best to sustain Koch, has had to acknowledge that 25% of the children examined by it show lesions due to bovine infection. Whether the number be large or small, it is our duty to guard against milk from tuberculous cattle. [H.M.]

3.—**Clinical Aspect of Chronic Myocarditis.**—J. W. Bell includes under myocarditis any morbid changes manifesting themselves clinically, the result largely of fibroid or fatty changes in persons at or beyond midlife previously free from valvular disease. Alcohol, tobacco, coffee, gout, syphilis, coronary disease, general arterial fibrosis, chronic renal disease, endo and pericarditis, anemia, phosphorus, etc., are among the causes. Death may occur without symptoms or physical signs. Breathlessness, vertigo, headache, precordial distress, palpitation, and later angina are the common symptoms. The pulse is irregular and sometimes intermittent. Asthma may develop. The impulse in the nipple-line is diffuse. The area of dulness increased, the first sound short and feeble with variable accentuation of the second sound. Early diagnosis is based largely on the state of the vessels and symptoms rather than on evidence of heart changes. Every cause of irritation should be removed. Nutrition should be stimulated by diet, exercise, and regular habits with tonic drugs. In the majority of cases, rest in bed is indicated for the first few weeks. [H.M.]

4.—**Medical vs. Surgical Treatment of Acute Appendicitis.**—G. N. Best discusses this subject from the standpoint of the modern doctor. As a general rule, it is better for the physician, and safer for the patient, to have the appendix removed in

the early stages of the disease. However, operative measures are not always possible nor permissible, in which case medical treatment must be resorted to. Frequently patients will refuse a surgical operation, and in country districts, even when they consent, it frequently happens that a hospital is too far distant and the environment of the patient too uninviting to resort to surgical measures, except as a last procedure. The advocacy on the part of some surgeons that the appendix should be removed in every case so soon as the disease is recognized cannot be accepted by the writer. The mortality of appendicitis under medical treatment is approximately somewhere between 10% and 15%; Dennis places the mortality under surgical treatment at 4%. From this the writer dissents and places it somewhere between 5% and 12%. In medical treatment a thorough evacuation of the bowels is most essential for this purpose; broken doses of calomel, followed by a saline, are best; deodorized tincture of opium internally, with hot or cold applications over the painful region, should be used. Since 30% of patients having one attack of appendicitis have one or more subsequent attacks, the interval operation should be recommended in case operation is not done in the primary attack. [A.B.C.]

5.—**Experimental Research in the use of Alcohol, Nitroglycerin and Amyl Nitrite in Shock and Collapse.**—George Crile gives the results of these experiments, with illustrative protocols. *Alcohol.*—In the experiments the immediate effect of intravenous administration was usually a decline in the blood-pressure. In the majority a compensatory rise followed; in some no change in this respect was noted; in but few was there a rise in the blood-pressure. The average height of pulse-wave was increased. There was no evidence that the heart beat more forcibly. In animals reduced to varying degrees of surgical shock the usual effect of an average dose of alcohol was the production of further depression; in smaller doses but little effect was noted, while in larger doses a more marked decline often occurred. *Nitroglycerin and Amyl Nitrite.*—The immediate effect of nitroglycerin and amyl nitrite upon the pulse was an increase in its volume and a decrease in frequency. The immediate effect upon the respiration varied. The immediate effect upon the blood-pressure in almost every instance was a fall. The decline was usually rapid. A rise in the blood-pressure was rarely observed. In the latter it was but temporary and usually followed by a fall. Compensation usually took place in a few minutes. Each time the doses were repeated the effects were almost as marked as the preceding time, even when the repetitions were at short intervals. Most of the animals tolerated very large repeated doses; excessive doses produced convulsions and respiratory failure. In the experiments in which the animal was in deep shock and the blood-pressure gradually falling, there was no evidence to show any decrease in the rapidity of the decline. On the contrary, as nearly as could be estimated, nitroglycerin distinctly increased the rapidity of the decline. The effect of amyl nitrite was in every respect similar to that of nitroglycerin. In many instances the heart beat irregularly after the injection. On the whole, nitroglycerin and amyl nitrite increased shock. [A.B.C.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

REVIEW OF LITERATURE

Metabolism in Fever.—P. Linser and J. Schmid¹ had the opportunity of making experiments in two cases of universal ichthyosis, in which an increase of the surrounding temperature produced a rise in the body temperature, without sweat secretion. They found that if the body temperature did not exceed 39° C., proteid decomposition did not take place. The latter occurred regularly when the temperature reached 40° or over. Hence, in patients with febrile diseases, having a temperature below 39° to 40°, the nitrogenous decomposition must be wholly due to the infection or intoxication, and not to the rise of temperature, as heretofore assumed. In artificial hyperthermia the administration of carbohydrates did not reduce the nitrogenous destruction to the same extent as during a state of

¹ Deut. Arch. f. Klin. Med., Bd. lxxix, p. 514.

normal temperature. The excretion of purin nitrogen, ammonia, amidoacid nitrogen, and phosphoric acid was increased. Sugar, acetone, diacetic acid, and betaoxybutyric acid albumin were not found in the urine. During a moderate rise in temperature there was a slight increase in the volume of respired air, a considerable (100%) increase in the consumption of oxygen, and a smaller (40%) increase in the production of carbon dioxide. The respiratory quotient was thus diminished. [B.K.]

Recent Cancer Mortality in the Thames Valley.—

Alexander Urquhart¹ presents a series of tables made up of statistics relative to the incidence and mortality of cancer in different parts of England. He states that these statistics justify the conclusions that the Thames Valley is still associated with a relatively high mortality from cancer. All the districts immediately bordering on the river show a rate in the decade 1891-1900 above the average rate for the whole of England, the excess varying from .15% to 2.53%. This uniform high rate along both banks of the river suggests that there may be a connection between the river floods and cancer. If we presume that cancer is a parasitic disease, the drying vegetation on the river banks, after the floods have subsided, may form a favoring nidus for the growth of the parasite. The fact that the majority of the riparian districts show a higher cancer mortality than others seems to support this probable view of parasitic infection. This, however, does not explain the cause of the increase of cancer which is everywhere apparent, but, given the other unknown predisposing factors which lower the vitality of the human organisms to an unresistant degree, we may have along the banks of the river a more or less constant manufacture of the noxious substances ready to attack the already weakened host. He asserts that his facts and figures, taken as a whole, are not only inconsistent with the parasitic theory, but they seem to accord more nearly with the latter hypothesis. [A.B.C.]

GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

REVIEW OF LITERATURE

Carcinoma of the Colon.—H. S. Clogg² bases a most admirable paper upon an analysis of 25 consecutive cases of carcinoma of the colon. The location was: Cecal region, 8; hepatic region, 3; splenic region, 6; sigmoid flexure and upper rectum, 8. The condition is essentially chronic, but acute symptoms may be present when first seen by the surgeon; in 10 cases complete obstruction was present and in 6 cases suppuration had occurred. Regarding diagnosis, Clogg emphasizes the importance of continued pain in the abdomen or slight constipation, associated with decline in health, in persons with no previous abdominal trouble, whose bowels have previously been regular and whose appetite and digestion appear to be in good order. Diarrhea was not noticed in any of the cases and hemorrhage from the rectum occurred in only two. From the findings in these cases, Clogg lays more stress upon glandular involvement than upon dissemination by the blood though the latter is usually claimed to be the great barrier to removal of malignant neoplasms of the colon; glands are usually infiltrated when symptoms are severe enough to bring patients for treatment. A careful operative and postmortem study of the regional glands involved leads to these suggestions for securing them: 1. In cecal growths some inches of ileum with its mesentery should be removed in addition to the greater part of the ascending colon. 2. For growths in the region of the hepatic or splenic flexures, the corresponding halves of the transverse colon and mesocolon should be removed. 3. In rectosigmoid growths practically the whole of the mesosigmoid is to be removed though this means the sacrifice of nearly the whole loop of bowel and, in the majority of cases, an artificial anus. [A.G.E.]

Reflex Disturbances Associated with Adherent Prepuce.—Robert³ T. Simon states that within the last few years he has seen three cases in which the symptoms were due to

adherent prepuce or a narrow urethral meatus, and in none of these cases was there reason to associate the symptoms with any trouble connected with the genital apparatus, and in each instance the diagnosis was made by exclusion. The first was a child of 18 months which suddenly became unable to walk. He dragged one leg and complained of pain in the hip; incipient hip disease was suspected, but this was ruled out. As a last resort the prepuce was examined, found adherent; when the child was circumcised recovery was immediate and complete. The second was that of a boy of 14, who complained of obstinate and severe intestinal colic. Being unrelieved by any form of medication adopted, examination revealed an adherent prepuce which, being relieved, all symptoms disappeared. The third was a boy of 3, who would wake up at night screaming with abdominal pain. Treatment failed until an adherent prepuce and a narrowed meatus were found. These conditions were treated surgically and complete relief was afforded. [A.B.C.]

TREATMENT

SOLOMON SOLIS COHEN

L. F. APPELMAN

E. LINDAUER

REVIEW OF LITERATURE

Treatment of Smallpox by Red Light.—Herbert Peck¹ reports the results of this treatment in 85 cases in three hospitals. There were two deaths, one of an unvaccinated child of 7, giving a mortality among unvaccinated patients of 8.3%; the other was of a debilitated tramp of 50, giving a mortality among vaccinated patients of 1.3%. Disfigurement was less than usual, and the character of the rash was apparently modified for the better. Delirium was, if anything, less frequent than under ordinary treatment. The number of cases is small, but Peck is sure that the results point to the advisability of a more extended trial of the treatment. An accompanying table shows the number of vaccination marks, the age of the patients, the character of the rash, and comparisons with other statistics. [A.G.E.]

Serum Therapy in Scarlatina.—Escherich,² of Vienna, has prepared a serum from streptococci derived from scarlatinous patients, horses being the medium of preparation. In 100 cases he reports a reduction of mortality to half. In spite of its certain value, the serum is of no use to combat local infections, and the secondary septicemia. [T.H.E.]

PATHOLOGY.

J. EDWIN SWEET

EDITORIAL COMMENT

The Etiology and Pathology of Smallpox.—About one year ago the announcement from the Pathologic Laboratory of the Harvard Medical School of the discovery of intracellular and intranuclear bodies in the lesions of smallpox, which bodies were probably to be looked upon as the specific cause of the disease, excited the most widespread interest. This interest can now be satisfied by the study of a collective report of the work of Dr. Councilman and his collaborators, in the February number of *The Journal of Medical Research*. The report fills an unusually large number, comprising about 350 pages, illustrated by numerous microphotographs and drawings. One naturally turns first to the "epicrisis," by Dr. Councilman, the summary of the results obtained and of the discoverer's own views of the entire study. The reader will be impressed by the remarkably modest, sober, and objective manner in which this summary is written. The first paragraph contains the main result of the work: "In the early stage of the specific lesions of the skin and mucous membranes in smallpox, bodies are found which vary in form, structure, and size. We regard these bodies as the parasites causing the disease. They occur within the epithelial cells, within the nuclei, and free. The forms within the nuclei are subsequent

¹ British Medical Journal, April 9, 1904.

² The Practitioner, April, 1904.

³ British Med. Jour., March 12, 1904.

¹ Public Health, April, 1904.

² La Escuela de Med., Mexico, March 31, 1904.

to those which develop within the cytoplasm. They are present in the greatest numbers in cases of the greatest severity and rapidity of course. They do not occur as isolated structures, but one form follows another by gradual transitions, forming a cycle which corresponds with the cycle of development of living things. In the different cases the same forms are found at the same period of the disease. The bodies increase rapidly in the lesions, and the lesion increases in extent by continuous infection of adjoining epithelial cells. The same forms are found in corresponding situations in the lesions of different cases." Several pages are then devoted to the differences between these bodies and the similar products of protoplasmic and nuclear degenerations. This differentiation may be difficult, but distinctive differences do occur which prove that these bodies are neither degeneration products nor artefacts. The absolute proof that they are living bodies has not yet been produced, but the evidence of growth can only lead to the conclusion that they are alive. It is impossible to cultivate the parasite on artificial media, and Koch's postulates cannot be fulfilled; this is also true of other diseases, but the etiologic factor in these diseases is accepted. The inoculation experiments in the ape are very conclusive. Councilman believes that the parasite shows two cycles of development, one represented by the cytoplasmic forms, the other by the intranuclear bodies. In vaccinia, both of the rabbit and the calf, only the cytoplasmic forms are encountered; in variola of man and the monkey, both forms are found. The intranuclear cycle is probably a sexual one. The mode of infection, the character and peculiarities of the eruption, and the role played by bacteria are discussed, and the epicrisis closes with two statements of general practical interest: "The most important and immediate practical result of the work should be the testing of the quality of vaccine virus by rabbit inoculation. As a means of diagnosis in obscure cases of variola, rabbit inoculation may be of great importance." "Smallpox can, but probably never will be, wholly eradicated. The chief obstacle which stands in the way of its eradication is an inability to recognize facts, and to make the proper deductions from them, which seems to be associated with certain orders of mind. The facts with regard to the production of smallpox immunity by vaccinia are perfectly established. The order of mind which leads to their denial will probably never disappear from the human race."

REVIEW OF LITERATURE

The Life-history of Cytoryctes Variolæ, Guarnieri.¹—The details of this study by Dr. G. N. Calkins are of too technical a nature to be reviewed at length here. The study of Councilman's preparations has led Calkins to place the parasite among the myxosporidia. He has further worked out a life-cycle of the sporozoon, which can only be followed satisfactorily with the aid of the diagrammatic scheme. There can be no objection, as Councilman says, to this cycle, yet it seems fair to question the basis for such a detailed life-history. The question of the mode of infection, and the possible role of a secondary host, together with the mode of transmission in the final host, is still entirely unsettled, and so long as these points are undecided, it would appear impossible to construct a true life-cycle for any organism.

The Pathologic Anatomy and Histology of Variola.¹—W. T. Councilman, G. B. Magrath, and W. R. Brinckerhoff. A study of material obtained from 54 autopsies, 37 of which were uncomplicated variola vera, 2 variola vera with hemorrhage, 2 variola vera—abortive, and 6 variola vera with complications; 2 were cases of variola pustulosa hemorrhagica, and 2 of purpura variolosa. The findings are described in detail, under the head of the following organs: Skin, mucous membranes, lungs, liver, spleen, lymph-nodes, bone marrow, testicles and ovaries, kidneys, adrenal glands, pancreas, heart and

arteries. The conclusions from this study cover four pages; possibly the most interesting are that the specific lesion, due to the presence of a parasite peculiar to the disease, is a focal degeneration of stratified epithelium, vacuolar in character, and accompanied by serous exudation and the formation of a reticulum; the occurrence of these lesions is sharply limited to the stratified epithelium of the skin and of the mucous membranes of the soft palate, the pharynx, and the esophagus. Beside the specific lesions, those of undetermined specificity and those due to bacteria may be distinguished. The paper concludes with a discussion of the literature with reference to protozoa and cell inclusions in vaccinia and variola.

On the Occurrence of Cytoryctes Variolæ, Guarnieri, in the Skin of the Monkey Inoculated with Variola Virus.¹—G. B. Magrath and W. R. Brinckerhoff. A study of 12 lesions from six monkeys experimentally inoculated; nine of these were local lesions, three were from animals in which a general exanthem developed. In these experimental lesions structures were found within the epithelial cells which are identical in form and staining reactions with the bodies found in the lesions of smallpox in man.

The Etiology and Pathology of Vaccinia.¹—E. E. Tuzzer. Among the conclusions we note: Cell inclusions of a definite and constant morphology and specific to vaccinia have been found in a large number of experimental vaccinations of rabbits and calves. Inclusions identical in every respect can be produced in the cornea of the rabbit by inoculation of human variola virus. These bodies do not represent cell degenerations, and they cannot be produced by any other process.

On Experimental Variola in the Monkey.¹—G. B. Magrath and W. R. Brinckerhoff. A study of the general reaction, the lesions of the skin, and the leukocytes in variola inoculata of the monkey. The disease follows a typical course with fever, and a polymorphonuclear, followed by a mononuclear leukocytosis. The disease produced in the monkey by inoculation with variola virus is not identical with variola vera in man; it agrees with variola inoculata in man. The lesions contain the specific parasite in the epithelial cells of the skin and the hair follicles. Successful inoculation confers immunity.

The Leukocyte Reaction in Variola.¹—G. B. Magrath, W. R. Brinckerhoff, and I. R. Bancroft. A greater or less degree of leukocytosis is found in all cases of variola. It is characterized by an increase in the mononuclear cell types, though minor variations are due to fluctuations in the absolute number of polymorphonuclear neutrophils. In fatal cases the leukocyte count may be high in the early stage of the eruption, but from then until death steadily falls.

The Infectiousness of the Blood in Variola.¹—G. B. Magrath and W. R. Brinckerhoff. Undetermined bodies were found in the blood of variola patients, in the blood of inoculated monkeys, but also in the blood of healthy men. They are possibly degeneration products. The blood of variola patients does not produce a variolous keratitis, when inoculated upon the cornea of the rabbit.

On the Infectiousness of the Late Stage of the Skin Lesion in Variola.¹—W. R. Brinckerhoff. The contagium is demonstrable in the variola disc, or crust. By appropriate treatment a product can be obtained from the disc in which the contagium is demonstrable, but which is free from bacteria. The contagium does not appear to multiply in fresh rabbit serum or in filtered eye fluid of calves.

The Central Nervous System in Variola.¹—E. E. Southard. The only finding in the nervous system which can be regarded as an essential part of variola is the hemorrhagic tendency sometimes seen in the cortex and cord in variola hemorrhagica. The most constant clinical finding is delirium, which is to be regarded as the delirium of exhaustion.

A Clinical and Experimental Study of the Bacteriolytic Complement of the Blood-serum in Variola.¹—R. L. Thompson. The results corroborate the work of Longcope² on the bacteriolytic complement in other diseases. In variola there is a diminution of complement in the early stages of the disease, followed by a return to normal, unless a secondary

¹ Journal of Medical Research, February, 1904.

² Univ. of Penna. Med. Bull., November, 1902.

¹ Journal of Medical Research, February, 1904.

infection supervenes, when the complement content continues to diminish.

The report concludes with a paper by I. R. Bancroft, "Clinical Observations on Variola."

The So-called Superior Cardia Glands of the Esophagus.—A. Ruckert¹ reviews the literature upon these glandular structures of the esophagus, and describes four instances in older persons, and six cases in the newborn. He concludes that these upper cardia glands are not normal in the human being, and the name is therefore not justifiable. The glandular erosions of the esophagus are due to a disturbance of fetal development. They are a ready cause for the formation of cysts.

The Cerebrospinal Fluid in Tabes.—G. Milian² finds a marked lymphocytosis of the cerebrospinal fluid in 11 of 18 cases of tabes. Mercury has no influence upon it.

Pathogenesis, Prognosis and Therapy of Tabes.—A. Belugou and M. Faure³ find a history of syphilis in 77% of 1,960 cases of tabes. The time between infection and the beginning of tabes varied from a few years to more than 20 years. The writers incline to the opinion that tabes can occur apart from syphilis, and in syphilis it is probably the injurious action of other conditions of life which have affected the nervous system, to which conditions such individuals are more exposed.

Alcoholism and Degeneration.—G. von Bunge⁴ has collected statistics bearing upon the question of why more than half of all the women in the cities of central Europe are not able to nurse their children for nine months or a year. The details of the statistics, covering 1,629 cases, must be referred to in the original. The principal conclusions are that chronic alcoholism of the father is the chief cause of the daughter's inability to nurse her child; and parallel with this inability are other symptoms of hereditary degeneration, especially an increased susceptibility to tuberculosis, nervous diseases, and psychoses. Another symptom of degeneration accompanying the insufficiency of the mammary glands is caries of the teeth. An interesting fact pointed out by v. Bunge is the relatively large number of cases where the eldest of the daughters of habitual drunkards are able to nurse their children, while the younger daughters are not. The possibility suggests itself that the father has gradually undermined his health, and at the time of the begetting of his younger daughters was not in condition to produce normal reproductive elements.

The Blood in General Paralysis and Tabes.—M. Klippel and E. Lefas⁵ find in general no change in the elements of the blood in cases of progressive paralysis. An increase of the neutrophilic leukocytes and later also of the lymphocytes was noted. An interesting observation is the occurrence of numerous nucleated erythrocytes.

Experimental Studies of Syphilis.—Second memoir:⁶ Metchnikoff and Roux⁷ described in a previous paper two successful inoculation experiments into chimpanzees, to which is to be added one by Lassar.⁸ In 12 further experiments with *Macacus* monkeys, Metchnikoff and Roux succeeded in only four cases. These four cases presented slight lesions, such as those described by Nicolle.⁹ The writers are endeavoring to obtain an attenuation of the syphilitic virus by passing it through the *Macacus* species, and eventually other species still less susceptible. The experiments with chimpanzees prove without doubt that the species is susceptible to syphilis, and consequently can be of great service in studying the disease.

Islands of the Mucous Membrane of the Stomach and Glands Similar to the Lower Esophageal Cardia Glands in the Highest Part of the Esophagus.—H. Schridde¹ has studied these islands of tissue by means of their macroscopic staining reaction in a Müller formalin solution, in which the epithelium of the stomach shows a deep brown color, contrasting strongly with the light yellow color of the

esophageal membrane. He concludes that the esophagus is originally lined with an epithelium of entodermal origin, which is later replaced by an ectodermal membrane growing downward from the mouth cavity. These islands represent remains of the original lining membrane.

The Cerebrospinal Fluid in the Secondary Stage of Syphilis.—P. Ravaut¹ found in 26 female patients suffering from papulous exanthema or the pigmented form a considerable increase of lymphocytes in the fluid; of 34 patients who showed no symptoms, or only roseola, only three showed a certain reaction of the meninges. The lymphocytosis does not have constant relation to any of the nervous symptoms but does seem related to the affection of the epidermis.

The Pathology of the Elastic Tissue of the Spleen.—B. Fischer² concludes from his study of 30 spleens that the elastic tissue of the spleen in diseased conditions can either remain passive or be directly destroyed, as in tuberculosis, etc.; in some cases the elastic tissue may disappear from the whole spleen, following extreme stretching of the tissue. A compensatory hypertrophy and simple hyperplasia may occur. A fibroelastic induration occurs in syphilis, etc. An hypertrophy of the elastic tissue surrounding the capillaries occurs frequently in leukemia.

Capsule Formation of *Diplococcus Pneumoniae* in Pure Culture.—M. H. Gordon³ calls attention to the well-known fact that the *diplococcus* of pneumonia grown in pure culture ordinarily does not reveal its capsule. He has lately discovered that the pneumococcus grown upon gelatin at 37° C. forms a capsule which is easily distinguished under the microscope. His directions for securing this result are essentially as follows: The gelatin used is 12% made as follows: One liter of distilled water to 1 lb. of minced beef; boil 30 minutes; filter; add 12% yellow-globe table gelatin; 1% peptone; $\frac{1}{2}$ % salt, make faintly alkaline with liquor potassæ; add white of egg and steam for 30 minutes; filter; pour into tubes; sterilize for 30 minutes on two successive days. A drop of the fluid gelatin culture is removed with a loop and is spread over a cover-glass; dried over the flame; allowed to stand in alcohol for a minute and then, without drying, transferred film downward to a watch-glass containing ordinary Ziehl's carbol fuchsin. The film is allowed to stain in the fuchsin for from a half to three minutes. The cover-glass is then dipped in a beaker of water and, after removal of the moisture, the preparation is mounted on a drop of water on a slide. On examining the specimen with an oil immersion, clearly outlined stain capsule can be seen around many of the diplococci. It is important only to dip the stain cover-glass lightly and rapidly into the beaker of water; if the specimen is washed until all excess of stain is removed the capsules are invisible. [A.B.C.]

Chemical Constitution of the Tubercle Bacillus.—W. Bulloch and J. J. R. Macleod⁴ have studied the chemical constitution of the tubercle bacillus and give in some detail the results obtained from a study of the acid-fast substance of that organism. Several kilograms of bacilli were used—the deposit obtained by filtering autoclaved cultures for the preparation of tuberculin. Their results are contrary to the usual belief that the acid-fast qualities of the bacillus are due to the presence of fat. Large percentages of fatty substances are obtained, but further examination shows that neither the fat nor fatty acids are acid-fast. A pure alcohol was also obtained, and this, when stained by carbol fuchsin, was found to remain unaltered after prolonged immersion in 50% nitric acid, in methyl alcohol and then in alcohol. From this the writers conclude that the acid-fastness and alcohol-fastness of the tubercle bacillus are due to the presence of an alcohol. [A.G.E.]

The Relation of Pathologic Conditions of the Choroid Plexuses to Mental Diseases.—G. Ashton⁵ has based his researches on 50 plexuses, 45 of which were from the insane. The most frequent changes he has found are (1) hyaline degeneration (29 cases) especially affecting the adventitia of the small

arteries, the endothelial cells lining the trabecular spaces and the connective tissue of the villi; (2) increase of fibrous tissue (20 cases); (3) cystic degeneration (17 cases). Mulberry bodies were present in seven cases. Newgrowths are rare, 1,500 postmortems showing none. Changes are most marked in general paralysis of the insane and senile dementia, less so in epileptic insanity, chronic mania, and chronic melancholia, and least in acute insanity. It is impossible to believe that these highly specialized masses of glandular substance, the actual size of which is rarely appreciated, and situated as they are in the very center of the cerebrospinal fluid can exist without having some effect upon the composition of this fluid, and so remotely upon the cells of the brain. As a secondary factor, aggravating the original morbid process in the brain, and retarding or preventing its arrest, these changes may have an influence of the most potent kind. [H.M.]

Etiologic Value of Eosinophiles in Bullous Dermatoses.—La Reed¹ claims that in a large number of these cases there exists an eosinophilia associated with elimination of eosinophiles by the skin. This symptom permits the classification of certain types, and constitutes an essential sign of a condition which should be distinguished as the true pemphigus type of Besnier-Brocq. Lesions of the hematopoietic organs may accompany this disease, and arthritis and osteomalacia may be observed in the foliaceous pemphigus. In those cases in which cutaneous or visceral suppuration is present the eosinophiles may disappear for the time being by reason, perhaps, of the weakness of the hematopoietic organs. La Reed believes that cutaneous eosinophilia is due to the eosinophilia of the blood, in explanation of which, however, he has nothing to offer. [J.H.W.R.]

Bacillus Fusiformis (Vincent-Miller).—G. Angelici² finds its occurrence in man and lower animals. Not growing well alone in culture media, it will live if cocci are added. Acetic acid favorably influences development, but sugars inhibit. *B. fusiformis* is the *B. hostilis* of Seitz. The writer is investigating its relation to various microorganisms with which it will exist and without which it will not; various gastric lesions and other morbid processes throughout the alimentary canal show the presence of *B. fusiformis*. [T.H.E.]

Coagulation of Blood.—This paper, by P. Morawitz,³ is a continuation of the studies reported in the last number of the same periodical. In these last experiments he shows that the blood-platelets contain large quantities of thrombogen. This substance has not yet been found with certainty in any other cellular elements; hence, the view is supported that the blood-platelets are not disintegration products of red or white corpuscles, but are distinct cellular elements. The presence of thrombogen in the platelets would thus account for the previous observations of the influence of large numbers of platelets on the rapidity of coagulation. It has also been observed that in extravascular coagulation of blood, small accumulations of blood-platelets form on the walls of the vessel. The white blood-corpuscles contain very little or no thrombogen. [B.K.]

Embolism of the Sylvian Artery Following Venous Thrombosis of the Leg in a Case of Patulous Foramen Ovale.—P. Hocheisen⁴ reports a case of the sort indicated by the title. The patient was a woman 61 years of age, who, as the autopsy showed, must have had a patulous foramen ovale all her life. She had never had cyanosis. The case is interesting on account of the fact that the embolus was situated in the right Sylvian artery. [D.R.]

Incomplete Coarctation of the Aorta.—G. R. Murray⁵ reports a case of this uncommon lesion that during life was diagnosed aneurysm of the thoracic aorta. The patient, a man of 48, was under observation for four years, previous to which he had suffered from shortness of breath for five years and cough for two years. During part of his stay in the hospital no pulsation could be felt in the abdominal aorta or the femorals. At autopsy the heart was found to be hypertrophied. The vessels arising from the arch of the aorta were much dilated and

had thickened walls. Immediately beyond the origin of the left subclavian artery the aorta was narrowed until it admitted only a body $\frac{1}{8}$ inch in diameter. The actual stricture was short, only $\frac{1}{2}$ inch in length. Beyond this the vessel rapidly expanded. On the proximal side of the stricture was a wide annular calcareous plate. [A.G.E.]

The Toxin of the Chancroid Bacillus.—In a preliminary report S. W. Sowinski¹ says that the diplo-bacillus of Ducrey is beyond doubt the specific cause of chancroid. Pure cultures of these bacilli produce chancroid in man and in animals (rabbits and guineapigs). The toxin of this diplo-bacillus produces local and general effects. Injected into the peritoneal cavity it causes suppuration and often death of the animal; injected beneath the skin, it leads to the formation of an abscess. Freezing of the toxin emulsion and subsequent thawing do not influence its toxic and pyogenic properties. The pyogenic activity is lessened by sterilization. The pus collections of the diplo-bacilli or their toxins have a spontaneous tendency to resolution. The bacilli die rapidly in the animal and human systems, hence they are seldom found in suppurating buboes. The latter cannot, however, be the product of the toxins alone, but the local presence of the diplo-bacillus is necessary to their formation. If the pus of a bubo is injected into animals, no local reaction takes place, owing to the absence of living bacilli, which, as already stated, die rapidly. [L.J.]

The Blood in Pulmonary Tuberculosis.—H. G. Pesel² finds the hemoglobin rate surprisingly high in all stages. Of the cases examined 85.7% had 70% or more hemoglobin. If the rate is low at first it will increase as the patient improves under treatment. The anemia of the tuberculous is frequently more apparent than real. The red cells are generally nearly or quite normal, sometimes abnormally numerous; 61.5% of the writer's cases numbered 5,000,000 or more. These numbers are obtained by the production of many immature and ill-formed corpuscles. Definite poikilocytotic forms were not found. In the majority of cases an increase in leukocytes is present at some stage. There is either a polymorphonuclear increase where the entrance of septic organisms has called forth resistance, or a basophile increase accompanying improvement under nitrogenous diet and hygienic surroundings. These forms may coexist, or the second may follow the first. On looking into each group he finds that when the leukocytes increased after treatment the initial count was not generally high. When they diminished the first count was fairly high in every case. This suggests that the leukocytes increase when their aid is needed and diminish when their protective work is done. The basophile reaction seems to be a useful indicator of progress. [H.M.]

The Agglutination of Staphylococci.—Klopstock and Bockenheimer³ have performed a series of experiments to determine the value of serums as a means of recognition between pathogenic and saprophytic staphylococci, with the following results: A serum produced with pathogenic cocci agglutinated not only the homologous genus, but also most other pathogenic varieties. Pathogenic staphylococci, which a specific serum agglutinated only slightly more than the normal serum of the same animal, are capable of producing a serum which agglutinates them and other pathogenic staphylococci easily. Saprophytic cocci are not agglutinated by a serum produced by pathogenic organisms and they can furnish serum which agglutinates them, but never pathogenic varieties in considerable dilution. Some saprophytic staphylococci do not produce any agglutinating serum. This shows the agglutinating method to be a useful means of differentiation between pathogenic and saprophytic staphylococci. Their method of experimentation is described in detail. They also found that only the pathogenic types were capable of producing hemolysins. The practical value of their experiments is pointed out by them. [B.L.]

Neoplastic Cells in the Blood.—M.M. Leper and Louste⁴ report a study of the blood of patients suffering from lymphadenoma, epithelioma, and sarcoma. From a puncture of the

¹ Journal Med. de Bruxelles, No. 46, 1903.

³ Archiv für Klinische Chirurgie, 1904, lxxii, 325.

⁴ La Semaine Médicale, February 3, 1904.

finger, 20 drops of blood are obtained and put into 15 cc. of 1% acetic acid solution. This mixture is then centrifuged and the sediment examined. In a case of lymphadenoma were found lymphocytes undergoing karyokinesis and from three cases of sarcoma were obtained large sarcoma cells, the latter differing in no way from the cells obtained from the tumor itself. This sarcomatous cythemia will be of diagnostic value if found to be frequent in cases of sarcoma while if it is found only in cases where the tumor has become generalized it will largely determine the prognosis. The blood has been negative in all the cases of epithelioma studied by the writers. [A.G.E.]

Excretion of Soluble Proteids in the Feces.—A. Albu and A. Calvo¹ have examined the feces for albumoses and peptone in health and disease. In healthy breast-fed infants albumin is constantly found, in healthy older children only occasionally. In both classes it occurs constantly when there is intestinal disease. In adults these substances are never found in health, and only in part of the cases of intestinal disease. There are three possible sources for the albumin: (1) Undigested proteids from the food, rapidly excreted by the diarrhea; (2) diminution of the absorptive power of the intestine; (3) products of intestinal inflammation. [B.K.]

The Influence of Radium on Agglutination.—P. P. Jagn² publishes a preliminary report of his experiments with radium. His object was to test the effect of radium on the specific properties of blood-serum in disease. So far only the serum of typhoid fever was tested. In all, 19 experiments have been made, using the radium bromid. It was found: 1. After an exposure of the typhoid blood-serum to the radium salt, lasting two to three days, the serum loses its agglutinating properties entirely. 2. An exposure of shorter duration does not destroy the agglutinating power, though the latter undergoes a considerable reduction. These phenomena the author is inclined to attribute to the so-called B-rays. [L.J.]

The Blood in Epilepsy.—F. S. Pearce and L. N. Boston³ give the results of a study of the blood of epileptics and also the outcome of experiments on animals. The former show that there is in idiopathic epilepsy a fairly wellmarked chlorotic type of anemia. Leukocytosis was present in all but one of the cases, the highest count being 18,000. Differential count of leukocytes revealed nothing of striking interest, the polynuclears being reduced in three cases and myelocytes present in three. The red cells were approximately normal in numbers, showed a moderate degree of poikilocytosis, and, in three cases, punctate basophilia. The results, therefore, gave no conclusive evidence of change *per se* in the cells of the blood of epileptics. The injection into rabbits of the defibrinated blood of epileptics gave rise to blood changes which indicated that a profound toxemia was induced in the animals. No such changes were induced by the blood of healthy students. Marked leukocytosis was caused in some instances but, in contrast to the form observed in septic processes, the true polynuclears were reduced while the eosinophiles were greatly increased. The eosinophilia resembling that seen in persons suffering from parasitic diseases, would suggest more careful observation regarding the possible relation between epilepsy and parasitic infections. [A.G.E.]

Pathology of Latent Malarial Infections Observed at Autopsy.—Charles F. Craig⁴ reports a series of cases in which no parasites were observed in the blood and no symptoms of malaria were detected before death. During the last three years, at the U. S. Hospital in San Francisco there have been seven such cases, in which the autopsy showed latent malarial infection. Three of these had benign tertian infections and four estivoautumnal infections of the tertian type. He first makes reference to the tertian cases, and describes the autopsy findings in the spleen and liver; the spleen was enlarged and otherwise abnormal; microscopically the sinuses and capillaries showed the presence of numerous parasites, infected red cells and pigmented leukocytes. While the infected red cells were not so numerous as in acute infections, still they were plainly noticeable. All the parasites in a particular case were

in about the same stage of development, but it had happened that the patients died at such periods that the entire cycle of the tertian parasite within the body could be worked out from the examination of sections of spleen in the several cases. Microscopically the liver showed congestion, which was venous in character, and sections examined for infected red corpuscles revealed none that were infected. The pathology of the latent estivoautumnal infections was practically the same as in the tertian. The chief point illustrated is that the malarial parasite, either tertian or estivoautumnal may undergo its entire normal human life cycle within the spleen without producing the suspicion of malarial disease and without being found in the peripheral blood. [A.B.C.]

Observations on Phagocytosis and Leukolysis.—F. B. Bukoemski¹ experimented on animals by means of virulent streptococci injected into the peritoneal cavity. He found that phagocytosis of these virulent cocci was clearly pronounced at first, the leukocytes seizing the streptococci very actively. Toward the end of infection phagocytosis becomes weaker, although even after death the peritoneal exudate contains leukocytes which have ingested cocci. After the injection of streptococci a condition of leukopenia is noted in the exudate, and is due to the abundant precipitation of leukocytes on the abdominal organs. During the infection the leukocytes retain their normal appearance. Leukolysis could not be observed. When streptococci are introduced in large quantities they have a markedly destructive effect on the nuclei of the mesenteric endothelial cells. [L.J.]

Substances that Respond to the Test with Acetic Acid and Serve to Differentiate Serous Exudate from a Simple Transudate.—Fabio Rivalta² quotes from several journals, the question having come up first in 1895. A drop of serous exudate let fall into a solution of the acid gives a turbidity due to the presence of two forms of globulin: Euglobulin or paraglobulin, and pseudoglobulin, this containing phosphorus, on account of which it is affected in a different manner from nuclealbumin. In transudates, both the globulins may occur. But their quantities are too small to cause the precipitation in the test as applied. Hofmeister and Wallerstein have carried the separation further. [T.H.E.]

Cells with Eosinophile Granulations.—E. L. Opie³ has made a thorough study of these cells, both as to their normal formation and their occurrence in certain parasitic affections. He maintains that they are derived from large mononuclear cells with eosinophile granulations that are found in the bone marrow. These cells undergo mitotic division and become the eosinophiles found in the blood; eosinophile cells manufactured in the bone marrow reach the tissues by way of the blood-vessels. Opie's second paper gives the results of experiments in which *Trichina spiralis* was fed to guineapigs. He found an increase of the eosinophile cells in the blood comparable to that which accompanies human infection by that parasite. This increase becomes constant at the end of the second week after infection and reaches its maximum at the end of the third week; at this time embryonic trichinas are in process of transmission from the intestinal mucosa by way of the lymphatic vessels and the blood through the lungs to the muscular system. Characteristic changes in the bone marrow accompany the increase of eosinophile cells in the blood, the former being the seat of multiplication of these leukocytes. Before death the number of eosinophiles decreases and infection with a great number of trichinas causes a rapid diminution in those cells; the latter cases prove quickly fatal. [A.G.E.]

The Blood in Malignant Disease.—E. N. Cunliffe⁴ finds that the most constant and characteristic feature is the decrease in the amount of hemoglobin and in the hemoglobin index. Decrease in the number of red cells is usually met with in advanced cases or in those complicated by hemorrhage, but many early cases show no diminution. Leukocytosis is the general rule, but is frequently absent in early cases, and sometimes even in advanced ones. The main factors in causing

leukocytosis are the occurrence of metastases, hemorrhage, cachexia, ulceration, and septic infection. Pyrexia has no apparent influence. The polymorphonuclear neutrophils are usually increased in number. The increase may take place in the absence of any leukocytosis and be a valuable sign of malignant disease. Abnormal cells, normoblasts and myelocytes, may be found in advanced cases. [H.M.]

Characteristics of Human Bile.—T. Kimura¹ has investigated the bile taken from the human gallbladder shortly after death. He finds its pigments to be variable in quantity, being low in tuberculosis and high in conditions of stagnation, such as heart disease. The specific gravity varies from 1.012 to 1.040, and the dry residuum from 2.68% to 20.63%. The relative viscosity varies widely, from 1.46 to 58.24. These factors are all greatly increased in cases of obstruction of the common bile duct. Urobilinogen is found regularly, urobilin very frequently; but both are wanting in cases of complete biliary obstruction, marked diarrhea, and in the newborn. This fact supports the enterogenous theory as to the formation of urobilin. Normal feces contain urobilin regularly, but it is wanting in cases of biliary obstruction. Meconium does not contain any. In a case of obstruction of the cystic duct, a hitherto undescribed brown pigment was found. [B.K.]

Influence of Radium upon Vegetable Organisms.—In view of the increasing interest in radium, the experiments of Dixon and Wigham² on the influence of radium upon vegetable organisms, are of importance. They found that upon seeds and algae the radium emanations had but slight effect. When bacterial cultures were exposed to the rays, however, the growth of the microorganisms was arrested within the area subjected to the emanations. This was not due to destruction of the bacteria in the sterile area, for they could be successfully transplanted to other media. [D.R.]

The Virulence of Human and Bovine Tubercle Bacilli for Guinea-pigs and Rabbits.—M. Dorset³ summarizes the work which has in part appeared in previous medical literature. The experiments are given in detail, a medium consisting of the mixed whites and yolks of hens' eggs being used for the isolation and propagation of all cultures. At least 10 human cultures, of varying virulence, were used. The comparative cultural characteristics and the animal findings are detailed. As a result, it is stated that the following general conclusions seem unavoidable: 1. Certain tubercle bacilli of human origin are indistinguishable either culturally, morphologically, or with regard to their virulence for rabbits and guinea-pigs from certain tubercle bacilli of bovine origin. 2. There is considerable variation in the virulence of human tubercle bacilli for rabbits and guinea-pigs. Dorset believes that in human and bovine tuberculosis we have to do with organisms differing usually in virulence, but between which there is no other essential distinction. He also states that until we know what influence a residence in the human body exerts upon bovine tubercle bacilli we cannot determine accurately the proportion of cases of human tuberculosis that result from infection from cattle. A more detailed study of tubercle bacilli derived from accidental inoculation of men with bovine virus is needed, and also further examination of bovine bacilli derived directly from cattle. [A.G.E.]

Behavior of the Large Mononuclear Leukocytes and the Transitional Forms in Carcinoma Ventriculi.—Kurpjuweit⁴ agrees with others, that the blood picture of carcinoma of the stomach is not uniform. From a study of 10 cases he concludes that the erythrocytes usually diminish in number, the hemoglobin even passing below normal. The leukocytes are usually increased. The relation of leukocytes to erythrocytes averages 1 to 366 instead of 1 to 666. Of mononuclear leukocytes the average percentage was 4.12, one case having as many as 10%, another only 1%. One case pursuing the ordinary course and showing the ordinary blood picture suddenly became worse; six hours before death the mononuclear leukocytes amounted to 33% of the total, the polynuclear to 35%.

the lymphocytes to 32%. The autopsy showed nothing extraordinary; the explanation brought forward is that considerable of the surface of the cancer broke down suddenly, toxins were formed, and changed the complex of the blood picture. [E.L.]

Traumatic Asphyxia.—H. H. Beach and Farrar Cobb¹ report that a man of 30 was caught and held by a moving elevator for three to five minutes; when released his face was black, and blood ran from the nose and mouth, and he was unconscious. The patient was revived, and on the second day, while the discoloration of the face and neck persisted, small portions of skin were removed for microscopic purposes, with a view to throw some light on the much disputed question of the etiology and minute pathology of this rare condition. The discoloration rapidly disappeared after the third day, and the patient recovered. The gross cause of this unusual clinical picture is a forcible compression of the chest extending over some minutes, accompanied by entire cessation of respiration. Knowledge of the pathology has heretofore been obtained from postmortem findings. Pressure asphyxia has been noted in persons pressed to death in struggling crowds. A report from Dr. Wright, who examined the specimens of skin, shows every section to be normal skin; there was no sign of blood in the tissue outside of the bloodvessels. This agreed with the provisional diagnosis, the authors regarding the discoloration as due to stasis from mechanical overdistention of the veins and capillaries, with or without paralysis from engorgement of or pressure on sympathetic nerves. Six other cases are collected and reported from the literature. [A.B.C.]

Cyodiagnostic Investigations of the Cerebrospinal Liquor.—Ernest Meyer² says his examination of 35 cases corroborate the views held by the French, that lymphocytes are present in the cerebrospinal fluid of chronic meningitis associated with organic disease. The absence of lymphocytes does not indicate that meningitis does not exist, but their presence is of great diagnostic value. Seventeen of his 35 were cases of functional disease, only one of which presented paralysis; in these series lymphocytes were absent. The aid that cyodiagnosis gives in differentiating functional from organic diseases needs no further elucidation; since many cases of paralysis develop slowly, Meyer believes the value of this method of diagnosis can be estimated only by repeated examinations. [J.F.]

The Pathology of Hemophilia.—W. A. Geier³ had occasion to make a thorough study of the blood and organs of a hemophiliac who died from the bleeding following an operation. As a result of his studies the author arrives at the conviction that the cause of hemophilia will be found in an abnormal condition of the blood, which contains cytoglobulin, a product of the destruction of the red cells and their nuclei. This destruction takes place in normal blood as well, but very slowly, and no excess of cytoglobulin is accumulated. In the hemophiliac this process is very rapid. A second important factor is the thinness of the vessel walls, their muscular poverty and inability to contract firmly. The frequency of bleeding into joints in hemophilia is explained by the liability of the joints to traumatic injuries, resulting in rupture of the friable vessels. [L.J.]

Congenital Absence of the Common Bile Duct.—G. D. Menzies⁴ cites the case of a female infant, apparently healthy at birth, in whom the skin and conjunctivas became yellow on the third day; the urine was bile-stained from birth. The feces were chalky white, but constipation was never present. The child thrived for five weeks, then became thin and asthenic and died at the age of five months without having developed special symptoms. Autopsy showed the internal organs to be bile-stained and the presence of several ounces of bile-stained fluid in the peritoneal cavity. The gallbladder was empty and unstained; the cystic duct ended in a culdesac; there was no common duct; the hepatic duct was dilated and full of bile. The liver was small, hard, dark-green in color and microscopically showed a moderate interlobular cirrhosis. [A.G.E.]

A great agency in the people's hygienic education is the sanitary bulletins and reports of city and State Boards of Health. According to the character of the individual men, or perhaps individual man, of these boards, will, of course, depend the character of these bulletins. Some will be scientific, and even ultrascientific, seeking only to stimulate original research and the sources which ultimately make and mold popular opinion. They have, to be sure, their place and proper function, but one cannot help being interested in those which aim directly at the education of the common people in sanitary affairs and health preservation. These should be widely distributed and it would be money saved if the local city, town, or State would appropriate the money to send the reports to every taxpayer in the district concerned. Such documents may well keep in mind the statistics and purely scientific aspects of reform, if mixed in judicious proportion with food better fitted for popular consumption—predigested as it were. It should not be forgotten that our scientific knowledge of preventive medicine is a long way in advance of the real possibility of lessening the deathrate, if the well-understood scientific laws were put in practice. Most commendable in the respect suggested is the admirable *Monthly Bulletin of the Indiana State Board of Health*. Every State should send such a monthly missionary tract to its householders.

Passenger Car Ventilation.—Who has not suffered from overheating, underheating, and ill ventilation of railway cars? It is strange that the abuse has been so long tolerated. The Pennsylvania Railroad Company, according to Dr. Charles B. Dudley, of Altoona, Pa., has grappled with the problem, and if there is not satisfaction on the part of the travelers in the future it will be their own fault, either in not complaining to the officers in charge of the installed ventilating devices, or to the higher officers of companies who have been negligent of the health of their patrons. The system of the Pennsylvania Company consists in taking air from the outside in through hoods covered with wire gauze to exclude coarse cinders, situated at diagonally opposite corners of the car, on what is known as the lower deck, near the top of the car. Thence the air passes through a vertical down-take through the floor to a space underneath the floor, which is bounded by the outside sill, the floor, the

first intermediate sill, and the false bottom. This space underneath the floor reaches the whole length of the car. From this space the air passes up through the floor, by means of slots in the floor, into the heater boxes; where the air is warmed by the radiators. From the heater boxes the air passes out through a proper tubular aperture, situated underneath each seat, into the main aisle, from which point it distributes itself throughout the car, and finally passes out of the car through ventilators situated along the center line of the upper deck, which ventilators are so arranged that when the car is in motion, or the wind blows across the top of the car, they produce a suction on the car, helping to exhaust the foul air. The amount of air taken through the car by the system when all the ventilators are open is about 60,000 cubic feet per hour, or approximately 1,000 cubic feet of fresh air per passenger. A passenger coach embraces about 4,000 cubic feet of space, so that the air in the car is changed 15 times an hour. Methods of compensating for differences when the car is in motion or still, have been devised. Have any other companies shown the enterprise of the Pennsylvania Company? The Pullman Company has not.

Superfluous Medical Societies.—Much has been written in recent years upon the excessive number of medical societies. The recent movement for the reorganization of medical societies has had a favorable effect in diminishing the chances for new societies. There yet exist, however, a number of organizations whose members should consider carefully as to whether the profession would not be much benefited by their extinction. There are also other societies that make a good showing on paper that have no members at all—that is, none that have paid dues or otherwise complied with the requirements of membership. These exist because the private gain of some one—usually a layman—is thereby favored. One society which nominally has a national scope has all its meeting expenses paid by a layman who owns the journal that publishes its transactions. Its meetings are attended by a handful, and a few papers are read. Officers are elected by those who pay no dues, the "slate" being fixed in advance by the layman who "pays the freight." Honored names are borrowed to head the list of officers, but their possessors are absent from the meetings. The official organ has a

large circulation of the mailing list sort—no subscriptions being paid. Its pages are filled with the articles read at the annual meetings and, in yet larger proportion, with paid-for "puffs" and "write-ups" of proprietaries that are advertised in its columns. Conducted in this way the journal is a "good thing" for its lay owner. One might be surprised at so many doctors lending themselves gratuitously for the profit of a layman, but in this case the loan was a forced one. The "members" of the society and the "subscribers" to the magazine, both were drafted from the ranks in almost all instances wholly without the knowledge of those levied on. The very impertinence of the scheme commands some admiration for the promoter. How much good might come from such talent properly directed! The practical result is the obvious conclusion that, as the "scheme" is no longer a secret, the nominal "members" should either forbid the unauthorized use of their names, or else attend the meeting and capture their own society. Having elected their own officers the members might then pay their own bills, decide where their papers shall be published, and put such checks about their "official organ" as will prevent its moral standing continuing to be a by-word among journalists, and among doctors.

A fallacy in the statistics of typhoid fever, and one well understood by physicians, is in the nonreporting of cases. The facts are so little understood by the laity and by some newspapers that the fallacy is supposed to consist in exaggeration. But, in fact, the fallacy is almost always in an underestimation of the number of cases. One cause of the misunderstanding is clearly set forth in a leader of our contemporary *The Cleveland Medical Journal*. In Cleveland the only cases of typhoid fever of which the Board of Health takes cognizance are those entered in the "contagious disease book," and none are so entered on the basis of blood sent to the city laboratory, whether the findings of the laboratory are positive or negative, but only upon the receipt of an independent report by the physician in charge of the case. In an investigation of this subject covering the months of January and February, it was noted that a number of physicians who were known to have had cases of typhoid fever during the period covered by the investigation had reported no cases to the Health Office. Other physicians volunteered the information that they had treated additional cases which they had not reported. Of 100 cases from which physicians sent blood to the city laboratory and received a report that the Widal was negative, 47 ran a typical typhoid course, but none were reported as typhoid fever. In January and February 184 specimens of blood from 178 to 180 patients were sent to the city laboratory; 43 of these, or 25%, had a positive Widal, but only 12 were reported as cases of typhoid fever. This indicates a total number of 31 cases of typhoid fever, as determined by the presence of the Widal reaction, which were not reported to the city, and a further number of 63 (47% of 135 patients for whom the Widal reaction was reported negative) who might justly be counted as having had typhoid fever from the further clinical course of the disease, or a

total of 94, being 15% of the 612 cases reported to the city in January and February as having the disease. The conservatism of physicians in reporting cases of typhoid fever is indicated by the fact that of 92 cases reported in January the subsequent course of the disease warranted the diagnosis, according to the statement of the attending physician in all but one case. The *Journal* says:

It is quite impossible to determine just how many cases of typhoid fever there are in the city at any time. In view of the failure on the part of physicians to report all of their cases it is undoubtedly true that the total number is decidedly larger than the number reported, even after making allowance for errors. From a comparison of the number of deaths from typhoid fever and the number of cases reported, and as well as from the facts given above, it seems unlikely that these reports have ever been more than half to two-thirds of the actual number of cases in the city.

"The Sanitary Condition of Guayaquil and Vicinity" is the title of an admirable study by Acting Assistant Surgeon Gruner in *Public Health Reports*. The certainty of the completion of the isthmian canal gives to Guayaquil a position, from a sanitary standpoint, not possessed a few years ago. The city becomes an important factor in all that concerns the sanitation of the canal zone. Its commercial importance, which brings it in frequent communication with the Isthmus, only 700 miles distant, is already great and with the opening of the canal will rank of first importance among the cities on the Pacific side of South America, among which it now ranks third, after Valparaiso and Callao. In Guayaquil, Dr. Gruner says that no mosquito screens are used in the hospitals, a fact that may excuse the editor of *Baedeker's Italy* for still advising that windows must be closed at night. The Board of Health of Guayaquil has almost no funds at its disposal; if it had power it would be reasonably prompt to undertake reforms of existing abuses. The vital statistics are comparatively worthless; only deaths are reported. If the preventable diseases were really prevented, the conditions would not be worse than in other tropical cities. As to what should be done, Dr. Gruner recommends the enactment and enforcement of rigid sanitary regulations; sewer the city; fill the low streets and lots; drain and fill the swamps at the city's edge; establish a quarantine station at the entrance to the Guayas River. The history of yellow fever in Ecuador proves conclusively that it is Guayaquil from which the infection spreads to the surrounding territory because of the intimate communication between these places. The same observation would hold in all other infections. Therefore to establish such a station is an essential part of any intelligent sanitary effort.

Pavilion F, Albany Hospital.—One year ago we had occasion to comment favorably on the results of the first year's work of the Department for Mental Diseases in the Albany Hospital. The second annual report¹ shows a continuance of the satisfactory conditions that obtained during the first year. The whole number of patients under treatment during the year was 171; of the 157 discharged,

¹Albany Medical Annals, May, 1904.

51 had recovered and 43 were improved. During the two years 65% of the discharged patients had recovered or were improved. The pavilion has been enlarged and now has 33 beds. In common with other departments of the hospital it has been opened to the students of the Albany Medical College for instruction in mental diseases. All nurses of the hospital are required to spend several weeks in the mental wards before their graduation and in addition are given lectures on the care of these patients. The department is no longer an experiment; it is a decided success. Authorities of general hospitals who are considering the advisability of setting aside a ward for the treatment of acute mental cases can do no better than study the statistics of Pavilion F. The two years of its existence have proved conclusively that a ward for mental diseases can be successfully and profitably maintained in a general hospital; we mean with profit to the patients, not necessarily from a financial standpoint. The authorities of the hospital are to be congratulated upon the fact that they have not only not sought but have declined any power which would put the Department for Mental Diseases on the footing of an institution for the insane. We trust that many institutions will shortly see their way clear to profit by this demonstration of the Albany Hospital.

The Water-supply of Cities.—The profession in Cleveland, and especially the alert editors and collaborators of the *Cleveland Medical Journal*, have shown an exemplary enterprise in arousing the attention of the cities about the Great Lakes as to the local water-supply. Studies like those of Dr. Handerson on Cleveland's water-supply should be made by those connected with the health bureaus of every city. The typhoid mortality of Cleveland has averaged nearly 50 per 100,000 of the city's population for the 30 years since the opening of the Health Office. These figures indicate how great has been the need of an improved water-supply for Cleveland. From the experience of other cities it is certain that an improvement of any account in the character of the municipal water shows at once in a diminution of the number of cases of and deaths from typhoid fever. It is, therefore, presumably true that the water from the new intake will give a lower typhoid mortality, and that conditions will be still better when the city mains and the new tunnel are thoroughly cleaned out. The *Cleveland Medical Journal* says:

While the exact character of the water at the new intake is unknown, a consideration of the typhoid mortalities of other cities along the Great Lakes may incline us to the opinion that a moderate pollution is to be expected at all times. Further, in the sand from the bottom of the lake near Cleveland it is probable that bacterial evidence of sewage pollution could be found if any search was made for it, since the colon bacillus has been isolated from similar sand taken from the lake near Buffalo at a point where contamination by Buffalo's sewage was considered impossible. The water from the new intake, therefore, may become dangerous in times of storm and flood. Ten or eleven of the 132 cities of the United States with a population of 30,000 or over take their drinking water from and deposit their sewage into the Great Lakes. Of these, Detroit, the ninth in the list, had the smallest average mortality in the years 1898 to 1901, 18 per 100,000; Milwaukee came next, the thirteenth on the list, with a mortality of 19; Buffalo is number

48 in the list, with a mortality of 27; Chicago, number 51, with 28; Cleveland, 83, with 39; Duluth, 120, with 65. If our suggestion is reasonable, that a typhoid mortality above 10 per 100,000 of the population of any municipality indicates a polluted water, then it would seem, on a consideration of these figures, that the burden of proof must lie with anyone who wishes to argue that Cleveland, even after the completion of the improvements planned, or, indeed, any other city taking its water from the Great Lakes, will have an unpolluted water-supply.

Stature and efficiency, at least of a military kind, is having new light thrown upon it by the events of the Russo-Japanese war. For several years there has been much newspaper and magazine discussion, with great bemoaning of the fact that the national stature, as shown in examinations of military recruits, has been deteriorating. In England, *e. g.*, the demands have been repeatedly reduced until even with the present minimal requirements it is possible to get volunteers only of the smallest men with the greatest difficulty. Even compulsory military service is seriously considered. But is it not, after all, a blunder—this admiration for mere size, and depreciation of the little man? All little men will certainly agree that it is so. But does not history and evolution prove it? Is not every step in the progress of civilization epitomized in the fact of the control of external mechanical forces by man's intelligence rather than the increase of his own bodily forces? Did anything come of the Prussian folly of regiments of seven footers? In the American Civil war the most enduring men and the best marchers were of small stature. A French count has left a legacy whereby under the supervision of the municipality of Rouen an institute for rearing giants is to be established. The trustees are to search the world for men and women of large stature, and are to pair them off in couples, place them in homes upon a farm, and allow them to breed like horses and cattle, expecting that the next generation will surpass them in stature and physical strength. Would these giants not be at a positive disadvantage in the national or social struggle for existence? The Russian peasant is certainly taller and of greater bulk than the Japanese. As our American philosopher puts it:

If I'm not so large as you
You are not so small as I,
And not half so spry.
Talents differ; . . .
If I cannot carry forests on my back,
Neither can you crack a nut.

Cure by "Operation Per Se."—Some time ago in one of our eastern hospitals a patient was "possessed" by the belief that he had a "worm in his leg." To be rid of the man's importunities, he was operated upon, and before his eyes a leech was extracted from the ailing spot. From the West now comes the (newspaper) story, possibly true, of another, also a hospital case, in which the inveterate belief in the existence of a tumor was removed by a feigned operation. Is the procedure wise and advisable? Of this one may venture a strong doubt. It seems to show more than a "phoria," a pronounced squint, one may say, toward the plan of treating, so ably advocated by Mother Mary Baker Patterson and the rest. Do such methods, in the long run, increase the

respect—or the disrespect—entertained by so many persons, of the medical profession, of hospitals, etc.?

The Witch Doctors of Pennsylvania.—Many would be surprised to learn that a very genuine and active relic of the belief in witchcraft still exists. "Hexerei" is today such a living nuisance throughout a number of counties of Pennsylvania that a determined effort, it is said, is to be made by the State Medical Board to uproot it. The duty has been too long postponed, and if it is thoroughly done there will be saved many lives and much suffering and expense on the part of the victims—often children—of this medieval superstition. Charms, incantations, doctors for milk-souring, and hocus-pocus of strange varieties, doctors and remedies for hysterics, colds, hemorrhages, pains, toothaches, whoopingcough, hair-growing and hair-destroying, for cuts, burns, wounds, sprains, etc., abound among these devotees and "pow-wow" curers. Their bible is an echo of middle age nonsense, of which these are samples:

To banish whoopingcough cut out three small bunches of hair from the crown of the head of a child that has never seen its father; sew this up in an unbleached rag and hang it around the person's neck.

If you burn a large frog to ashes and mix the ashes with water you will obtain an ointment that will, if put on the place covered with hair, destroy it and prevent it from growing again.

The medical men who have undertaken the cure of this disease deserve all encouragement and help.

The fear of being buried alive, one would have thought, should by this time have died out. The death of Miss Frances Power Cobbe demonstrates how vivid is that morbid solicitude. Her will directs her medical attendant to "sever the arteries of the neck and windpipe, nearly severing the head altogether," of her body, on pain of invalidating her will entirely. It should be noted that Miss Cobbe's demand in her will comes with an astonishing illogicality from one who has so bitterly opposed vivisection, and especially that of human beings. To "completely sever the arteries of the neck and windpipe" (why are the arteries of the windpipe so important? to avoid future talking?) and "nearly severing the head altogether" would have no significance if the subject were really dead. But if alive, is not that a bad form of vivisection? At one time mortuary chambers were established in Germany and elsewhere in which dead bodies were placed, a bell-rope being attached to the hand of each. No one has ever heard, or heard of, the bell being rung. There seem to be no well-authenticated and conclusively demonstrated instances of the actual burial of the living, although there are of course many of supposed death with subsequent resuscitation, prior to burial. The signs of life are now so well understood by all capable physicians that the danger of premature burial may be said not to exist if the laws pertaining to the subject in most civilized States are observed. None needs imitate Miss Cobbe, unless, like her, he has a predisposition to convictions as deep-seated as they are unfounded, and have also a theoretic suspicion, to use the softer word, of the honor and science of the medical profession.

BOOK REVIEWS

The Therapeutics of Mineral Springs and Climates.—By I. BURNEY YEO, M.D., F.R.C.P. W. T. Keener & Co., Chicago, 1904.

Dr. Yeo, as a practical therapist has no superior nor has any one a wider acquaintance with the important subject matter of this volume. His clear and concise style in writing is well known. From such a combination of qualities in the author we have the right to expect a good book and we are not disappointed. From the standpoint of the American physician, however, the book is incomplete, scanty attention being given to the excellent springs and resorts on this side of the Atlantic. A few of the more prominent ones are indeed mentioned and judiciously characterized, but for complete information on resorts near at home the American physician must look elsewhere. On the other hand the information given concerning European resorts is very satisfactory and the practical advice sound.

Diseases of the Skin: An Outline of the Principles and Practice of Dermatology.—By MALCOLM MORRIS. New edition. W. T. Keener & Co., Chicago, 1903.

In the present edition of Morris' wellknown manual of "Diseases of the Skin," a considerable amount of new text has been added descriptive of diseases not considered in previous editions, and the number of black-and-white illustrations has been more than doubled. Blastomycetic dermatitis, porokeratosis, parakeratosis variegata, and those tuberculous eruptions to which the French have given the name tuberculids, are among the most important of the new diseases described. It is somewhat difficult to decide just what is the author's position in regard to the parasitic origin of eczema since in one place we are told "The parasitic theory must therefore for the present be dismissed as 'not proved,'" while in another it is stated: "Eczema in a large proportion of cases is of parasitic origin." The employment of the Finsen treatment and the röntgen ray in lupus vulgaris is somewhat briefly considered and apparently without much enthusiasm; and tuberculin is still believed to have "a distinct place" in the treatment of this disease. This edition, except in a few comparatively unimportant particulars, is thoroughly up to date, and will be found a useful guide in the recognition and management of diseases of the skin.

The Medical Epitome Series: Organic and Physiologic Chemistry.—By ALEXIUS MCGILLAN, M.D. Lea Brothers & Co., Philadelphia and New York.

This book is really a companion volume to the one by the same author on Physics and Inorganic Chemistry. The first 174 pages are given to organic, the remaining 60 to physiologic chemistry. A list of questions is appended to each chapter. The same may be said of this as of the preceding volumes, brief but very well arranged, and furnishing a vast amount of information in small compass. The editor of the series has been exceedingly fortunate in his selection of authors.

BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

Electricity. The Chemistry of Ether: A treatise generalizing a fundamental hypothesis applicable to Electricity, Chemistry, Physics, Physiology and Pathology; with chapters on General and Gynecologic Electrotherapeutics. Illustrated by 134 engravings and containing tabulations of Polar Differentiations and Current Comparisons.—By GEORGE ADAM, M.D., recently Professor of Therapeutics and Electrotherapeutics, College of Physicians and Surgeons, San Francisco, Cal. Price, \$4.50. Whitaker & Ray Co., San Francisco, Cal.

Immune Sera, Hemolysins, Cytotoxins, and Precipitins.—By PROF. A. WASSERMANN, M.D., University of Berlin: Authorized translation by CHARLES BOLDUAN, M.D. Cloth, \$1.00. John Wiley & Sons, New York, 1904.

Krankheiten und Ehe: Darstellung der Beziehungen zwischen Gesundheitsstörungen und Ehegemeinschaft.—Edited by PROF. DR. H. SENATOU and DR. MED. S. KAMENIR. New York: Rebman Company.

Simon's Clinical Diagnosis: A Manual of Diagnosis by Microscopic and Chemical Methods, for Students and Practitioners.—By CHARLES E. SIMON, M.D., late Assistant Resident Physician at Johns Hopkins Hospital, Baltimore. New (fifth) edition, thoroughly revised and much enlarged. Octavo, 695 pages, 150 engravings, 22 colored plates. Cloth, \$4.00 net. Lea Brothers & Co., Publishers, Philadelphia and New York, 1904.

AMERICAN NEWS AND NOTES

GENERAL.

Requests to Charity.—New York: By the will of Solomon Loeb, a sum aggregating more than \$60,000 was left to various hospitals and charitable institutions; among others being the Montefiore Home, Mt. Sinai Hospital, Home for Aged and Infirm Hebrews, etc.—Baltimore: By the will of Mrs. Ellen M. Bolton, the Home for Incurables, of Baltimore, will eventually receive half, and possibly her entire estate, valued at \$25,000.

Miscellaneous.—Philadelphia: At a meeting of the Board of Trustees of Jefferson Medical College, May 16, the following clinical professors were elected full professors, with seats in the Faculty: Drs. Howard F. Hansell, W. Joseph Hearn, Henry W. Stelwagon, H. Augustus Wilson, Edwin E. Graham, Orville Horwitz, S. MacCuen Smith, D. Braden Kyle, Albert P. Brubaker, Solomon Solis Cohen. Dr. John H. Gibbon, surgeon at the Pennsylvania Hospital, was elected Associate Professor of Surgery; Dr. Randle C. Rosenberger, Assistant Professor of Bacteriology, and Dr. Aller G. Ellis, Associate in Pathology.—The annual commencement exercises of the Jefferson Medical College, of Philadelphia, will be held in the American Academy of Music, on Friday, May 27, 1904. The annual meeting of the Jefferson Alumni Association will be held at the Bellevue Hotel, Philadelphia, May 26, 1904. The annual banquet of the Association will be held immediately after the meeting, at which Dr. Albert Hoffa, Professor of Orthopedic Surgery in the University of Berlin, upon whom Jefferson College will confer the honorary degree of LL.D. at the commencement exercises, will be the guest of honor. Dr. J. L. Faure, surgeon to L'Hôpital Herold of Paris, who has been making a tour of the United States, will be in Philadelphia, May 23 and 24, as the guest of Drs. W. W. Keen and John G. Clark. Dr. Faure will give two clinics, one at the University Hospital, May 23, and one at the Jefferson Hospital, May 24. The Philadelphia Pediatric Society was addressed at its last meeting, May 10, by Dr. Roland G. Freeman, of New York. Subject: "The Feeding and Care of Children after the First Year." The University of Pennsylvania, on June 10, 1904, will hold dedicatory exercises at the opening of the laboratories of pathology, physiology and pharmacology.—New York State: Dr. Warren L. Babcock, Chief Surgeon of the State Soldiers' Home Hospital, at Bath, N. Y., has been selected by the Board of Trustees of Grace Hospital as superintendent of that institution, to succeed Dr. A. L. Putnam. He will assume his new duties about June 1. Dr. Abram Tucker Kerr has been elected to the chair of anatomy in the medical department of Cornell University, Ithaca, N. Y. Dr. Kerr received his medical degree in the University of Buffalo, in 1897, and was for a time acting professor of anatomy in the Buffalo Medical College and later was made assistant professor and demonstrator of anatomy in that institution. In 1900 he took charge of the work in anatomy at the Ithaca division of Cornell University, and he is now promoted to full professorship. Dr. William P. Spratling, Superintendent of the Craig Colony for Epileptics at Sonyea, near Rochester, N. Y., has been chosen superintendent of Bellevue and Allied Hospitals at a meeting of the Board of Trustees, vice Dr. William Mabon, who was recently appointed president of the State Commission in Lunacy.—New Mexico: The twenty-third annual session of the New Mexico Medical Society was held at Albuquerque, May 11, 1904.—Baltimore: Dr. Charles R. Bordin, Assistant Professor of Anatomy at the Johns Hopkins University, has accepted the chair of anatomy at the University of Wisconsin.

EASTERN STATES.

The Protozoan in the Cause of Disease.—The *Journal of Medical Research* publishes an article by Dr. James H. Wright, director of the Clinico-Pathological Laboratory at the Massachusetts General Hospital, on his asserted discovery of the protozoan causing the so-called aleppo boil. The cause of this disease has never been known, and its interest lies in its close relationship to the protozoa found in smallpox and in scarlet fever, both of which have been tentatively demonstrated by Boston men.

NEW YORK.

Libel Suit Decided in Favor of Criminologist.—Arthur MacDonald, formerly criminologist at Washington, in a libel suit against the New York *Sun*, was allowed by the jury in the Supreme Court of Brooklyn, \$20,000 damages.

Street Sweepers to Undergo Physical Examination.—The Medical Examiners of the Street Cleaning Department have been instructed to make a physical examination of the 5,000 sweepers and drivers employed by the city. A considerable percentage of the men who have asked for sick leave lately were found to be suffering from tuberculosis, and Commissioner Woodbury wants to know just how badly his force is infected. He does not believe that the work of street cleaning is unusually dangerous, but if tuberculosis is spreading he wants to know it, so that some means may be devised for the protection of the men. The examination will take about 15 days.

Consolidation of Medical Societies.—At a meeting of the Joint Committee of Conference held at the New York Academy of Medicine, May 6, 1904, the following resolutions were passed: *Resolved*, That the president and the secretary of the Joint Committee of Conference be authorized and directed to make a certificate provided for in the tenth paragraph of the agreement, and the council of the committee be directed to proceed with diligence to obtain a final order for the consolidation of the corporations, pursuant to the terms of the agreement, and that the form of the certificate to be made by the chairman and the secretary, be in the form of the draft certificate submitted to this committee, which is as follows: Supreme Court, New York County. In the matter of the application of the Medical Society of the State of New York, and the New York State Medical Association for an order consolidating the said corporations, pursuant to the act, Chapter 1 of the laws of 1904. This is to certify that the Joint Committee of Conference mentioned in the agreement for the consolidation of the Medical Society of the State of New York and the New York State Medical Association, which agreement was unanimously adopted by the Medical Society of the State of New York, at its annual meeting at Albany, on January 26, 1904, and by the New York State Medical Association at a special meeting of the association held in New York, on March 21, 1904, has not ordered the submission of said agreement or of any questions in connection therewith, to the county medical societies or associations referred to in said agreement, and that the conditions precedent to an application to the Court for an order consolidating the Medical Society of the State of New York and the New York State Medical Association have been fully complied with; and this certificate is made pursuant to the "tenth" paragraph of said agreement. In witness thereof, the undersigned, Abraham Jacobi, Chairman of the Joint Committee of Conference, and Wisner R. Townsend, Secretary of the Joint Committee of Conference, do hereunto subscribe their names at the City of New York, this — day of May, 1904. Thirty out of 35 county associations have ratified. One, Onondaga, has refused to ratify; four have not yet reported. The associations that have ratified represent a membership of 1,711, and those that have not acted, a membership of 42. The one refusing to ratify has 14 members. Ratifications have been received from 47 out of the 51 county societies; four have not yet acted. Those which have ratified represent a membership of 5,569. Those which have not yet acted, a membership of 164. According to the agreement, article 10, declares "that whenever the chairman and secretary of the Joint Conference Committee shall certify that the conditions precedent to an application to the Court have been fully complied with, the presidents of the respective corporations shall, and they are hereby authorized and required in the name and behalf of their respective corporations to petition the Supreme Court for an order to consolidate in accordance with the term thereof. Therefore all county associations and societies that have not ratified will be asked to appear before the Court at a specified date appointed by the Court, and show cause why the consolidation should not be completed according to the terms of the agreement, despite their failure to ratify."

PHILADELPHIA, PENNSYLVANIA, ETC.

Victims of the Butler Typhoid Epidemic Sue for Damages.—In Butler, Pa., an organization has been effected, composed of members of the recent frightful typhoid epidemic in that town, and suit has been instituted against the water company furnishing the water to the town. It is held that this company has been guilty of negligence in furnishing impure water to the city, the use of which resulted in the great epidemic and consequent damage to the victims, hence the suit. This will be watched with interest by both the legal and medical fraternities, as the claim for damages under such circumstances is a new one. Some hold that prosecution for criminal negligence would be more to result in punishment of the company.

Nurses' Associated Alumnae.—Uniformity in the standard of training and State registration of nurses, and reciprocity were the aims discussed in the convention of the Nurses' Associated Alumnae in the Drexel Institute, Philadelphia, last week. A member of the association gives a brief review of the work accomplished, as follows: Friday morning, after the usual orders of business meeting, the following papers were read: "Section on State Registration," by Miss S. A. Bowen, Boston City Hospital Alumnae; "The Effect of Registration upon the Educational Standards of Training Schools, as Shown by Results in New York State," by Miss S. F. Palmer, Editor *American Journal of Nursing*; "The Justice of an Examining Board Composed of Nurses," by Miss Cabiness, Johns Hopkins Hospital Alumnae; "The Necessity for Low Standards in the Beginning," by Miss I. C. Rose, the Illinois Training School Alumnae; "State Reciprocity," by Miss Nutting, Johns Hopkins Hospital Alumnae. Miss Nutting tried to show that toward reciprocity in nursing we take our first step when we ask for laws which shall establish standards of education for nurses and require that those wishing to practise as professional nurses shall prove before competent examining boards that they conform to those standards. Investigation shows us an entire lack of uniformity in instruction in training schools throughout the country. Our school (Massachusetts) has a

course of four years. And there are other schools having a course of only a few weeks. It is fair to say that three years will become the accepted uniform period. Of 5,000 so-called schools in America, 230 have accepted this term. Until we can further emerge from this disorganized condition which permits every hospital or sanatorium in the country to maintain a school for nurses on its own lines, until we can establish some unanimous standard, we may continue to secure laws in certain States, but they will vary so greatly that the standards of one State may not prove acceptable to another. We must raise the profession to the highest possible standard, and have uniform teaching in the training schools. Saturday morning all papers were on "Central Directories." All sessions had a full attendance.

SOUTHERN STATES.

The Cat Pest and Congress.—Washington is likely to have a cat pound, where all stray felines may be impounded and the stillness of the night hours thus preserved to the citizens. The objection to ownerless cats is that they are likely to spread disease and are breeding far beyond the requirements as rat catchers. For many years there have been hosts of wild cats in the Treasury Department, inhabiting the intricate subterranean corridors of that remarkable structure. Their justification, given many times officially, is that they help Uncle Sam to save his money by hunting down the rats and mice that would otherwise eat up all the greenbacks and bonds stored in the vaults. The present movement against the irresponsible cat was begun by a physician, who said he knew that the death of two children was stated by a medical association to have been due to the germs of diphtheria carried by stray cats with which the children had played. It will be necessary for Congress to grant legislation which will enable the District government to provide for the licensing of cats and the impounding of those which have no owners.

WESTERN STATES.

Summary of a Decade.—The Bulletin of Chicago's Health Department for the week ended May 7, 1904, says: During the decade 1894-1903 there were 246,189 deaths reported from all causes in this city. Of this number, pulmonary tuberculosis caused 24,265 deaths, or 9.8%, and pneumonia 28,665, or 11.6% of the total. Of the 10,161 deaths from all causes reported during the first 4 months of this year, pulmonary tuberculosis caused 1,154 deaths, or 11.3%, and pneumonia caused 2,328 deaths, or 22.9% of the total. That is to say, while the pulmonary tuberculosis mortality is 15.3% higher this year than during the previous 10 years, the pneumonia mortality is 97.4% higher.

Chicago Prepares for Fourth of July.—One policeman, one fireman, one doctor, one volunteer school teacher, and one naval militiaman will be on hand July 4 to guard each of several mimic theaters of war that have been arranged for by the managers of the public Independence Day celebration in Chicago. The program proper will begin upon the morning of the Fourth, and free firecrackers and torpedoes of the harmless variety will be supplied to each small boy for the asking. In the afternoon bands of the National Guard will give concerts in the parks and a military promenade will take place. A committee upon medicine and science, to have charge of the work of providing safeguards for persons injured by toy pistols or fireworks, and to prepare statistics on lockjaw, has been appointed.

Mortality of Michigan during April, 1904.—The total number of deaths returned to the State Department for the month of April was 3,212, or 194 less than the number registered for the preceding month. The deathrate was 15.7 as compared with a rate of 16.0 for March. Deaths at important ages were as follows: Under 1 year, 518; 1 to 4 years, 172; 65 years and over, 1,008. Deaths by causes: Tuberculosis of lungs, 235; other forms of tuberculosis, 37; typhoid fever, 81; diphtheria and croup, 47; scarlet fever, 25; measles, 27; whoopingcough, 15; pneumonia, 302; influenza, 104; cancer, 145; accidents and violence, 184. There was a marked rise in the number of deaths from typhoid fever, and a decrease in the number reported from pneumonia and influenza, as compared with the preceding month. No deaths from smallpox were reported for April.

Milk Inspection in Chicago.—The Bulletin of Chicago's Health Department for the week ended May 7, says: During the week the laboratory analyzed 547 samples of milk and cream; of these 6.03% were found below grade. This high percentage of low-grade samples is due to the fact that at this season of the year there is a large number of fresh cows. The dairy inspector destroyed over 100 rusty milk cans. The department has decided that milk cans must be in first-class condition and thoroughly bright and clean. Filthy, rusty cans will be destroyed wherever found, because these cans cannot be thoroughly cleaned and sterilized; some milk remains in them and becomes sour. A small amount of sour milk, added to a can of fresh milk, will cause it to sour very readily, especially in warm weather, and, next to dirty milk, sour milk is a very potent factor in the cause of intestinal diseases among children.

FOREIGN NEWS AND NOTES

GENERAL.

A Modesty Peculiar to Her Sex.—The poorhouse in Budapest contains among its inmates a woman named Jetty Einzig, who, according to her baptismal certificate, is 116 years old. She gave her age as 105, and when confronted with the certificate and asked why she had not told the truth, she replied it was because she felt ashamed to be so old!

Bubonic Plague in Formosa.—A. C. Lambert, vice-consul-general at Daitotai, which is a new name for Tamsui, the old capital of Formosa, reports to the State Department that during the month of March there were 558 cases of bubonic plague on the island, with 369 deaths. The consul shows that the plague has been epidemic for the last five years in the southern part of the island, but, with one exception, this March record is the worst for the corresponding month in any preceding year.

OBITUARIES.

John Milton Duff, a wellknown physician and surgeon, at his home in Pittsburg, May 14, of blood poisoning, following an operation. Dr. Duff was clinical professor of gynecology in the West Penn Medical College, obstetrician-in-chief and abdominal surgeon in the Rhine-man Hospital, surgeon at the South Side Hospital, gynecologist at the Kaufman Clinic and President of the Section of Obstetricians and Gynecologists of the American Medical Association in Pittsburg. He was ex-president of the Pittsburg and South Side Medical Society and member of a dozen other medical societies. He was the author of many valuable medical papers. He graduated from the Western University of Pennsylvania after the Civil war, in which he participated as a soldier in Company B, 107th Pennsylvania Volunteer Infantry.

William Waterworth, at his home in Brooklyn, May 12, aged 53. After being graduated at Western Reserve College, at Hudson, Ohio, in the class of 1875, he was graduated from the Bellevue College of Medicine, afterward becoming an interne of the Brooklyn Hospital. He was a visiting physician at the Brooklyn Eye and Ear Hospital, and an active member of the Kings County Medical Society. He was a Freemason, a member of the Royal Arcanum and of the Union League Club. His activities in his profession involved much work of a purely humanitarian character and his charities will never be known except to the beneficiaries.

Luther D. Jacobs, Emporia, Kansas, at a hospital in Chicago, April 28, after an operation upon the stomach. He was a graduate of the University of Pennsylvania, member of the American Medical Association, of the National Association of Railway Surgeons, ex-president of the Santa Fe Medical and Surgical Society and fellow of the Academy of Medicine.

Bernard Mackay, of New York City, was struck and instantly killed in Madison Square, May 12, by a fire engine. He had been deaf for nearly 40 years, which accounts for the accident. He was educated in Paris, where he studied medicine, though he never practised, owing to his deafness, and he was 71 years of age.

James Gray Thomas, at his home in Mobile, Ala., aged 69. He was a prominent surgeon of Mobile; served as a surgeon of the Confederate army during the Civil war, and in 1889 was appointed commissioner from Alabama to the Paris Exposition. At the time of his death he was a member of Governor Jelks' staff.

Giles S. Mitchell, at his home in Cincinnati, May 5; a graduate of the Medical College of Ohio, Cincinnati, in 1875; member of the American Medical Association; professor of gynecology in the Cincinnati College of Medicine and Surgery and surgeon to St. Mary's Hospital, Cincinnati.

John Stansill, from heart disease, at his home in Rockingham, N. C., April 25, aged 55; a graduate of the University of Maryland School of Medicine, Baltimore, in 1872; member of the American Medical Association and of the Medical Society of the State of North Carolina.

William H. McGee, at his home in Belvidere, N. J., May 10, aged 56; a graduate of Bellevue Medical College, N. Y., in 1872. He was a member of the Warren County Medical Association and resident physician for the Pennsylvania Railroad Company.

Clinton Cushing, at his home in Washington, D. C., May 11; a graduate of Rush Medical College, Chicago, in 1865. He was one of the oldest and best known physicians of Washington, having retired from active practice some years ago.

Albion P. Tophit, at his home in Portland, Maine, May 9; a graduate from Dartmouth College, and later from Bellevue Medical College, New York. He has practised in Portland since 1878, being one of the best known physicians in the city.

Emma L. McCollum Clawson, of Battle Creek, Mich., from pneumonia, at Los Angeles, April 24, aged 39; a graduate of the University of Michigan, Ann Arbor, in 1891. She was a member of the American Medical Association.

John L. Dodge, from the effects of an overdose of chloroform, which he evidently took to relieve a severe headache, at his home in Boliver, Miss., May 10; a graduate of the Louisville University in 1887.

Augustus Reimer, from Bright's disease, at his home in College Point, N. Y., April 29, aged 66; a graduate of the University of Göttingen, Germany, in 1880; one time coroner of Queens County, New York.

James Griffin Conly, at his home in Elk Point, S. D., May 8, aged 66; a graduate of Rush Medical College, Chicago, in 1862. A surgeon in the Third Wisconsin Volunteer Infantry during the Civil war.

John B. Blanton, at his home in Chico, Texas, April 25, aged 65; a graduate of the Medical College of Virginia, Richmond, in 1860; regimental surgeon in the Federal service during the Civil war.

John A. Gibbons, at his home in Keokuk, May 1, aged 41; a graduate of the College of Physicians and Surgeons, Keokuk, Ia., in 1883; at one time demonstrator of anatomy in that institution.

Walton Fuqua, at his home in Stewartville, Va., April 28, aged 32; a graduate of the Medical College of Virginia, Richmond, in 1896; member of the Medical Society of Virginia.

J. Ellwood Peters, from apoplexy, at his home in Jenkintown, Pa., May 16, aged 40. Dr. Peters was the oldest practicing physician in Jenkintown, having been there since 1874.

P. C. Robinson, from apoplexy, at his home in Pittsburg, May 15; a graduate of Jefferson Medical College, Philadelphia. He served in the Confederate army during the Civil war.

M. O. Butterfield, committed suicide at the home of his brother, in Venice, Ohio, by shooting himself, May 1, aged 51; a graduate of the Medical College of Ohio in 1880.

Thomas B. Saulsbury, of Towson, Md., at the Maryland General Hospital, Baltimore, May 1, aged 53; a graduate of the College of Physicians and Surgeons in 1882.

Edward Reed Wheeler, of Spencer, Mass., from agna pectoris, at Winthrop Beach, April 30, aged 64; a graduate of Bellevue Hospital Medical College in 1894.

Louis Bedford Welch, of Chiroch, Pa., in West Elizabeth, Pa., April 27, aged 68; a graduate of the University of Maryland School of Medicine in 1879.

John R. Hawkins, at his home in Sioux Falls, May 8; a graduate of Rush Medical College in 1900; member of the American Medical Association.

Melvin W. Caster, from pneumonia, at his home in Clayton, Mo., April 30, aged 73; a graduate of the Medical College of Ohio, Cincinnati, in 1877.

Robert M. Price, from pneumonia, at his home in Centerville, Md., April 30, aged 62; a graduate of the Baltimore Medical College in 1881.

Herbert Linderman, at his home in Philadelphia, May 15, aged 37; a graduate of the Medico-Chirurgical College, Philadelphia, in 1891.

Grant H. Richtmeyer, at his home in New York City, April 21, aged 39; a graduate of the University of Vermont, Burlington, in 1890.

Henry C. Whitehead, at his home in Fort Worth, Texas, April 22, aged 43; a graduate of Vanderbilt University, Nashville, in 1893.

Henry L. Standinger, at his home in St. Louis, April 24, aged 63; a graduate of the Humboldt Medical College, St. Louis, in 1867.

Benjamin F. Moulton, at his home in Lawrence, Mass., May 3, aged 59; a graduate of Harvard Medical School in 1867.

Joseph P. Chartrand, at his home in Quebec, April 25, aged 43; a graduate of Victoria College, Cobourg, Ont.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended May 14, 1904:

Changes in the Medical Corps of the U. S. Army for the week ended May 14, 1904:

FELTZ, ROBT. L., contract surgeon, leave granted February 27 is extended one month.

MURRAY, First Lieutenant **ALEXANDER**, assistant surgeon, is granted leave for twenty-one days.

HUGHES, LEONARD S., contract surgeon, will report for duty to the commanding officer, department rifle range, Point Bonita, Cal., relieving Contract Surgeon Gustavus I. Hogue, who will report at the Presidio for temporary duty until the return to that post of Contract Surgeon Frank H. Titus, when Contract Surgeon Hogue will rejoin his proper station.

GEDDINGS, First Lieutenant **EDWARD F.**, assistant surgeon, is granted leave for two months from about May 15, with permission to apply for an extension of one month.

RUTHERFORD, First Lieutenant **HENRY H.**, assistant surgeon, now in Hot Springs, Ark., on sick leave, will report to the commanding officer, Army and Navy General Hospital, for such duty as he may be able to perform.

FORD, First Lieutenant **CLYDE S.**, assistant surgeon, leave granted for ten days is extended to twenty days.

WEED, F. WATKINS, contract surgeon, now at Baltimore, Md., will report at Fort McHenry for duty.

EBLE, CHARLES F., sergeant first class, orders of April 29 are revoked.

EBLE, CHARLES F., sergeant first class, Fort Thomas, will report to the commanding officer, Third Infantry, at that post, to accompany that regiment to Alaska, and Companies L and M thereof to Fort St. Michael, reporting on arrival to the commanding officer, to relieve Sergeant First Class James R. Filgate. Sergeant First Class Filgate will proceed to San Francisco, Cal., on the transport Crook, reporting to the commanding general, department of California, and by letter to the military secretary of the Army for further orders.

BUSHNELL, Major **GEORGE E.**, surgeon, now on duty at the General Hospital, Fort Bayard, will assume command of that hospital upon the departure of Lieutenant-Colonel Edward T. Comegys, deputy surgeon-general, in compliance with orders heretofore issued.

LA GARDE, Major **LOUIS A.**, surgeon, Par. 19, S. O. 46, February 25, W. D., is revoked. Major La Garde will report to Rear Admiral John G. Walker, United States Navy, chairman Isthmian Canal Commission, for duty with the commission upon the Isthmian Canal of Panama.

The following changes in the stations and duties of officers are ordered: First Lieutenant **Chester J. Stedman**, assistant surgeon, is relieved from duty at Columbus Barracks, Ohio, to take effect upon the departure from that post of the battalion of the Third Infantry, and will then report to the commanding officer of that battalion for duty en route to Fort Lisicum, Alaska, and upon arrival at that post will report in person to the commanding officer thereof for duty, relieving First Lieutenant **Cosam J. Bartlett**, assistant surgeon. Lieutenant **Bartlett** will proceed on the transport Crook to San Francisco, Cal., and report by telegraph to the military secretary for further orders. First Lieutenant **John R. Bosley**, assistant surgeon, is relieved from duty at Fort Thomas, to take effect upon the departure from that post of the Third Infantry, and will then report to the commanding officer of that regiment for duty en route to Fort Egbert, Alaska, and upon arrival at that post will report to the commanding officer thereof for duty, relieving Captain **Jere B. Clayton**, assistant surgeon. Captain Clayton will proceed to Fort William H. Seward, Alaska, for duty.

The following changes in the stations and duties are ordered: Captain Irving W. Rand is relieved from duty at Ord Barracks, Cal., and will report to the commanding officer, cantonment, Presidio, for duty. Contract Surgeon Frank H. Titus is relieved from duty at the Presidio, to take effect upon the arrival of Captain Rand, and will proceed to Ord Barracks, Cal., for duty. Contract Surgeon H. Newton Klerulf is relieved from duty at the Presidio, and will report to the commanding officer of the cantonment at that post for duty.

Changes in the Medical Corps of the U. S. Navy for the week ended May 14, 1904:

SPRATLING, L. W., surgeon, detached from duty with the Marine Battalion on the Isthmus of Panama and ordered to duty with the Panama Canal Commission—May 6.
 RODMAN, S. S., passed assistant surgeon, commissioned a passed assistant surgeon with rank of lieutenant, from December 14, 1903—May 6.
 SUTTON, R. L., assistant surgeon, detached from the Bureau of Medicine and Surgery, Navy Department and ordered to duty with the Marine Battalion on the Isthmus of Panama—May 6.
 LEDBETTER, R. E., assistant surgeon, ordered to the Lancaster—May 7.
 BRAISTED, W. C., surgeon, detached from the Naval Hospital, New York and ordered to the Relief; authorized to delay one week en route—May 10.
 MILLER, J. J., assistant surgeon, detached from the Naval Museum of Hygiene and Medical School and ordered to the Denver—May 11.
 ZALESKY, W. J., assistant surgeon, ordered to the Naval Hospital, Philadelphia, Pa.—May 11.
 NORTON, O. D., surgeon, detached from the Navy Yard, League Island, Pa., and ordered to the Illinois—May 12.
 GATES, M. F., surgeon, detached from the Naval Hospital, Philadelphia, Pa., and ordered to the Navy Yard, League Island, Pa.—May 12.
 BLACKWOOD, N. J., surgeon, detached from the Illinois and ordered to the Torpedo Station, Newport, R. I., with additional duty in attendance upon navy and marine officers not otherwise provided with medical aid at Newport, R. I.—May 12.
 WILSON, G. B., surgeon, detached from the Torpedo Station, Newport, R. I., and ordered to the Naval Hospital, Chelsea, Mass.—May 12.

Changes in the Public Health and Marine-Hospital Service for the week ended May 12, 1904:

CARRINGTON, P. M., surgeon, detailed to represent the Service at the meeting of the American Medical Association, June 7, 1904, stopping at the Bureau en route—May 10, 1904.
 NYDEGGER, J. A., passed assistant surgeon, granted extension of leave of absence, on account of sickness, for one month from April 6—May 9, 1904.
 SPRAGUE, E. K., passed assistant surgeon, relieved from duty at Calcutta, India, and directed to proceed to the United States—May 4, 1904.
 KERR, J. W., passed assistant surgeon, granted leave of absence for one month from May 20—May 9, 1904.
 GOLDBERGER, JOSEPH, assistant surgeon, relieved from duty at Tampico, Mexico, and directed to proceed to Monterey, Mexico, for duty—May 6, 1904.
 HOLT, J. M., assistant surgeon, Bureau letter of February 9, 1904, directing him to report to Passed Assistant Surgeon V. G. Helser, at Manila, P. I., for examination for promotion, revoked—May 12, 1904.
 BURKHALTER, J. T., assistant surgeon, granted extension of leave of absence for ten days—May 9, 1904.
 WIGHTMAN, W. M., assistant surgeon, granted leave of absence for seven days, under paragraph 191 of the regulations—May 1, 1904.
 MCKEON, F. H., assistant surgeon, to proceed to New York, N. Y. (Stapleton), and report to medical officer in command for duty and assignment to quarters—May 9, 1904.
 PETTYJOHN, JOSEPH, assistant surgeon, to proceed to New York, N. Y., and report to Surgeon G. W. Stoner, Immigration Depot, for duty—May 4, 1904.
 SWEET, E. A., assistant surgeon, to proceed to New York, N. Y., and report to Surgeon G. W. Stoner, Immigration Depot, for duty—May 4, 1904.
 SPRATT, R. D., assistant surgeon, to proceed to New Orleans, La., and report to medical officer in command for duty and assignment to quarters—May 9, 1904.
 ALEXANDER, E., acting assistant surgeon, leave of absence for ten days from May 1, 1904, granted him by Department letter of April 26, revoked—May 10, 1904.
 RICHARDSON, N. D., acting assistant surgeon, granted seven days' leave of absence from February 25, 1904, under paragraph 210 of the regulations.
 SLAUGHTER, A. W., acting assistant surgeon, granted leave of absence for fourteen days from June 1—May 10, 1904.
 COMFORT, N. C., pharmacist, reassigned to duty at Manila, P. I., effective February 7—May 4, 1904.
 NEVES, GEORGE, pharmacist, directed to proceed to Cairo, Illinois, and report to medical officer for temporary duty during absence on leave of Pharmacist C. G. Carlton—May 9, 1904.
 SIENBURG, FRANK, pharmacist, to proceed to San Francisco, Cal., and report to medical officer in command for duty and assignment to quarters—May 6, 1904.

Appointments.

F. H. McKeon, of Connecticut; J. Pettyjohn, of Georgia; E. A. Sweet, of Massachusetts; and R. D. Spratt, of Alabama, commissioned as assistant surgeons—May 2, 1904.

Reinstatement.

Frank Siedenburgh, of Illinois, reinstated as pharmacist of the third class—May 3, 1904.

SOCIETY REPORTS

ASSOCIATION OF AMERICAN PHYSICIANS.

Nineteenth Annual Meeting, Held at Washington, D. C., May 10, 1904.

[Specially reported for *American Medicine*.]

The meeting was called to order by the president, Wm. T. COUNCILMAN, of Boston. The first feature of the program was the delivery of the **president's address**. In this, Dr. Councilman reviewed the condition of the Association and called particular attention to the disadvantages resulting from the limitations upon membership. He asked that careful consideration be given to the question of increasing the number of members and suggested, as one means whereby the end might be accomplished without detriment to the work of the society, that a class of associate members be established from which future members should be chosen, and, that active membership be limited to 20 years; at the end of that period members to be transferred to the roll of honorary membership. This would about cover the average active period of a man's professional life and provide regularly a sufficient number of vacancies to accommodate the desirable portion of those on the waiting list.

Officers Elected.—The following officers were elected for the ensuing year: President, Edward L. Trudeau; vice-president, Frank Billings; secretary, Henry Hun; treasurer, J. P. Crozer Griffith; recorder, S. Solis Cohen; councillor, F. Forchheimer; representative in the executive committee of the Congress of American Physicians and Surgeons, Wm. Osler; alternate, F. H. Williams.

The Influence of Suprarenal Extract upon Absorption and Elimination; with Demonstrations.—S. J. MELTZER and JOHN AUER. Meltzer explained the experimental work whereby it was shown that the action of certain drugs was very much retarded when they were given in association with suprarenal extract. It was shown that this action was not a matter of chemic naturalization, but due to biologic changes. If small doses of adrenalin be injected into a frog, it becomes paralyzed in a few moments, but this is not a muscular paralysis, since stimulation of the sciatic nerve causes the muscle to contract in a normal manner. If the effect of the adrenalin be allowed to wear off now, and strychnin given, even in more than the usually fatal dose, it produces no effect, or only after a long period of delay. In order to determine whether this was really a matter of delayed absorption experiments were made with a substance which is ordinarily very rapidly taken up by the tissues. If fluorescein be injected subcutaneously into a rabbit, the conjunctivas and mucous membranes very quickly take on the characteristic yellow stain and the Ehrlich's line appears in the pupil. If, however, such an animal be previously given adrenalin, the coloring effects do not appear for a much greater length of time. As this coloring matter has first to be absorbed into the blood and then eliminated through the tissues of the organs, this may not have been purely a matter of delayed absorption, but rather one of delayed elimination. By carefully timing, on a series of animals, the appearance of the color in the serum, and later in tissues, it was demonstrated that both absorption and elimination are delayed by the adrenalin. These differences were most strikingly shown in the tissues of the kidney; the studies upon the urine were not as distinctive, because even a minute portion of the fluorescein colors the fluids of the body intensely. An effort was then made to determine whether transudation would also be delayed by adrenalin. For this purpose salt solution was introduced into the peritoneal cavity, where, as we know, it ordinarily changes very rapidly with the blood, and fluorescein was injected into the vessels. Specimens were shown demonstrating that the fluid from the peritoneal cavity of the control animals contained more coloring matter after eight minutes than that from the adrenalin injected animal after sixteen minutes. The work seemed to show that the use of adrenalin delays the absorption, elimination and transudation of other substances introduced in the body. The principal practical conclusion drawn was that in certain cases toxic materials introduced into the tissues might be delayed in their action by the use of adrenalin.

Discussion.—W. GILMAN THOMPSON said that in his use of adrenalin therapeutically he had not observed that it had any effect whatever upon the kidneys, and that it might do so experimentally because of the large dose or its continuous employment, he doubted if it would do so in therapeutic doses. H. A. HARE said that his conception of the action of adrenalin had been that it was quite brief in its effect, and he was surprised to hear that it could prolong the effect of other remedies. He also called attention to the belief that the local application of adrenalin through the ischemia produced, seemed to increase the danger of infection. Dr. Meltzer, in closing, said that the popular conception of the action of adrenalin, as expressed by Dr. Hare, had its origin in a knowledge of its action on the blood-pressure only. In some experiments he had been able to watch its effect upon the bloodvessels for several hours. The effect upon nonstriated muscle was much longer than that upon the striated muscles. He explained the delayed absorption and transudation by the theory that there exists a ring of contrac-

tile tissue around the pores of the capillary endothelium, and that the varying size of this ring, under the stimulus of the adrenalin, determines the rapidity with which other substances may pass through the pores.

Polyuria in Typhoid Fever.—F. H. FUSSELL, H. S. CARMAN, and HUDSON.—TYSON reviewed the literature of typhoid fever to show the general opinion that as a rule the quantity of urine passed during the first week or ten days of this disease is usually diminished, that after the second week the quantity increases, and that during convalescence it is almost invariably copious and of low specific gravity. Some authorities were quoted to show that polyuria occurs in a small percentage of cases, and that rarely the amount passed may be as great as 10,000 cc. The case which he reported was that of a married man, aged 40, admitted to the hospital on about the eighth day of his typhoid fever with a temperature of 103°. On the day after admission his polyuria began, and continued during the height of the fever. The largest amount passed during one day was 7,200 cc. The amount of urea excreted was constantly normal in percentage. The polyuria lasted, to a greater or less degree for a month, and during this period he was nervous and extremely thirsty. The patient has been under observation for a year since his recovery from typhoid, and presents no evidences of organic kidney disease or diabetes.

Discussion.—DOCK called attention to some work which had been done in regard to the retention of waters in fever, as the result of which the rule has been laid down that at first there is an actual retention of fluid in the body, but that after deference the amount secreted increases until there may be a polyuria. He had been interested in noticing the effect of cold baths in typhoid upon the excretion of urine, and had found that where these were used there was not much retention during the fever. He therefore believed that the theory of treating fevers by "washing out" is to a certain extent possible. WITHINGTON inquired as to the nervous condition of the patient preceding the onset of polyuria, and CABOT and OSLER both asked as to the connection between the polyuria and the typhoid, OSLER pointing out the fact, that in certain conditions, such as tuberculous peritonitis and retroperitoneal tumors, polyuria frequently occurred as the result of local irritation. THAYER remarked that the quantity of water the patient is drinking might play an important part in these cases, and spoke of some observations made by CUSHING (Cleveland) in this connection. He pointed out that typhoid fever patients probably do not always get as much water as they desire in spite of the liberal attitude of the physician in charge. CUSHING has been carrying a rubber tube from the water tank to the bedside and attaching it so that the patient may suck water from it whenever he desires. He has found that these patients drink enormous quantities of water and pass large quantities of urine, and he is also under the impression that this is a beneficial feature in their treatment.

Cases of Venous Thrombosis Occurring in the Course of Typhoid Fever.—W. S. THAYER presented an analysis of 42 cases of venous thrombosis occurring in the course of typhoid fever. Thirty-nine were instances of venous thrombosis that occurred among the 1,465 cases of typhoid treated in the Johns Hopkins Hospital; two were instances of this complication which were admitted during the period of convalescence and one was a man who had suffered from double iliac thrombosis coming on during typhoid fever but who entered the hospital for treatment two years later. In five of the 39 cases occurring in the hospital there was a fatal result; mortality, 12.3%. In two instances the thrombus was the primary cause of death. As to the distribution of the lesions, the thrombus occurred in the lower extremities in 40 instances; in the upper extremity in one instance; and in the pulmonary artery in one instance. The vessel occluded was located, on the left side of the body in 26 cases; on the right side in 5 cases; on both sides in 9 cases; no record in 2 cases. The particular vessels affected were: The femoral vein in 21 instances; the popliteal vein in 5 instances; the iliac vein in 5 instances; the internal saphenous in 3; the veins of the calf alone in 5; the axillary vein in 1; the pulmonary artery in 1; and the pulmonary artery and common iliac in 1. In 36 of the 39 cases the development of the thrombosis was associated with fever. In 11 cases it was associated with chills. The first definite symptom of thrombosis in every instance was pain. In all of the cases there was swelling of the affected part, and in some instances there was redness over the affected vessel. In 16 cases the thrombotic mass was felt as a palpable cord. Leukocytosis was almost always present and its extent depended, in part at least, upon the extent of the lesion, the highest count noted being 25,000 and the average count above 10,000. A study of the prognostic features showed that venous thrombosis in the lower extremity is always a serious complication of typhoid fever, and although the immediate danger is not great, the after-results are often grave; the affected extremity is often considerably and permanently enlarged, there is marked varicosity and usually more or less permanent disability when the femoral or iliac veins are affected. Thrombosis of the veins of the calf is less severe.

Discussion.—PEABODY referred to the belief that the coagulability of the blood is increased by the presence of an increased amount of the calcium salts in the blood and to the possibility that this could be overcome and thrombosis prevented by the administration of sodium citrate. STENGEL said that he had had a number of experiences with the appearance of the gen-

eral symptoms produced by the thrombus before the local symptoms were noted. He had seen two cases of thrombosis of the pulmonary artery. WELCH called attention to the accumulating evidence in support of the old theory that the thrombosis in these cases originates from a primary inflammation of the walls of the vein—an infective phlebitis. This notion was once supposed to have been overthrown by Virchow, but the recent work of the French school, in particular, tends to show that although the question is by no means settled the inflammatory theory must be reconsidered. One of his assistants, Dr. Longcope, has recently gone carefully over these pathologic specimens in his laboratory and demonstrated the presence of bacteria in over 70% of the cases. PRINCE said that, in this connection, he would like to report a case of typhoid that began with phlebitis of the veins of the leg. The patient was one who had previously suffered a number of attacks of phlebitis and presented the history of a gouty diathesis. CAREY referred to the marked disproportion between the general systemic symptoms and the local condition. He recalled a case where the local trouble did not seem to be very great, but where the chills were as violent as in the vicious types of malaria. He believed, however, that most of these patients recovered entirely from the local edema. THOMPSON differed with Carey as to the ultimate results. He had eight cases under observation for from 6 to 10 years, and in no one was there anything like complete recovery. All of them are weak and show edema after any exertion. TYSON questioned whether the pain which was such a marked feature of the thrombosis might not be due to the sudden vascular obstruction and explained in the same way as that which accompanies angina pectoris. OSLER called attention to the difference in clinical picture between the hard swollen, painful leg of phlegmasia alba dolens and the condition described as occurring in typhoid. He said that he did not believe that the average experience with this condition would show quite such hopeless results as appeared in the report. He had known of a number of cases in private practice that had shown complete recovery and thought that the hospital had simply had an experience of an unfortunate series of cases.

Clinical Studies in Arteriosclerosis.—ALFRED STENGEL. The author had carefully studied the blood in a series of these cases. In measuring the blood-pressure he uses Stanton's apparatus in preference to the Riva-Rocci, because it is devised to estimate both the diastolic and systolic curves. He does not believe that there is always high pressure where there is arteriosclerosis. He had observed that the diastolic pressure is always high, but the systolic pressure is not necessarily so; the mean pressure is generally high. He found a marked contrast between the appearance of the patient and the condition of the blood. In spite of the very marked anemia of the advanced cases there is often a high blood count and high percentage of hemoglobin. He had also noted that one of the first signs of arteriosclerosis was a sustained first sound of the heart, and this prolongation was considered an important point in determining the early development of arteriosclerosis.

Discussion.—KINNICUTT asked whether the cases of low blood-pressure that STENGEL had encountered were in what might be called senile arteriosclerosis, and said that his own observations had been that the blood-pressure in senile arteriosclerosis has been rather lower than that seen in pathologic sclerosis. BOHEN called attention to the fact that many elements enter into the production of high or low blood-pressure, and that as only the net results are expressed by the measurements, it is impossible to say whether the changes from normal are due to alterations in the vessel-wall, the innervation, or the cardiac force. He agreed with Stengel in the observation regarding the prolongation of the first cardiac sound, and added that the sound is often impure in character. STENGEL replied to Kinnicutt that the cases of low pressure he had referred to were in pathologic and not senile sclerosis.

An Investigation of the Effects of Cardiac Stimulants: Especially Strychnin, on the Blood-pressure in Febrile Conditions.—R. C. CABOT. This paper will appear in a future issue of *American Medicine*.

[To be continued.]

Medical Students Will Quit the College of Physicians and Surgeons in New York.—It is reported that a month ago the tuition fee at the College of Physicians and Surgeons was raised from \$200 to \$250 a year. The students held a meeting, and a long petition was sent to each member of the Board of Trustees. In the petition were included letters from Johns Hopkins, Harvard, Cornell, and other medical colleges, to the effect that they made it a rule, when tuition prices were raised, that students who had already been entered with a view to taking the entire course should not be affected by the increase. The students argued that it was a manifest injustice to increase the fee after they had entered the institution on the understanding that the charge would be \$200 per year. The trustees replied a few days ago, and refused to grant their request. A meeting of students was held recently, and 98 decided not to return, but to go to Cornell, Johns Hopkins, and other colleges. Another professor, Dr. Robert W. Taylor, resigned recently, making the seventh who has resigned within the year. The six preceding him were Professors Bull, Lefferts, Weir, Peabody, Tuttle, and Elliot.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

ULCERATIVE ENDOCARDITIS: REPORT OF A CASE.*

BY

WILLIAM H. MORRISON, M.D.,
of Philadelphia.

Ulcerative or malignant endocarditis is a disease of sufficient rarity to make the report of even a single case of some interest.

On October 16, B. S., a lad of 12, came under my observation with the following history. He had been perfectly well and healthy up to the age of 8, at which time he presented symptoms indicating the presence of scarlet fever, namely, fever, sore throat and eruption. However, he did not seem to be ill and a physician was not consulted. Five weeks later he suddenly developed high fever, swelling of the legs and puffiness of the face. The condition was diagnosed as one of kidney and heart trouble and the boy was under homeopathic treatment for six or seven months subsequently. During this time, there were frequent attacks of epistaxis. Recovering from this condition, the boy seemed to be fairly well with the exception that any extra exertion such as running, or playing with other children, led to violent action of the heart, dyspnea, dry cough, and cyanosis. There was no history of rheumatism or of disease other than mentioned.

During the five years following the attack of nephritis his condition remained about the same until August, two months

exception of remittent fever, rapid pulse, mitral systolic murmur and enlargement of the liver and spleen.

A careful record of the temperature was now begun and continued for a period of eight weeks, the thermometer being used morning, noon and night. The temperature curve shows an exceedingly irregular and remittent fever. As a rule the highest point was reached at noon, the morning and evening temperatures being approximately the same and 3° or 4° below the midday figure. The average morning temperature was between 99° and 100° while the noon temperature was between 102° and 103°.

Taking into consideration the history of old cardiac disease, the presence of a continuous, irregular temperature and the absence of the evidences of local disease with the exception of those referable to the mitral valve, a diagnosis of ulcerative endocarditis seemed to be warranted and a correspondingly unfavorable prognosis was given.

On October 29, there was a sudden attack of severe pain in the right iliac region associated with a fall of the temperature to 97°. This was readily relieved by a small hypodermic injection of morphia. No tenderness or other sign of trouble in this region remained after the subsidence of the pain. Two days later, there was a second and milder attack of pain in this region.

December 1, two weeks before death, there was suppression of urine with edema of the face. This continued for two days. The urine at this time contained a trace of albumin and a few blood-corpuscles. Ten days before death there occurred an attack of syncope which was repeated on the following day. Petechias made their appearance for the first time one week before death, in the form of small dark spots on the eyelids and about the face. During the following days they appeared in small numbers on the surface of the abdomen. Failure of strength steadily progressed and the boy died of exhaustion, December 13, four months after the onset of the attack of typhoid fever.

X, attack of severe pain in right iliac region.

before I saw him. He then began to complain of lassitude and weakness. This was shortly followed by fever, loss of appetite, severe headache and backache, pain in the abdomen and diarrhea—the stools at first being thin and offensive, sometimes light in color and sometimes dark. There was no pain in the right iliac region. The physician who saw him at this time diagnosed typhoid fever. The diarrhea continued for five weeks when the bowels gradually returned to their normal condition. The fever, however, persisted but its exact degree is not known as the thermometer was used infrequently. Emaciation and weakness progressed and as the patient showed no improvement he was placed under my care two months after the onset of the attack.

Examination at this time revealed great emaciation, with the skin dry, harsh and slightly jaundiced. The temperature was 101.5°, the pulse 100 and the respiration normal. There was no pain referred to any part of the body; no delirium or mental confusion; no cough; no evidence of pulmonary trouble. The area of cardiac dullness was slightly increased and on auscultation a loud systolic mitral murmur was found. No murmur referable to the other valves of the heart could be detected. There was no pain over the precordia, no palpitation and no edema of any part of the body.

The area of splenic and hepatic dullness was slightly increased, but there was no tenderness over either organ. The appetite was good, sometimes craving, and digestion was well performed. There was no diarrhea, but on the contrary, a tendency to constipation. The abdomen was scaphoid and there was no tenderness in the epigastrium or in the right iliac region. There were no symptoms referable to the kidneys. There was no edema, the urine was passed in normal quantity and examination failed to reveal either albumin or casts. At no time had there been chills or sweating. There was no bone disease, no middle-ear trouble and no focus of suppuration could be discovered in any part of the body. There were no petechias or other cutaneous eruption.

There was entire absence of symptoms and signs with the

The autopsy made 24 hours after death revealed the following conditions:

The surface of the small intestine was studded with numerous milium infarcts. The large intestine showed no infarcts. The vermiform appendix was two inches in length and normal.

The spleen was enlarged, measuring 4 in. by 6 in., and presented three large old infarcts measuring 3 in. to 1½ in. at their bases. There were no signs of breaking down.

The liver was slightly enlarged, but no infarcts were discovered.

The kidneys presented the evidences of chronic inflammatory disease and showed numerous fresh milium infarcts.

The lungs were normal, with the exception of one large infarct in the right lung.

There was no evidence of embolism of any of the larger arteries. The heart showed a slight hypertrophy. The valves of the right side were normal. The mitral valve, however, presented extensive disease of both leaflets, the entire auricular surface of the valve being covered to the depth of half an inch with friable vegetations. The entrance of the pulmonary veins into the auricle was also surrounded by vegetations. The aortic valves were normal. No bacteriologic study of the material from the mitral valves was made.

Child Labor.—In an address recently, Colonel Dulaney, chief factory inspector of Pennsylvania, who outlined a new bill he proposes to bring before the next Legislature, dealt with the bill which Alexander Simpson prepared, but which was defeated through the efforts of the glass manufacturers in the last Legislature. He explained that his substitute covered practically the same ground, but exempted glass manufacturers. This, he said, was on account of the difficulty experienced by them in conducting their business in accordance with the demands of such a law. The bill provides that no child under 14 years of age shall be employed in any factory, and no child over that age shall work more than 10 hours in every 24, nor more than 54 in a week.

* Read before the Kensington Branch of the Philadelphia County Medical Society, April 19, 1904.

ORIGINAL ARTICLES

A STUDY OF 91 OPERATIONS FOR THE RELIEF OF VARIOUS FORMS OF HERNIA, WITH THEIR COMPLICATIONS.*

BY

ORVILLE HORWITZ, B.S., M.D.,

of Philadelphia.

Clinical Professor of Genitourinary Diseases, Jefferson Medical College; Surgeon to Jefferson Medical College Hospital; Philadelphia Hospital; Consulting Surgeon to the State Hospital for the Insane, and Jewish Hospital.

The operations performed by us for the relief of various forms of hernia as here set forth represent the work achieved during the past 12 years in private practice at the Philadelphia Hospital, and at the Jefferson Medical College Hospital. Unfortunately the majority of patients were inmates of either one or the other of these establishments, and consequently many were lost sight of after they had quitted these institutions, so that the number of patients who permanently recovered after a radical cure had been attempted cannot be definitely ascertained. The opportunity has been afforded us in 29 cases to watch the permanency of the results obtained by operation, and from this number we are in position to give some definite information regarding the subject.

As none of the cases under consideration was adapted to the employment of any of the palliative measures in vogue which are applicable to so many forms of hernia, this important division of the subject will not be considered in the study of the cases herein recounted.

The various operations performed are classified as follows:

- 32 cases indirect inguinal hernia (strangulated).
- 27 cases indirect inguinal hernia (radical operation).
- 8 cases indirect inguinal hernia (palliative).
- 5 cases direct inguinal hernia (strangulated).
- 1 case direct inguinal hernia (radical operation).
- 3 cases direct inguinal hernia (palliative).
- 3 cases femoral hernia (strangulated).
- 2 cases femoral hernia (radical operation).
- 3 cases umbilical hernia (strangulated).
- 3 cases umbilical hernia (radical cure).
- 4 cases ventral hernia (incisional), radical operation.

The complications were:

One case of bilateral hydrocele with inguinal hernia; radical cure.

Two cases of unilateral hydrocele, inguinal hernia; radical cure of both.

One case of tuberculosis of testicle, inguinal hernia; castration with radical operation for hernia.

Four cases of inguinal hernia with undescended testicle; castration and radical operation for hernia.

Three cases of inguinal hernia with undescended testicle; transplantation of testicle and radical operation for hernia.

One case of inguinal hernia with encysted hydrocele of cord; radical operation for both conditions.

One case of long-standing strangulated femoral hernia, gangrene of bowel with rupture, necessitating abdominal section (Richter's hernia).

One case of hernia reduced *en masse*, necessitating abdominal section.

One case of appendiceal abscess rupturing into an inguinal hernia sac.

One case of long-standing hematoma of the tunica vaginalis testis with large incarcerated omental hernia simulating malignant disease of the testicle.

In two cases of strangulated inguinal hernia, an ovary was found in the sac in one, and a portion of the bladder in the other. Gangrene of the constricted bowels in seven cases necessitated the establishment of an artificial anus; bowel opened without disturbing constriction, and left in situ in one; resection of bowels in three cases and the removal of a doubtful spot about the size of a thumb nail, with closure of the opening in one.

Death ensued in 16 cases, as follows: One femoral, two umbilical, one direct inguinal, 12 indirect inguinal.

In 12 of the cases death was due to peritonitis; strangulation had existed for many hours before resorting to operations, taxis having been persisted in for a lengthened period without avail.

Of the four remaining cases, one patient died from exhaustion, one died from intestinal perforation of a damaged bowel, following operation; probably caused by intestinal distention succeeding paralysis of the bowels. Death occurred on the fourth day after the operation. In one, in which the individual suffered from chronic Bright's disease, uremia was developed. In this case local anesthesia had been employed. The remaining case was one in which a radical operation had been attempted for the relief of a large reducible hernia. Examination of the urine before the operation showed the kidneys to be healthy; suppression of urine intervened, and the patient succumbed.

Operations for the relief of hernia may be divided into three classes:

1. Herniotomy, an operation which is performed when strangulation exists; it is always an emergency operation; the mortality depends not only on the age, character of the hernia, and condition of the patient, but is greatly influenced by the length of time that the protrusion has continued, as well as the amount of force put forth, and the duration and frequency with which attempts at taxis have been made.

2. The so-called "radical operation," when the hernial protrusion is not strangulated and an effort is made to effect a permanent cure.

3. A palliative operation, by which is meant surgical intervention in cases in which, owing to the large size of the hernia, atrophy of the muscular structures of the abdominal wall ensues; the large size of the hernial outlet, and the changed condition of the inguinal canal exists, and a permanent cure following a radical operation is not to be hoped for. Nevertheless, in properly selected cases, individuals suffering from this condition are materially benefited by surgical interference. The general health improves; the obstinate constipation so frequently associated with this state is relieved. The annoying sensation of abdominal tension and pain disappears; the patient being able to keep the contents of the hernial protrusion within the abdominal cavity by means of an apparatus, an impossibility before surgical interference.

There were 42 operations performed for the relief of different forms of strangulated hernia, of which number, 3 were femoral, 3 umbilical, 5 direct, and 32 indirect inguinal. It is significant to note, that in every instance when death resulted from herniotomy the operation had not been performed for several hours after the constriction occurred, and in almost every instance violent and prolonged taxis had been made at short intervals for a lengthened period of time. In one case, that of an old man, aged 73, the strangulation was unrelieved from four o'clock in the morning until eight in the evening, during which time the patient was kept constantly under the influence of ether, taxis being frequently resorted to. On opening the sac the tissues were found to be blood-stained and the serous coat of the bowels stripped off in patches. The intestines presented a most doubtful appearance. The reports of many similar instances are to be found in the literature on the subject.

This statement is confirmed by reference to the "Year Book of Medicine and Surgery for 1903," in which several cases that had occurred during the last year are reported. Bertram cites four cases of strangulated hernia, in which the bowels were found to be gangrenous and resection became necessary. In each instance the rupture was supposed to have been reduced by *forcible* taxis. In one case DaCosta discovered a disorganized and crushed testicle in the inguinal canal following the manipulations made to relieve a strangulated hernia.

Gibbon operated upon a case of intestinal obstruction in which a strangulated hernia had been reduced during the preceding 48 hours. Eight inches of the bowel was found to be gangrenous, making resection necessary.

Crowley,¹ writing on this subject, corroborates our views when he says: "More injury is invoked in a few minutes by brute force taxis than the constriction could cause of itself in several days." He very aptly paraphrases the old adage of Desaut: "To think well of a

* Read before the Philadelphia County Medical Association, January 30, 1904.

strangulated hernia when taxis has not been used," into "Think favorably of a strangulated hernia when taxis has not been abused." "Dangerous as taxis is in unskilful hands, it is often the cause of death in experienced hands by the dangerous delay in operating."

From a compilation of statistics of St. Bartholomew's, St. Thomas', and Guy's Hospitals, from May, 1861, to October, 1892, by Croft,² the inference is drawn that the deathrate of herniotomy is largely increased by the unnecessary delay which is allowed to take place between the occurrence of the strangulation and the operation. Bowbly concurs in this view, and adds that "In cases in which the strangulation is of long duration the danger of death is increased by having to perform a serious operation on a patient who is exhausted from starvation, pain, and vomiting." It is now generally conceded that taxis should not be resorted to if the strangulation has existed for two days or even one day, if there be local signs of inflammation, edema, emphysema, gangrene, or if stercoraceous vomiting be present, or when the patient is in a condition of collapse, or when the hernia is found to be irreducible before strangulation supervened; nor should an effort at reduction be made in cases in which the patient is brought to the hospital with a history of the strangulation having existed for some hours, during which period violent, unsuccessful efforts have been repeatedly made. The majority of surgeons are in accord in the belief that an inflamed hernia should always be treated by operation, and never by taxis.

We believe that gentle taxis should be attempted for the period of about 10 minutes after the strangulation occurs. Should this fail, preparations should at once be made with a view to an operation. As soon as the patient is under the influence of an anesthetic, another gentle effort should be made to relieve the constricted bowel; if this does not succeed an immediate operation should be resorted to. It is generally conceded that taxis of a strangulated femoral hernia is fraught with more danger than that of the inguinal variety (Craly). Cases are recorded of rupture of the bowel occurring in violent efforts at reduction in femoral hernia; statistics prove that there is more danger of a reduction taking place *en bloc*, when the protrusion occurs at the femoral than at the inguinal outlet. Taxis, therefore, can be persisted in for a longer period and with less danger when the rupture is of the latter than of the former variety. It is true that in a small percentage of cases, delay, the local employment of ice, etherization and taxis will sometimes result in relieving the strangulation. The number of cases in which this method of treatment succeeds is so small in comparison with the number in which it fails that it is wise to err on the safe side and operate early, thereby preventing the individual being brought to the operating table with a damaged intestine, and reducing the chance of recovery. We feel assured that no modern surgeon would be content, after a fair effort at taxis had failed, to allow several hours to elapse without affording operative relief to the patient, and would object to trusting to time and renewed resort to taxis to reduce the hernia. Symptoms of intestinal obstruction persisting after reduction of a strangulated inguinal hernia calls for immediate abdominal section, as the probability is that the hernia has been reduced *en masse*. One symptom that we have observed to be frequently present, characteristic of acute intestinal obstruction, is the peculiar character of the uncontrollable vomiting; the individual turns on his side and ejects a large quantity of watery, mucoid material, sometimes tinged with greenish bile. This is repeated at short intervals until the bystanders frequently wonder from whence all the fluid matter is derived.

A case of this description came under our observation during the past winter. We were called to see a strangulated hernia which the hospital resident had been unable to reduce. Under the influence of an anesthetic,

reduction was easily accomplished. On visiting the institution late the following afternoon, we were informed that the patient was suffering from ether vomiting which had continued from the time taxis had been resorted to. Examination disclosed the fact that the abdomen was somewhat tender and rigid on the left side; there was no distention. Temperature 99°; pulse 110. At intervals the patient would turn on his side and eject large quantities of fluid matter. On opening the abdomen the hernia was found to have been reduced *en bloc*; a fibrous band was found constricting the bowel, which was gangrenous, necessitating resection. It is important to see that the bladder is emptied before taxis is made. In one case which came under our cognizance, an old man of 75, with a strangulated inguinal hernia, there was also retention of urine, the bladder being distended almost up to the umbilicus. Repeated efforts at reduction had been made without avail. The patient was catheterized, after which the protrusion was returned without much difficulty.

The so-called "Richter's" hernia is an unusual occurrence, and it is thought a brief history of the ailment as it presented itself to us will not be uninteresting.

The patient was a middle-aged man, who had been an inmate of the Insane Department of the Philadelphia Hospital for some years. Owing to his mental condition an accurate history of the case could not be obtained. The attendant stated that he noticed that the patient had been ailing for a day or so. There was some nausea and vomiting and he acted as though he were in pain. Purges of various kinds were administered with success. Temperature rose to 102°; pulse 115. The abdomen becoming distended, it was decided to transfer him to the surgical wards of the institution. On examination a small lump was discovered, located over the femoral outlet, about the size of a large marble. It was hard, indurated, and slightly movable; no impulse on coughing. A strangulated femoral hernia was suspected, but the resident stated that the lump had existed for at least two weeks before the patient was taken ill and had been treated as an enlarged lymphatic gland. An exploratory abdominal operation was decided upon. On opening the peritoneum, gas and fecal matter escaped. There was diffuse peritonitis. It was found that a portion of the circumference of the ileum had become constricted at the femoral outlet, which was gangrenous, accompanied by rupture, with extravasation of the contents of the bowel. The intestine was resected, a circular enterorrhaphy being performed. All symptoms of obstruction disappeared. The bowels moved freely several times after the operation. Patient died of general peritonitis on the fourth day after operation. Postmortem examination showed the anastomosis to be perfect.

The following case is of interest from the fact that a gangrenous omental hernia existed with practically no constitutional symptoms. The case was seen in consultation with Dr. Stillwell in January last.

The patient, aged 42, had suffered for two years from a reducible inguinal hernia for which he had worn a truss. Three days before he was first seen by us the hernia had become distended and reduction was impossible. As it gave rise to no pain, no further attention was paid to it until the following day when it began to be more or less tender. Unsuccessful efforts at reduction had been made by his physician. The tumor began to increase somewhat in size, the overlying skin becoming reddened and the parts tender to the touch. Temperature rose to 102°; there was slight nausea and vomiting but no symptoms of obstruction, the bowel moving freely. When first seen the hernia was found to be about the size of a lemon, tender to touch; temperature 99°, pulse 120. On opening the sac a mass of gangrenous omentum was exposed to view. The interesting feature of this case is the fact that with a partly gangrenous omentum there should have been little or no constitutional symptoms. Before operation the temperature had fallen from 102° to 99°; the tumor was tender on pressure but there was less pain than there had been previously; the most significant point being the pulse, which was 120 and quite out of proportion to a temperature of 99°.

Of the cases of inguinal hernia operated upon, with the exception of three, these being among the earliest herein recounted, the incision employed was similar to that made for the radical cure in nonstrangulated cases. The advantage of this mode of exposing the sac, over the old method of raising a fold of skin at right angles to the external abdominal ring, and transfixing it, is too obvious to need any comment. In two cases in which the bowels were gangrenous, the general condition of the patients being desperate, the constriction was not

molested; the gangrenous portion of the bowel was freely incised and left in situ. One individual recovered, and the other died, apparently from exhaustion, the patient being well nigh in *articulo mortis* at the time of operation. In a third case the gangrenous portion of the intestine was resected and the divided ends of the gut stitched to the edges of the wound. This person recovered with the formation of a fecal fistula. In three cases resection of the gangrenous portion of the intestines was performed; one being a strangulated femoral hernia, the so-called "Richter's" variety already alluded to; the second, a strangulated umbilical hernia, and the third an indirect inguinal hernia. The latter patient recovered, the other two died of peritonitis. In one case it was found that the area of gangrene was limited to a spot about the size of a thumb-nail. This was resected and the wound closed by continuous Lembert suture. The patient made an uninterrupted recovery. The Murphy button was employed in one instance, the patient's condition being such at the time of operation as not to warrant unnecessary delay. In one case, the O'Hara anastomosis forceps were employed, and found to be most satisfactory. We, as a rule, do not advocate the employment of any of the various instruments devised to accelerate the operation of intestinal anastomosis. We have been able to resect an anastomosis quite as quickly without the aid of any of the devices suggested, as with them. It is a great advantage to acquire the dexterity of operating rapidly without being hampered by the use of special instruments.

The advantages to be derived from a resection of a gangrenous bowel with anastomosis, over that of establishing an artificial anus, are too evident to need comment. It is only in those cases in which the patient's condition is such that any unnecessary delay would add to the danger of a fatal result that an artificial anus should be established. Local anesthesia was employed when the patient's condition at the time of operation was desperate. It was not found, as is so frequently claimed, that the intestines could be manipulated without pain.

In every instance in which the patient's condition warranted the attempt, an effort was made to effect a radical cure after the constriction had been relieved and the contents of the sac returned. The additional work necessary to produce a permanent cure, as a rule, requires but very little additional time, and should always be attempted whenever possible. In cases in which general peritonitis existed, accompanied by paralysis of the bowel, the method of treatment suggested by Dr. Andrew J. MacCosh⁸ was adopted:

Two ounces of a saturated solution of magnesium sulfate was injected into the small intestine as high up as possible by means of a hollow needle attached to an aspirating syringe, the little wound of the bowel being closed by means of a Lembert suture. We are convinced that in at least three cases life was saved by this means of treatment. When peritonitis was present, the abdominal cavity was irrigated with a large quantity of hot normal salt solution and drained. If there had been no injury to the bowel, .65 gm. (10 gr.) of calomel was administered as soon as the patient had recovered from the effects of the anesthetic. A large dose of the mild mercuric chlorid in paralysis of the bowel, with marked distention, is always beneficial; not only does it have a tendency to induce peristaltic action, but it is an excellent diuretic, having a proneness to prevent suppression of urine, which sometimes accompanies abdominal complications. Small doses of the remedy, repeated at short intervals, will not produce the active vermiculation which is obtained by the administration of a single large dose.

In one case of strangulated hernia, on opening the sac, after separating the omentum and intestines, there was found to be, lying posteriorly, what appeared to be a cyst. The nature of the cystocele was not at first rec-

ognized, protrusion of a portion of the bladder being suspected; the urine was withdrawn by means of a catheter, when the tumor immediately subsided, thereby verifying the diagnosis. There were no symptoms present before operation which would tend to show that the bladder was in any way connected with the hernia. We have had the opportunity to observe two similar cases; the patients were inmates of the Philadelphia Hospital, and came under the care of our colleagues. In neither case were there any symptoms present that would lead a surgeon to suspect that the bladder was in any way implicated. In one of the patients the bladder was opened by mistake, and in the other the organ was recognized and returned to the abdominal cavity. Hernia of the bladder may occur alone, or it may be associated with a protrusion of the intestine and omentum. The diagnosis of the condition is but rarely made before operation. The condition may be suspected if there is an unexplainable frequency of micturition, and the history of the tumor shows that it diminishes in size or disappears after urination. The suspicion that the bladder forms a portion of the hernial contents can be determined by drawing off the urine, by means of a catheter. On removing the urine the size of the swelling will diminish; after evacuating the bladder, it can then be dilated by means of either air or water and the tumor will immediately reappear.

The following case serves to illustrate the fact that the condition is seldom suspected before operation:

A patient was admitted to the genitourinary department of the Jefferson Hospital in July last on account of a urinary fistula in the right groin, communicating with the bladder, through which there was a constant dribbling of urine. Two years previous to his first visit to Jefferson Hospital a sur-

Urinary fistula communicating with bladder, following operation upon inguinal hernia. The cross shows position of fistulous opening.

geon, connected with another institution, had operated upon him for what was presumed to be an inguinal hernia. The tumor was found to contain the bladder, which was accidentally incised, and left in situ, giving rise to a permanent urinary fistula. A plastic operation was performed, closing the opening, the patient was discharged cured three weeks later. The cross in the accompanying picture shows the position of the opening of the fistula.

Charles Adams⁹ reports a case of a child who was affected with the usual symptoms of inguinal hernia, no vesical symptoms being present. On opening what was presumed to be the sac, it was discovered that the surgeon had incised a diverticulum of the bladder. Hernia of the bladder alone may be mistaken for an ordinary hydrocele or a hydrocele of a hernia sac. Several cases are on record in which a hernial protrusion of the bladder has been tapped under the belief that the cyst was a hydrocele of the vaginal tunic. On opening the sac the

bladder may be recognized if present, by the discovery of what appears to be a cystic tumor, which usually forms part of the wall of the sac; the usual presence of fat over the cyst, and outside of the sac, the characteristic unstriped muscular fibers, composing the wall of the bladder, and also occasionally the longitudinal veins which are found in the vicinity of the fundus of the organ, which are frequently much engorged and consequently prominent should aid in making a proper diagnosis. Moreover, when the sac has been twisted, preparatory to resection, if the bladder is included, suspicion should be aroused by the unusual thickness of the structure.

Brunner divides hernia of the bladder into three classes: Extraperitoneal, paraperitoneal, and intraperitoneal.

Vesical hernia is said to be more common in men than in women. It usually occurs with the inguinal variety, although a few cases are on record in which it has been found to exist as a femoral protrusion. It is more common on the right side. According to Eccles it is present in about 1% of the inguinal cases. Lossen⁵ reports three cases of hernia of the bladder that came under his observation; all of the inguinal variety. In studying the literature of the subject, he found that out of 3,000 operations for hernia, a portion of the bladder was found in 1.6% of the cases. The most elaborate review of the literature of this subject is to be found in an article published by Alessandri.⁶

When a portion of the bladder is found to form a portion of the contents of the hernial sac, it should be freed from any adhesions that may exist and returned to the abdominal cavity. Should the protrusion of the viscus assume the form of a diverticulum, it is generally considered wisest to resect the pouch and close the opening made in the bladder by two rows of sutures.

In a private patient operated upon at the St. Joseph Hospital for what was presumed to be an incarcerated inguinal omental hernia, the sac was found to contain the ovary and fallopian tube with a piece of indurated omentum. The latter was resected and the ovary and tube freed from adhesions and restored to the abdominal cavity. The tumor had existed for three years, during which time it had been gradually increasing in size with increased induration. The patient stated that it was the seat of much pain during menstruation. The cause of this was inexplicable before operation.

Little is known as to the etiology of hernia of the ovary. The diagnosis is but seldom ascertained before operation. The condition may be either acquired or congenital, the latter form being the most common. The sac may contain only the ovary or the fallopian tube; both structures, however, may be present, associated with other viscera. The rupture usually occurs on the left side; cases are on record in which the protrusion has been bilateral. Statistics show that the inguinal variety is by far the most common. The ovary has been found in Scarpa's space, and even in the obturator foramen. So far as we have been able to ascertain, there is no case on record in which the ovary has been found associated with a femoral hernia.

Paul F. Morf,⁷ in reporting a case of inguinal hernia in which were found a bit of omentum and the fallopian tube, without the ovary, collected the reports of 24 similar cases in which 13 were inguinal, 5 of which were in infants; 10 were crural and 1 was obturator.

A study of hernia and its literature during the past 15 years shows that the subject of its radical cure has exercised the ingenuity and talents of surgeons to a remarkable degree. Different methods of attempting to effect a radical cure of the inguinal variety have been suggested by as many as 25 operators, viz., Ferguson, Nélaton, Ombrédanne, Bernhardt, Deaver, Ball, Stinson, Landphear, Mayhean, Phillips, Czerny, Socin, Thomas, Schawtz, Barker, Martin, MacCuen, Bloodgood, Eccles, Beck, Fowler, Kocher, Halstead, Bassini, and Benjamin.

These gentlemen each recommend a different method of operation in hopes of achieving success.

Many of these operations still have their advocates; some are forgotten; others have fallen into disuse; a few are yet on trial. The fact that so many different methods of operating are still to be tested would seem to prove that the proper method is thus far to be selected, in the hopes of procuring a fundamental cure; this depends on the particular condition that each case presents, as well as the character of the tissue of the individual with whom the operator has to deal. As Eccles very aptly puts it: "Uniformity of procedure in suturing the canal implies that all inguinal hernias are alike and implies similar treatment, a fact that experience entirely and necessarily discredits, each case having to be dealt with on its own merits." This statement appears to us to be the keynote of the situation and explains why a particular operation will not succeed in each instance, and hence the existence of so many different methods to effect a radical cure that are in vogue.

In spite of the fact that the profession is at variance as to the most suitable operation to be selected for the radical cure of hernia, accumulated evidence derived from a large number of different operations has narrowed the choice of methods adopted, by the majority of surgeons in this country, down to a few; which may be enumerated in order of their popularity as the Bassini, Halstead, Kocher, Bloodgood, and Fowler; the last named being still on trial. Each has its advocates; as has been already pointed out, none is probably suitable to every variety of inguinal protrusion. Frequently the surgeon must use his ingenuity, and experience, as a guide to the best method of procedure.

The popularity and confidence evinced by the profession, in the United States, for the Bassini operation are probably largely due to the writings of Bull and Coley, who published an article in the *Annals of Surgery* for 1898, in which it is demonstrated that attempts to effect a radical cure of inguinal hernia were disappointing until the Bassini method of operating, together with the employment of the absorbable suture, was adopted. The results of 1,053 operations are tabulated, of which 522 were performed by Bull and 531 by Coley. Of this number, 618 were performed by the Bassini method, among which there were but 12 relapses; 371 were in children under 14 years of age, and but 3 relapses occurred, giving a percentage of 0.75; 274 were in adults, over 14 years of age; of these 9 cases recurred, making 3.7%. Primary union took place in 95.5%. In a new series of 917 cases, operated on since 1890, 486 patients were well a year after the performance of the operation. Of these, 295 were kept under cognizance and found free from recurrences for periods varying from three to seven years. The mortality in this series of operations was five deaths, or .04%. Since the reports of these cases, the mortality has continued to decrease until today, in unstrangled cases, when the individual has been in a physical condition to submit to a radical operation, the mortality is less than .5%.

De Garmo⁸ gives the record of 250 Bassini operations for inguinal hernia, no deaths resulting. There were 216 patients operated upon; in 34 the operation was performed on both sides. The brilliant results obtained by Bull and Coley, by the Bassini method, together with the low mortality, which is in accord with the experience of numerous other surgeons, has had much to do with the popularity of this operation. From our own experience, and from the knowledge gained from the study of the literature of the subject, we have learned to believe that the Bassini is the proper method to pursue for the radical cure of the majority of patients afflicted with inguinal hernia; but cases will arise from time to time in which we must deviate from the directions suggested by Bassini and select some other means of operating in order to effect a cure. When the conjoined tendon is either so attenuated, or so obliterated,

that Hesselbach's triangle has lost its strongest support, transplantation of the rectus muscle is employed after the method suggested by Bloodgood;⁹ the remainder of the operation is performed by the Bassini method.

While some authorities still advocate aseptic silk and silver wire for the buried sutures when closing the various structures, the mass of clinical evidence is against their employment; the material of choice being kangaroo tendon and chromicized catgut. Coley has noticed 14 cases in which sinuses with relapses of the hernia have followed the employment of the silver wire suture. Four similar cases have come under our observation. In 250 operations performed by Coley,¹⁰ in which kangaroo tendon was used as buried sutures, in 96% primary union occurred, and in no instance was the healing attended by the formation of a sinus. Attention is called to the fact that "A large proportion of cases of suppuration formerly attributed to catgut or imperfectly sterilized buried sutures was really due to other causes, chiefly to infection by the hands of the operator or assistants; it is only necessary to compare the results of wound healing before and after the use of rubber gloves."¹¹ Of 29 cases in which a radical cure was attempted, and in which the after course could be traced, the result may be tabulated as follows:

18 cases indirect inguinal; Halstead 1; Fowler 1; and the remaining after the manner suggested by Bassini.

6 cases indirect inguinal hernia; strangulation existing at the time of operation. In these cases, after relieving the constriction, the Bassini or Bloodgood operation was performed.

1 case indirect inguinal hernia; Bloodgood operation.

1 case ventral hernia; following a celiotomy.

2 cases umbilical hernia; one the ordinary method, the other the Mayo operation.

1 case femoral hernia; Bassini method.

Of the 18 cases of nonstrangulated inguinal hernia, all have remained permanently cured for a varying period from one up to ten years save in one instance in which a recurrence took place one and a half years after operation. In this instance, the protrusion was large and had existed for several years, during which time a truss had been worn constantly. The case was one in which a Bloodgood operation should have been performed. Unfortunately the radical cure was attempted before this method of operating had been suggested. Of the six cases in which a radical cure was attempted at the time that the strangulation was relieved; one recurred in nine months, and another in two years after operation, this patient being 73 years old when the herniotomy was performed; the hernial protrusion having existed 15 years. In none of the remaining cases has recurrence taken place. Only six months, however, have elapsed since the operation for relief of femoral hernia was performed. Clinical evidence has shown that if a recurrence is likely to occur, it usually takes place within six months after the operation, and that the chances of recurrence are greatly diminished after one year.

The case of umbilical hernia operated upon after the method suggested by Mayo has been found to be the most satisfactory for the relief of this form that we have ever employed. It is nine months since the operation was performed and up to this time the individual continues in excellent health; there is no tendency to recurrence. Mayo¹² reported 19 successful operations by this method. Absorbable sutures were employed in all the operations, save in the one in which a Halstead operation was employed, when silver wire was used for the buried sutures. After convalescence, the wire occasionally gave rise to some local symptoms of irritation, and one year after the operation a sinus formed leading down to one of the sutures, which it became necessary to remove. In three similar cases, operated upon by different surgeons, we have been called upon to remove one or more of the buried silver wire sutures which had been employed to close the canal. The employment of the nonabsorbable suture is not recommended.

In the cases in which either a unilateral or bilateral hydrocele existed as a complication, the hydrocele was partially resected in one, and in the two remaining patients the Doyen method was adopted. All eventually recovered. So far there has been no tendency to a recurrence of either the hernias or hydroceles. In the case of hydrocele of the cord, the tumor was the size of a small orange, which was dissected out in its entirety.

In the case of tuberculosis of the testicle, complicated with hernia, it was found necessary to resect the entire vas deferens together with the removal of the testicle. Two years have elapsed since the operation; so far there has been neither a return of the rupture nor any evidence of further tuberculous infection; it is true that the patient has had the advantage of fortifying his constitution by a sojourn for a year and a half in New Mexico.

In seven cases of undescended testicle, associated with inguinal hernia, one was an iliac retention, the testicle being found in the iliac fascia near the internal abdominal ring. In the remaining cases the organ was located either in the inguinal canal or at the external abdominal ring. In four of the cases the hernia had insinuated itself beyond the retained testicle and had passed into the scrotum. In one case the presence of the testicle prevented the protrusion of the bowel beyond the external ring. In this case both the rupture and the testicle were found in the inguinal canal.

Authorities differ in opinion as to the efficiency of a misplaced testicle. Astley Cooper, Curling, Hunter, and Griffiths, from a study of this condition in man, and the lower animals, believe that an undescended testicle fails to secrete fertilizing fluid. Should the condition be bilateral the individual is frequently not only impotent but sterile. On the other hand, Monod, Arthaud, Jacobson, ourselves, and others, are convinced that in the early stage the testicle is still functionally perfect; that the danger of the organ becoming atrophied and functionless is less in the abdominal form of the retention than it is in the inguinal variety.

If the individual is under 30, and is strong and vigorous, the chances are in his favor of not being sterile. If, however, he is effeminate; has a falsetto voice; small undeveloped penis, and absence of hair on the pubis, the condition being bilateral, the testicles having been the seat of repeated attacks of orchitis; the probabilities are that the patient is incapable of procreation. Provided the testicle was healthy, even if somewhat atrophied, it has been our custom to save it whenever it was possible to do so. On more than one occasion we have been gratified to find that the transplantation of an atrophied testicle has developed into almost its normal size when placed in its normal position. Many cases are on record in which men with undescended testicles have married and succeeded in impregnating their wives. For this reason the individual should always have the benefit of the doubt; the sexual glands should not be sacrificed if possible; moreover, it is well known that the loss of one, or both, of the glands is frequently conducive to great mental depression and even melancholia. Dimi-tresco,¹³ after a careful study of the effect of castration, emphasizes the fact that teratology teaches that the testicle has a double function; that of a vascular gland as well as one of excretion. As White very tritely expresses it (White and Martin), the testicle has a twofold function: "The reproduction of the species and the development of the secondary characteristics of the individual." Physiologists have long since recognized the fact that the sexual glands secrete what is known as the "internal testicular secretion," the character of which is unknown, but is supposed, on being absorbed into the economy, to preserve the tone and vigor of the nervous system. In other words, the secretion serves to keep the individual in the normal groove. This is illustrated by the wellknown physiologic axiom that individuals known to be incapable of producing spermatozoa

retain all the characteristics of the male but are unable to procreate (Griffiths¹⁴).

Postmortem examinations made by John Hunter, Goslin, Simon, Tenon, and others, on men whose testicles were well developed, but in whom there existed a congenital absence of the vas deferens, showed that though these individuals were known to be strong and sexually vigorous, yet they were sterile. Clinical experience has taught that in resection of the epididymis and vasa deferentia in cases of diseased condition of those organs, the testicle retains its normal size, sexual vigor is unimpaired, the mentality of the patient remaining undisturbed. This observation places the testicle among the ductless glands. From what has been said it would appear that one of the functions of the testicle is to elaborate a secretion, the absorption of which is of vital importance to the preserving of the normal condition of the nervous system. If this theory be true, the organ should never be sacrificed if there be a chance of its being preserved. In one instance, after freeing the adhesions of an undescended testicle, it was found that on placing the organ in the scrotum the tension on the cord was very great. In order to relieve this condition, the method suggested by Mr. Wood was adopted. The globus major was dissected free from the testicle, far enough down to permit of the organ being inverted. By this means one and a half inches in length was gained. After a testicle had been transplanted not only was it fastened, by means of a suture to the bottom of the scrotum, but the cord was stitched to the pillows of the ring.

A brief history of the following case is of interest, as it may be classified as an accidental radical cure of inguinal hernia:

The patient was seen two years ago, in consultation with Drs. Musser and Ott. He had a large reducible inguinal hernia on the right side which had existed for eight years, for the relief of which he had worn a truss. Five days before he was first seen by us, an acute attack of appendicitis had been developed, accompanied by the formation of an abscess. The rupture, which had been reduced at the onset of the appendicitis began gradually to protrude, presenting all the symptoms of an inflamed hernia, being tense, painful, and irreducible. It increased in size daily. There was nausea and vomiting, with high temperature, but the bowels moved regularly. On opening the appendiceal abscess it was found that the pus had burrowed down and had been discharged into the hernial sac, while the hernial outlet had become obliterated. The abdominal abscess as well as the hernial sac were drained. Since recovery there has been no sign of recurring hernia.

Eleven patients were treated by what may be denominated the "palliative operation"; these cases were of long standing with large hernias, enormous hernial outlets, and atrophied muscular abdominal walls. Eight were indirect, and three were direct inguinal hernias. Two had been incarcerated for a long time; three were partially so; and three were reducible, but the individuals were unable to retain the mass by any form of apparatus that was employed. Four were of large size, the remainder being of the dimensions of the average hernia. These individuals were annoyed by flatulence, eructations, constipation, occasional nausea, and colicky pains. In each instance, the individuals were incapacitated for work so that they necessarily became involuntary idlers and habitues of the Out-Wards of the Philadelphia Hospital. In none of these cases was it presumed that the operation would result in a permanent cure. It was undertaken simply in order to relieve the symptoms and in hopes that after convalescence the individuals would be enabled to retain the intestinal protrusion by means of a properly applied truss. In each instance the result justified what might be regarded as an experimental operation; all were much improved and all were enabled to retain the bowels by means of a suitable apparatus.

In cases of this description, the surgeon cannot follow the fixed rules laid down for any recognized operation; he must utilize his experience and judgment with such

available resources as he may have at command. In two cases in which the rings were large and the conjoined tendon weak, or absent, the Bloodgood method was adopted. For the closure of enormous hernial outlets, with large protrusion associated with an atrophied condition of the muscular structure,—cases hitherto considered as inoperative, Witzel¹⁵ suggested the closure of these large apertures by means of buried silver netting. Gopel reports 11 umbilical and seven inguinal hernias operated upon by this method with but two failures. Willy Meyer¹⁶ strongly advocates the employment of the silver filigree in cases of the kind and reports three successful operations. He calls attention to the fact, which is insisted upon by Witzel, and emphasized by Phelps, that even in those instances in which the wound becomes infected and suppuration supervenes that the filigree pad should be kept intact. In event of the wound becoming infected it has been suggested that the sinus be enlarged sufficiently to permit a curet to be employed, after which the wound should be filled with pure carbolic acid, which is to be washed out with alcohol.

In spite of the apparently favorable results obtained in the few reported cases, we cannot help feeling sceptical as to the value of the procedure, and are inclined to believe that a more extended experience with this method, of attempting to close large hernial outlets, will prove unsatisfactory. As has already been pointed out, the employment of the buried silver suture, from the use of which so much was expected, when first introduced to the notice of the profession, has not come up to the expectations and has in consequence been abandoned by the majority of surgeons. We can see no reason why, therefore, the employment of silver netting, filigree, or allied devices, should not meet a similar fate. Nevertheless, this method of attempting to relieve what was hitherto supposed to be an inoperable condition is still on trial. It certainly merits the careful study and serious consideration of the profession. The gratifying results obtained in the few cases that have been reported are most encouraging, and it is hoped that a more extended experience, with this mode of treatment in cases of this kind, will result in demonstrating that a large number of these unfortunate sufferers who are now condemned to a life of pain and misery may be capable of being relieved.

In each case of the kind operated upon by us, a different method was employed. Eccles calls attention to the fact that in many cases in which large hernias have been operated on, and their contents restored to the abdominal cavity, that a hernia is apt to make its appearance at one of the other outlets. Fortunately, this has not occurred in any of the cases under consideration. It is claimed that in hernias of enormous size, or of long standing, especially if the sac contains an unusual amount of bowel and omentum, with some one of the solid viscera, such as the uterus or liver, that the abdominal cavity becomes contracted, when necessarily the hernial protrusion cannot be restored. As Petit aptly expresses it: "The protrusion has forfeited its right of domicile." This condition must be very rare, as shown by reference to the literature on the subject, where it will be found that hernias of enormous size have been successfully restored to the abdominal cavity even after they have protruded for years. Among recent reports of cases of the kind, we find one which was relieved by operation recounted by Robson.¹⁷ The patient was aged 62; six feet in height, and the tumor reached to his knees. F. T. Stewart¹⁸ reports a successful operation on an enormous ventral hernia, which contained half the stomach, all of the transverse colon, the omentum, and most of the small intestines. A somewhat similar case, as regards size, is reported by DaCosta.¹⁹ Both patients were operated on successfully. Two cases of unusually large hernia are reported by Keen.²⁰ The study of these few selected cases, out of the many that might be cited, seems to show that there

is little fear but that the ability of the operator will enable him to restore the contents of a large hernia to the abdominal cavity; yet it is not uncommon to hear surgeons say that the hernia is too large or has existed too long to permit the contents to be restored to the abdominal cavity.

In our judgment, in selected cases of long standing, incarcerated hernias and those that are reducible, but cannot be retained by the employment of a truss, the chance of relief should be attempted and comfort afforded by a palliative operation. Not with the hope of making a permanent cure, but to relieve the distressing symptoms which naturally accompany such a condition an effort should be made to retain the rupture by means of a suitable apparatus. We are convinced that too many surgeons give too little attention to the selection of a suitable truss in nonoperative cases. As a rule, the patient is sent to a truss maker, who applies the variety of instrument that in his judgment is best suited for the case. It is true, that the average truss sold by instrument makers will usually serve to retain the ordinary hernias. Occasionally the truss does not hold the protrusion in place, when the patient is told that it is impossible to retain the rupture by means of an apparatus. A careful study of the cause which prevents the truss from being satisfactory, together with the anatomic peculiarities which exist in each instance, will result, in the earlier stages of reducible hernias, in keeping them satisfactorily in place by the use of a suitable device. The truth of this assertion was forcibly brought to our notice by a patient under our care, who had been repeatedly fitted with trusses, both in this city and in New York, and without success. While residing in a little country village during the summer months, a harness-maker devised for him an apparatus consisting of pads and straps, which not only retained the rupture satisfactorily, but from which he has experienced no discomfort.

It is generally conceded that age makes but little difference in the mortality when operating on strangulated hernias, provided the constriction is relieved without using taxis inordinately, before resorting to operation. The extremes of life seem to bear the operation well. Audion²¹ exhibited a child before the Paris Society of Obstetrics, who had been successfully operated upon for the relief of a strangulated hernia, one hour after birth.

O'Callaghan²² claims that those aged individuals whose only infirmities are those incidental to advanced years bear critical operations better than the majority of middle-aged people. This condition, he claims, applies especially to women. This is in accordance with our own experience. As one of the surgeons to the Philadelphia Hospital, we are constantly called upon to operate upon very old people affected with strangulated hernia. The prognosis is favorable if there is no marked organic disease, the physical condition of the individual being merely that of senility and the operation being performed very shortly after obstruction has occurred. If the opportunity for performing herniotomy has been delayed and prolonged and violent taxis has been employed, the majority of patients die either from exhaustion or peritonitis. In the cases under consideration the youngest patient was 14, and the oldest 78. In the latter case not only was herniotomy performed for the relief of a strangulation, but a radical cure was attempted as well. Two years elapsed before a recurrence took place.

Regarding the age when a radical operation can be performed for the relief of hernia with the greatest certainty of a favorable result, the views advanced by Coley have been generally accepted in this country, the most favorable period being about the sixth year. In the adult without good cause it is not well to attempt a radical cure after 60, and not then in very large and incarcerated hernias.

Coley teaches that if after an operation a recurrence is liable to take place, it usually does so within six months, and that if the patient remains in a healthful condition for one year it is usually safe to predict that recurrence will not take place. In three cases we have had a recurrence after two years. We believe in the main that Coley's views are correct.

There is a certain class of patients subject to hernia who are unfit for a radical or palliative operation unless the protrusion becomes strangulated, when the danger is greatly increased, but of course the individual must be allowed to take his chances. Unsuitable cases for either a radical or a palliative operation are the obese, in whom the abdominal wall bulges far forward; persons who suffer from any disease of the viscera, and those who have an incarcerated hernia of enormous size and long standing. Those who necessarily wear a truss after an operation are individuals who suffer from a direct inguinal hernia; those in whom an infection of the wound has taken place after an operation; all operations which might be classed under the head of palliative; in old hernias of long standing; in individuals who have to earn their livelihood by hard labor; in emergency herniotomy when the patient's condition would not warrant the employment of the length of time required to do a radical operation; and in children in whom it was found that the hernial ring was unusually large. According to Eccles, those who have a poorly developed muscular abdominal wall and a family history of tendency to hernia should always wear a properly fitting truss after undergoing an operation.

From the study of the cases recited in this paper, the following conclusions may seem to be warranted:

1. The safety of the patient as well as the lowering of the mortality in strangulated hernia depends on gentle taxis being exerted for a short period, which if unsuccessful, should be succeeded by an immediate operation.

2. Herniotomy for the relief of strangulated hernia in the aged is not a dangerous operation, provided it is performed as soon after the constriction has taken place as possible.

3. An inflamed hernia should not be treated by taxis but should be subjected to an operation.

4. No one method of attempted radical cure is applicable to every variety of rupture. The Bassini is suitable to the largest majority. The Bloodgood for those in whom a large abdominal ring and weak or atrophied conjoined tendons exist. The relief of special forms and conditions of hernia must be met by the ingenuity of the surgeon, selecting the operation to the indications presented.

5. The palliative operation is applicable to a large number of selected cases of reducible hernia in which the protrusion cannot be kept within the abdominal cavity by means of a truss, and also in some forms of incarcerated hernia.

6. A radical cure may be safely attempted on patients who have reached their sixth year and on those who have arrived at their sixtieth year.

7. Individuals who submit to what is known as the "palliative operation" should continue to wear trusses after recovery.

8. In cases not applicable to a routine method of operation, the surgeon should strive to do what in his judgment would be the best means of effecting the removal of the entire neck of the sac on a level with the parietal peritoneum; he should if possible, firmly close the opening in the peritoneum after the removal of the sac; he should obliterate the depression of the peritoneum in the vicinity of the internal abdominal ring, bring in apposition the structures, and close the apertures which form the canal through which the rupture protrudes.

9. An aseptic result following a radical operation, with primary union, is essential to obtain a permanent cure of hernia.

10. In cases of undescended testicle associated with hernia, every effort should be made to save and transplant the organ.

11. The method of operating for umbilical hernia suggested by Mayo is probably the most satisfactory for that variety hitherto suggested.

12. Absorbable sutures are preferable to those of non-absorbable material.

In Administering Quinin to Children.—Bordet mixes the quinin with olive oil and puts the amount required into a teaspoonful of cold milk. The child takes this mixture easily. —*La Escuela de Med. Mexico.*

MALPOSITION OF THE HEAD (TORTICOLLIS, CANTED OR TILTED HEAD) WITH RESULTANT ILL-HEALTH, SPINAL CURVATURE, ETC., DUE TO EYESTRAIN.

BY

GEORGE M. GOULD, M.D.,
of Philadelphia.

For years I noticed that many patients, during the practical tests of refraction, habitually held the head in an abnormal position, either sideways, sideways and downwards, or more rarely in some other constrained and unnatural position. These dim memories of such cases, as I gather them to a hazy focus, make me think I must have been bothered with at least hundreds during my 15 years of practice. But like so many important "little" things, these were stupidly ignored, or the attention was not sufficiently fixed upon them to stimulate any effective question as to the cause or significance of the phenomenon. With the explanation of the mystery described in a previous paper, my aroused attention has enabled me to discover about 20 cases within two or three months; and this in the ordinary run of practice. The cause and mechanism of habitual malposition of the head during refraction has now become so clear to me that before establishing the accurate diagnosis of the astigmatism I am able to foretell with considerable accuracy what will be the axis in the dominant eye. The steps leading to the conclusion are roughly as follows:

1. The patient must sit with body erect, head upright, accurately facing the test-letters, the refractionist himself being in such a position that he will observe with ease and quickness any abnormal position of the head of the patient. Some mechanism could be easily devised to aid in the detection of malposition, but I think the best one is the observant eye, and the ever alert attention of the oculist. The old method of absolute inattention to the position of the patient, whereby he sat at any angle with the cards, with legs crossed, with arms and head in any position, the oculist himself standing or sitting anywhere and anyhow, was proper only so long as one was ignorant or scornful of the existence or results of eyestrain.

2. Does the patient's head persistently remain in or return to an abnormally inclined, canted, twisted, depressed, or elevated position? If so, (a) is the patient righthanded and righteyed? If righteyed, the peculiar axis of astigmatism causing the malposition of the head is probably in the right eye. As I have pointed out,¹ right-eyedness is more primary and of more importance than righthandedness, and the two are always associated. (b) Is the patient lefthanded and lefteyed? If so, the ametropic defect is probably in the left eye. Traumatism, leukoma, a high degree of ametropia, or of amblyopia, may, of course, rarely compel a reversal of the natural function of dextrocularity or sinistrocularity.

3. All astigmatism, it should be premised, that can produce head-canting, must be from 8° to 25°—usually from 10° to 18°—to either side of axes 90° or 180°. Compensation of a less degree of aberration than 8° would not be noticed or would be made by the adaptations of the ocular structures, muscles, etc., Compensation for an astigmatic axis farther than 25° from 90° or 180° could hardly be made by the head-inclination, and nature would meet the difficulty in some other way—by amblyopia, heterophoria, morbid reflexes, etc.

4. Is the tilt of the head dextrad? If so, the axis of astigmatism of the dominant eye is in the neighborhood of 75° or 165°. If hyperopic, the axis in the great majority of cases will be about 75°, because most young hyperopes have the axes clustering about 90°, and rarely about 180°. If myopic, the axis will probably be in the neighborhood of 165°, because most myopic astigmatisms are about the 180° axis.

¹ Science, April, 1904.

5. Is the tilt of the head sinistral? If so, the axis of the dominant eye will be usually about 105° , rarely 15° .

6. If the head is thrown directly backward or forward, in a stiff and constrained position, it is probably due to hyperphoria, and the effort to bring the two visual axes to a horizontal.

In the large majority of cases the head is canted to the right, because most young people are righthanded, righteyed, and hyperopic. Hence, the greater number of head-tilters have the axis of their hyperopic astigmatism of the right eye at about 75° .

The explanation of the malposition of the head is, of course, simple, though heretofore unexplained so far as I am aware. The lines of the vast majority of the objects fixed by the eye are at axis 90° , and the next largest number at 180° . Trees, houses, picture frames, doors, windows, figures of wall paper, etc., scarcely need to be mentioned, because the printed letters of every book and newspaper are more important creators of the feeling of and demand for uprightness in objects, and in the mechanisms of visual sensation. If one who is dextrocular and with astigmatism at axis 90° , will place his correcting lens in the right eye at 70° or 75° , and then observe the small test letters with the head upright, and then canted to the right, it will at once become clear why patients with the astigmatic axis organically at 75° habitually incline the head to the right without accurate correction or without any correction.

It hardly needs to be added that, as all orthopedic surgeons know, persistent malposition of the head, especially in the young, will induce secondary spinal curvature.

The number of patients with these canted heads is astonishing. The number of those with secondary and unsuspected abnormally curved spines is not less remarkable. Out of my score of cases of canted heads, I have asked several (or their parents, physicians, etc.) if there was any knowledge of spinal abnormalism. So certain were they that it did not exist that an examination was with difficulty permitted; then the fact, hitherto unknown, was perfectly apparent. In most of these cases I have secured the confirmatory and scientific diagnosis of the wellknown orthopedic surgeon, Dr. H. Augustus Wilson and detailed and accurate reports of a number of cases with photographs will be published in due time. To gather the data, and to wait for cures, by glasses alone, requires time, of course. This preliminary note is made in order to place the method in a general way before oculists and orthopedists, in order that the mystery of the diseases of a large number of patients may be resolved. If only five in a thousand of eyestrain patients have this slightly oblique axis of astigmatism, there must be many thousands of sufferers in the whole country. I suspect the proportion is much higher. Viewed only from the standpoint of the refractionist, the reason for many puzzling failures to cure the ordinary eyestrain reflexes may find a solution in the foregoing suggestion.

To illustrate, I briefly epitomize a few cases to be described more fully in the future:

CASE I.—That already reported in *American Medicine* of March 26, 1904. For about two years there was no detection of the abnormal axis of astigmatism of the right eye, nor of the so-called torticollis, nor of the spinal curvature, because I had allowed the girl to hold her head to the right while being refracted. There was no cure of her headaches, gastric reflexes, malnutrition, etc., by my axis of astigmatism erroneously placed at 90° instead of 75° . There was no discovery of the pain in the chest, coughing, "consumption," etc., and no cure of these symptoms, because of the same blunder in diagnosis. The accurate axis of astigmatism was discovered by the protest of the patient that she "could not see" when her head was held in an upright position. By placing the right axis at 75° she was "unable to see" (*i. e.*, to see clearly and easily) with the head in the old life-long canted position, and the entire train of symptoms—the cough, pain, "consumption," headache, denutrition, canted head, and spinal curvature, all disappeared in a few months. I have received a letter from

her local physician expressing the greatest delight and wonder at the girl's sudden restoration to health, and her "complete transformation."

CASE II.—A young man complained of severe migrainous symptoms, melancholy, inability to carry on clerical work, loss of positions, etc.; he habitually held his head to the right, was "lop-shouldered," awkward, etc. Examination by an orthopedic surgeon revealed pronounced spinal curvature, hitherto unsuspected. He could see well only with the tilted head, and only poorly for continuous writing, even with the head thus inclined. With the astigmatism corrected he can see only with the head erect. His symptoms are disappearing.

CASE III.—A lady of 29 had never weighed over 98 pounds, had always been in feeble health, was very "nervous," had suffered much from headaches, gastric troubles, denutrition, etc. All the physicians and oculists consulted could not find out what ailed her, and could not give her relief. I failed as badly as the rest for over two years. With the experience of Case I fresh in my mind, I noticed at a recent visit that the head was canted to the right. All her photographs show this odd position of the head since childhood. I asked her if she was lefthanded. Emphatically and sorrowfully she said yes, and described the many troubles and worries she had had all her life because of her lefthandedness, and the unsuccessful results of the foolish training she had undergone to make her righthanded. Asked if she had any spinal trouble or curvature, she said she had had spinal pain all her life, but no spinal curvature, so far as she knew. Examination by her local physician and by an orthopedic surgeon showed the existence of the unsuspected curvature. I prescribed correction of her astigmatism, estimated carefully with the head erect, and in three weeks she gained about 10 pounds and was the happiest of women in the relief of many distressing symptoms. The glasses ordered were as follows:

R. + Cyl. 1.75 ax. 70° .

L. + Sph. 0.25 + Cyl. 0.87 ax. 120° .

She had been coerced into writing with her right hand. The tilt of the head to the right shows that she had for the intellectual tasks of reading and writing become righteyed, although much confused and "mixed" as regards other acts. The ametropic error is highly suggestive when one considers her other troubles. A more accurate report made in conjunction with Dr. Wilson will be published.

CASE IV.—This patient, a girl of 13, was sent to me by the orthopedic surgeon, Dr. H. Augustus Wilson, with the diagnosis of rigid dorsal scoliosis, the convexity to the right, and with the head persistently tilted to the right. I found her wearing the same correction, or malcorrection, in each eye: + Sph. 0.75 + Cyl. 0.50 ax. 90° .

Her static correction is:

R. + S. 1.37 + C. 0.62 ax. $75^\circ = 20/20$.

L. + S. 1.00 + Cyl. 1.25 ax. $90^\circ = 20/20$ slowly.

There was perfect muscular balance. Thus, even at 13 this girl is, perhaps, hopelessly injured for life by reliance upon the traveling optician, and the neglect of an axis of astigmatism deflected 15° out of symmetry.

CASE V.—Mrs. H., aged 34, has "never been without backache for five minutes all her life." She has had sick-headaches, or typical migraine, since she was a child, and other headaches between the crises. She has had great daytime sleepiness, flatulent dyspepsia, intense "nervousness," melancholy, uric acid symptoms, "rheumatism," etc. She was treated for spinal curvature at about the age of 18 and pronounced cured. The curvature was thought to be due to a fall. This was found to be one of the rare cases in which the head was persistently tilted to the left and also slightly backward. As she was not lefthanded, I said that her axis of astigmatism must be about 105° in the right eye, or if she had acquired sinistocularity (left-eyedness) the axis of the astigmatism in that eye must be about 105° . Upon testing, I found the following error:

R. + S. 2.00 + C. 0.62 ax. $100^\circ = 20/40$ +

L. + S. 2.50 + C. 0.25 " $105^\circ = 20/30$ +

with 9° of esophoria.

Thus, whether dextrocular or sinistocular, the tilt of the head was necessarily to the left. She is, however, righthanded and righteyed, although the right eye is the more amblyopic. Examination of the spine shows, despite the "cure" at 18, that it is curved to the left in the dorsal region.

CASE VI is interesting because of a rare peculiarity. The patient, a woman, 30 years old, has suffered much and long; she has never weighed over 85 pounds. She has had her ocular muscles tenotomized many times, and was wearing simple spheric glasses from the tenotomist. Her true refraction is:

R. + Sph. 3.25 + Cyl. 1.00 ax. 180° .

L. + Sph. 3.00 + Cyl. 0.87 " 105° .

Under the influence of these latter glasses she has had sudden relief of distressing symptoms, and as sudden reestablishment of normal muscular balance. The highly interesting facts are that, even with the ametropic correction given above, she has only 20/40 visual acuity with the right eye, but 20/20- with the left; that she has herself noticed that she tilts her head to the left in near-work (not for distance); that her left axis is 105° ; and that with proper glasses she does not tilt the head. Thus it is clear that the amblyopia of the right has produced a partial left-eyed-

ness, greatly complicating the other reflexes of eyestrain, and all relieved by proper correction of the astigmatism.

The investigation of the significance and suggestiveness of the ocular cause of inclined or tilted heads, and of many cases of spinal curvature, will probably throw much light upon other obscure problems of ophthalmology, neurology, and especially aid vastly in the practical solution of many difficulties and perplexities of practical refraction work and of the daily life of patients. One can foresee how it may be one of the causes of heterophoria of all kinds, especially of cyclophoria; of a number of chronic and inflammatory conditions of the fundus; of strange reflex ocular neuroses, etc. It will certainly explain many of our failures to cure migraine, hysteria, neurasthenia, and many other reflex ocular neuroses, even after the most painstaking ocular tests made without the knowledge of the slightly variant axes of astigmatism, the canted heads, etc. The extent to which it may influence ophthalmic and general medical practice appears incalculable. It may even lessen the prejudice of those who criticise "the exaggerations of the hobby-riding oculist," although this is hardly probable.

SOME FACTS CONCERNING RADIUM AND THE USE OF THE INTRAGASTRIC RADIODE.¹

BY

J. A. STORCK, M.D., PH.M.,
of New Orleans, La.

Professor of Diseases of the Digestive Apparatus, New Orleans Polyclinic; Professor of Physiology and Materia Medica, New Orleans College of Pharmacy; Visiting Physician to Charity Hospital, New Orleans.

Radium derives its name from the Latin radius, a ray, a term descriptive of the radiant energy which characterizes the metal. The fact that certain bodies possess the power of emitting invisible and penetrating rays was first brought forward by Seguin. Many years ago it was noticed that if a coin or a print were shut up in a box in close proximity to a sheet of blank paper, an image was made, even in the absence of solar light. These mysterious functions were formerly accounted for as the product of superhuman agency; but Seguin suggested that the bodies capable of producing this singular phenomenon did so by giving off a continuous stream of impalpable particles, projected at such a velocity as to make an impression on the substance which they bombarded. This hypothesis was rejected by physicists, who declared that such a radiation of matter going on forever without loss of weight was impossible. Though, indeed, almost inconceivable, yet this hypothesis is the best explanation so far offered to account for the strange behavior of the latest scientific wonder, radium.

The discovery by Röntgen of the röntgen rays, led to much speculation and experimentation. It was probably on a hint from M. Poincare, the mathematician, that M. Henri Becquerel was led to the investigation, and finally, in 1896, to the discovery of the radioactive properties of uranium and its compounds. These radioactive properties are the wellknown Becquerel rays. The discoveries cited led to further research by Mr. Schmidt and M. Curie. Working along these lines they discovered thorium, which, like uranium and its compounds, has also the power of discharging an electroscope. In 1898, Madame and M. Curie discovered that uraninite, or pitchblende, has four times the radioactivity of metallic uranium. While engaged in further research on pitchblende, Madame Curie found what was supposed to be an element, and named it polonium, after her native country, Poland. It was in 1899, after much widespread research and eager investigation, that Madame and M. Curie and M. Bemont made the discovery of the remarkable substance, radium.

Radium is obtained from uraninite or pitchblende,

which is found in Saxony, Bohemia, Cornwall and Colorado, and yields only about three grains of radium to the ton. Professor William Ramsay says that radium is undoubtedly an element in the sense in which the term is generally used. It belongs to the alkaline group of elements. No pure radium has as yet been produced, its bromid and chlorid salts being generally used for experimental and medicinal purposes. Among the curious facts stated concerning radium, Professor Lippmann, of the Sorbonne, claims to have established the fact that radium has the power of continually generating heat without drawing upon any external source of energy. Its salts are always hotter by from 2° F. to 5° F. than the surrounding atmosphere, and it is capable of dissolving its own weight of ice every hour.

Beside the heat rays, three kinds of radiation are constantly being evolved from radium, namely, the alpha, beta and gamma rays. The alpha rays are of very slight penetrating power and are stopped by the thinnest sheets of metal or paper. They carry positive electric charges and are thought to be particles shot off from the radium atoms with enormous velocity.

The beta rays are more penetrating, carry negative electric charges, and are exactly like the cathode rays of a Crookes tube.

The gamma rays are analogous to röntgen rays, will pass through many substances opaque to light, and will penetrate several coins placed one on top of the other.

The most rational explanation of this strange phenomenon is given by J. J. Thomson in his corpuscle theory, which assumes the existence of particles of matter called ions, thousands of times smaller than atoms. It is supposed that myriads of these corpuscles are thrown off at such a tremendous velocity as to generate the force which is known as radioactive energy. Seguin's idea, we may recall, gives reinforcement to the Thomsonian corpuscle theory. The incessant bombardment occasioned by the particles thrown off from radium may be demonstrated by the Crookes spintharoscope.

About 1899, Becquerel discovered that the rays of radium were deviated by a magnetic field in the same manner as the cathodic rays. Professor Rutherford and Frederick Soddy have found that if the active air of radium be cooled by passing it through a tube cooled by liquid air, it loses its activity, the active power remaining in the cold tube. On warming the tube, the active portion is carried forward, and with it the power of discharging an electroscope.

"There is this difference between the radiant energy of radium and the röntgen ray. Radium induces an activity which persists, while the activity of the röntgen ray ceases on the removal of the ray." Radium is said by Becquerel to have the property of imparting its radioactivity to other bodies with which it comes in contact. Sir Wm. Ramsay and Mr. Soddy have shown that the emanation from radium is a gas, and that this contains helium. They have determined that the fresh emanations from radium do not show the spectrum of helium, but as it decays, helium is produced in minute, but ever-increasing quantities. As radium gives off helium, itself an element, radium is thought to be composed of two or more elements. Or, is it possible, that the ancient and much-derided theory of the transmutation of metals receives an exemplification in the transformation of radium into helium?

In the summer of 1902, at a meeting of the British Association, Dr. J. J. Thomson is said to have stated that if a square centimeter of surface were covered with pure radium, it would lose only 1 mg. in 1,000,000 years. This corresponds to similar statements made by Becquerel.

Among the peculiar properties of radium we may mention these:

Radium transforms oxygen into ozone, it colors glass and changes white phosphorus into red; it decomposes silver salts on sensitized photographic plates. Its rays

¹ Read before the Orleans Parish Medical Society, March 26, 1904.

pass through aluminum, wood, etc., only partially through glass, and not at all through thick lead foil.

Mr. McLennan found that rain caught in a vessel and immediately evaporated to dryness imparted radioactivity to the vessel in which it was evaporated. It is claimed that the waters of the celebrated springs at Bath, England, contain radium and therefore give off radioactive emanations.

Caution must be observed in carrying radium about the person. Becquerel reports a burn from carrying a small particle in a glass tube in his vest pocket; while Curie, in the investigating spirit of the scientist, subjected himself to quite a severe burn from this substance.

Uranium is taken as the unit in measuring the radioactivity of radium; 1,000 radioactivity signifies that radium is 1,000 times more active than metallic uranium.

As radium loses some of its luminosity on exposure to moisture, it is desirable to keep the metal in sealed glass or aluminum tubes. Its luminosity may be increased by subjecting it to a high temperature.

No sooner had the wonderful properties of radium been made known than physicians began to speculate on its therapeutic properties. When the price reached such a figure that small quantities fit for medical experimentation could be purchased, physicians began to use it in the treatment of different diseases, and some report it of considerable value as a therapeutic agent.

Dr. John McIntyre, of Glasgow, reports the cure of two cases of lupus, one of the hand in three weeks, and one of the nose in four weeks. He also reports a case of rodent ulcer much benefited after two weeks' treatment. Dr. Oudin, of Paris, says that he has cured some cases of lupus, but he does not give the details. Professor Gusenbauer reports to the Vienna Medical Society, that in 20 cases of cancer treated by radium during the six months ending July 1, all showed more or less improvement and in two cases cure was established.

Drs. Willy Meyer and W. J. Hammer, of New York, record a case of recurrent cancer in which the röntgen rays and Coley's fluid had been used for about a year without avail. Radium of 300,000 activity was used in this case, and while a cure was not effected, much improvement was noticed, the growth becoming much smaller and less painful.

Dr. Andrew H. Smith, of New York, saw a patient with a rodent ulcer who had been treated by the röntgen rays without benefit. After five treatments by the

Fig. I.

Fig. I.—Emanation spray.

radium rays, perfect healing of the parts took place. In the *British Medical Journal*, Soddy suggests that the emanations given off from radium bromid, dissolved in water, may be used in the treatment of pulmonary tuberculosis. The inhalation of these emanations leaves a thin film of radioactive substance in the lungs. This causes the phenomenon of induced radioactivity, which remains in the air cells of the lungs, exercising a germicidal power over diseased tissue long after the emanations have been exhaled. This leads us to infer that these emanations might be used in the treatment of tuberculosis and cancer of the intestines, and also in cancer of the stomach. For this purpose an apparatus such as here shown may be utilized (Fig. I). Caspari, Ashkassi and Sir Henry Crookes have proved that radium has marked bactericidal properties. There are several attachments now on the market for applying

radium to different parts of the body. Fig. II shows a radiode devised by Dr. J. B. Shober. It consists of an aluminum capsule containing radium, and a long rubber handle, allowing it to be used in the nose, throat, vagina, rectum, etc. The whole instrument can be inserted in a glass tube (Fig. II, b) and thus employed, or the radiode can be used alone without the glass tube.

Wishing to test the effect of radium on cancer of the stomach, and being unable to find any literature on the subject, or any mention of radium having been used in the treatment of this disease, I devised an instrument specially intended for this purpose. I call it an intragastric radiode. It consists of an aluminum capsule containing 10 mg. of 7,000 radioactive radium, attached to a flexible copper wire passed through a suitable

Fig. II.—Shober radiode. Fig. III.—Storeck intragastric radiode. Fig. IV.—Intragastric radiode end projecting from rubber tube.

rubber tube (a stomach tube will answer every purpose), the capsule being allowed to project beyond the end of the tube. The intragastric radiode is so manipulated as to come immediately, or as nearly as possible, in contact with the growth. So far I have had experience in its employment only in one case, that of a white male, aged 70, a wretched subject and an inoperable case.

The diagnosis in this case was positively established before beginning the use of radium.

The patient is markedly emaciated and cachectic, has vomited blood (coffee-ground vomit), and the tumor at the pyloric orifice is easily palpated. Several examinations of the stomach contents showed absence of hydrochloric acid, rennin and pepsin, and the presence of lactic acid and the Boas-Opller bacilli. He complained of severe pain. The application of radium in this case was made three times a week, allowing the radiode to remain in the stomach on an average of three minutes. After the third application he claimed to be relieved of his pain, and after the fifth application, vomiting, which had been almost continuous, had almost completely subsided. Since beginning the use of radium in this case, three weeks have elapsed, and there has been no recurrence of the pain. I notice no diminution in the size of the tumor, and the cachectic condition is about the same as before treatment. He says that he eats somewhat better. I shall continue the use of radium in this case, with the hope of giving more positive benefit to the patient.

In discussing the strange and unaccountable characteristics of radium, Lord Kelvin says that the discovery of the Becquerel rays has placed the first question against the principle of the conservation of energy.

In a recent article, Sir William Crookes says: "Certainly no discovery of modern times has had such wide-embracing consequences and thrown such a flood of light on broad regions of hitherto inexplicable phenomena, as this discovery of M. and Mme. Curie and M. Bemont. The existence of matter in an ultragaseous state, material particles smaller than atoms; the existence of electric atoms or electrons; the constitution of röntgen rays and their passage through opaque bodies; the emanations from uranium; the dissociation of the elements—all these isolated hypotheses are now focused and welded into one harmonious theory by the discovery of radium."

THE TREATMENT OF PNEUMONIA.¹

BY

R. S. THORNTON, M.B., C.M., EDIN.,

of Deloraine, Manitoba, Canada.

Pneumonia is a disease which will not submit to cast-iron rules of treatment. It presents a great variety of types. While the pathologic process in the lung in all cases is the same, the clinical conditions to which it gives rise are so varied that we have, in practice, not one disease to treat, but many. In no disease does the patient himself constitute so large a factor in the question of treatment as in pneumonia.

Pneumonia presents different aspects and problems to be met according as it occurs in the infant, in the period of adolescence, in the aged, in the strong and robust, in the plethoric, in the anemic and nervous, in the debilitated, in the alcoholic. It presents different questions at various stages in the same case. The type is also modified by conditions outside of the patient. Pneumonia as it attacks the dweller in cities has features different from that affecting the dweller in rural districts. It varies with East or West, with North or South, with highland or lowland, with moist climate or dry, with summer or winter. It is recognized as a germ disease, so we naturally find that different epidemics present types of varying virulence.

These conditions may, in part, account for the very contradictory methods of treatment advocated; some writers lay greatest stress on the need of stimulant treatment being probably influenced by a greater experience with asthenic types, others lay equal stress on the need of sedative treatment probably because of a greater experience with sthenic types, while a third class strikes a middle course and advocates the expectant method.

The expectant plan of treatment is based on the opinion that pneumonia is a self-limited disease, following a regular course, terminating by crisis at or about the eighth day, to be followed by a more or less prolonged convalescence, with or without permanent injury to the lung. In fatal cases death is due to the virulence of the disease, to exhaustion, to embarrassment of the circulation, to complications.

From these premises it is argued that little need be done except to treat symptoms and sustain the strength, but while we agree with the premises, the conclusion does not seem to be warranted by experience. The course of the disease may be favorably modified, and crisis averted even in typical cases, and the first days of the disease are those in which we can do most to help our patients. It will be granted by all, that there are many cases in which because of the severity of the attack or of some weakness in the individual, a fatal result is inevitable in spite of all advantages of nursing and treatment. On the other hand, there are many cases in which the infection is so slight or the area of lung involved so small, or the patient's system so unfavorable to the development of the disease, that the attack will terminate favorably without treatment, or

become abortive, crisis occurring by the third or fourth day. But between these extremes there is a large middle class, constituting the majority of all cases, in which proper management is of the utmost importance and there is no disease under the care of the physician in which so much may be done by proper management to bring about a successful result. I use the word management rather than treatment because we are so apt to associate the latter term with medicinal treatment. The administration of medicines is by no means our first or our most important duty, and while I am convinced of the efficacy of proper medicinal treatment at certain stages and conditions of the malady, I am also convinced that the final issue depends just as much on proper attention to many details, any one of which by itself may be of little moment but which in the aggregate may decide the balance between success and failure.

The great variety of types and conditions has already been referred to. It will be impossible to deal with these in detail in this discussion, and I shall direct attention to a few considerations applicable to all cases, for since the pathologic process is the same there must be some principles in common.

What is the chief indication that ought to be kept in mind first, last, and all the time, the one measure, having which some others may be neglected, and lacking which all others may fail to win through? Is there any indication of such primary importance? I think there is. It is rest. Pneumonia is an inflammation and if there is one principle in therapeutics established beyond question it is that of the necessity and value of rest in all inflammatory processes. This is so obvious that one feels almost like apologizing for mentioning it, and yet we all fail in giving full effect to the principle, and in the various textbooks I do not find it emphasized as it ought to be. It means here rest, both general and local. It means a firm bed—not a feather tick which allows the patient to slide around and wearies the muscles for lack of support. It means the use of the bed-pan, the urinejar, the feeding cup. It means that every muscular movement that can be avoided must be avoided, so that the heart which has the great strain of the illness to bear, shall not have one unnecessary beat, or the embarrassed lung one unnecessary respiration. It means especially that there must be no talking, that visitors must be rigorously excluded, that no one shall be in the sickroom except those directly ministering to the patient. We have all seen cases which have been doing well, running a course of moderate severity, in which we have confidently expected a perfect recovery, yet one day we find the temperature up, the pulse quickened, the patient restless and excited and a train of unfavorable symptoms set up which go from bad to worse, the whole disturbance having its origin in a prolonged or exciting conversation. Doubtless some pneumonia patients have in this sense been "talked to death."

All this means a nurse to give effect to these directions, a trained nurse if possible, but in any case some one individual, whose whole duty it should be to attend to the patient.

The temperature of the room must be as equable as possible at 65° to 70°. The atmosphere should be moistened, especially in winter, when stoves or furnaces dry the air. The moist atmosphere is soothing to the irritated respiratory membrane, and it may be medicated with some volatile antiseptic, such as carbolic acid, creosote, and so on, the selection being made to suit the taste of the patient. The food of the patient must be concentrated and nourishing.

The next point I wish to discuss is the use of poultices. In hospitals generally these have been discarded. In our practice here we find a strong popular sentiment in their favor which it is difficult to antagonize. The non-use of poultices in a severe case may give rise to adverse criticism. Why should we put on poultices and what do we expect them to do? Lauder Brunton says "poultices

¹ Read before the Southwestern Manitoba Medical Association.

are almost always of use when there is pain." Now the acute pain of pneumonia takes place usually before complete consolidation sets in during the acute congestive condition, and especially as the disease process approaches the pleura. There can be no doubt that the poultice gives relief and is gratefully welcomed by the patient. But when consolidation has taken place the poultice should be discarded. It cannot affect the disease process in the lung. It is heavy, requires frequent changing, exhausts the patient, and interferes with the principle of rest, which we have already insisted on. No matter how carefully it is done, the changing of the poultice always quickens the heart-beat (sometimes 20 beats to the minute), and some considerable time elapses before it returns to its former rate. This, too, at a time when the heart is feeling the great resistance to the circulation in the lung. If, then, poultices are used at all they should not be continued beyond the stage of congestion. There are other methods of using heat, more convenient to apply and not open to these objections. A smart mustard plaster, pure, applied warm, and retained till the skin is thoroughly reddened, then the cotton jacket, and the hot water bag if continuous heat is desirable will give as satisfactory relief. The cotton jacket must not be too thick or it, too, may be objectionable.

The general constitutional treatment of pneumonia must be that of a toxemia. It is, therefore, of the utmost importance that the bowels and kidneys be kept acting freely, and a sufficient quantity of water must be taken to let them do so, not only to eliminate the waste products, but to diminish the absorption from the alimentary canal of the products of fermentation going on there. As an initial purge, a dose of calomel is often of great service, but the best results are secured by the administration of a saline laxative.

Coming next to the question of drugs and still following the indication of rest, we find certain disturbing factors, such as pain, restlessness, sleeplessness, delirium, and cough. These must be allayed so far as possible, and for the pain there is nothing better than an initial dose of morphin—1 cg. ($\frac{1}{8}$ gr.) by the mouth or hypodermically, to be repeated after some hours if the pain demands it. It is not well, however, to continue its use beyond this point, because it locks up the secretions, thus interfering with the proper action of stomach, bowels, and kidneys, and rather increases the tendency to cerebral congestion. But we have a most valuable weapon in the use of another opium derivative—codein. This drug does not interfere with the secretions, and does not affect the digestion, and while acting as an excellent general sedative, it does so without depressing the heart. Indeed, by slowing the pulse slightly and thus saving the heart unnecessary exertion, it indirectly acts as a stimulant. It has a specially soothing effect on the respiratory mucous membrane, and while it checks the irritating cough it does not interfere with the necessary expectoration of the sputum. It is a very safe and satisfactory medicine to use with children. It is best given in small repeated doses, from 5 mg. to 16 mg. ($\frac{1}{12}$ gr. to $\frac{1}{4}$ gr.) for adults, and from 1 mg. to 5 mg. ($\frac{1}{60}$ gr. to $\frac{1}{12}$ gr.) for children according to age and condition, once in three hours.

At this point, while considering the question of sleep and rest, I would emphasize the importance of carefully considering the directions given to the nurse. It is an instructive experience to stay continuously with your patient for 12 hours. Medicine is to be given say once in three hours, food at similar intervals, and all the other details to be attended to, so that, unless you carefully contrive to have as many things as possible done at one time, the patient is being constantly disturbed.

There are three drugs used more or less constantly in

pneumonia for their effect on the circulation—aconitin, digitalin, and strychnin. Aconitin, or its congener—veratrin—is recommended in the early stages of sthenic cases. By the advocates of the expectant treatment, the use of either of these or similar drugs is condemned as heart depressant. If, by quieting the circulation, we can save the heart from over-exerting itself, we are doing it better service than when we stimulate, if it require it, and that is precisely what aconitin does. It reduces temperature, and therefore tissue waste. It dilates the arterioles, decreasing blood-pressure and the pulse-rate. In medicinal doses it does not depress the heart. That occurs only when relaxation is excessive.

Digitalin and strychnin are especially of value near and after the time of crisis, when the right ventricle is apt to be losing ground and dilating because of the opposition in the lungs. I would merely point out that the use of digitalin should be begun some time before its effect is wanted, as its action on the muscular fibers of the heart takes some time to make itself manifest.

In passing, let me enter a plea for the more general use of the active principles rather than the uncertain strength of tinctures and fluid extracts. We all use strychnin, and few, I think, would care to depend in emergency on such uncertain quantities as are represented in tincture of nuxvomica. Let us do similarly with aconitin, digitalin, and other drugs. For hypodermic use we are careful to select the pure single agents, and the accuracy of hypodermic medication depends as much on the drugs used as on the method of employing them. Surely it is as reasonable to be as accurate in administering drugs by the mouth.

So far I have not mentioned alcohol in the form of whisky or brandy, and simply for the reason that for many years I have abandoned its use altogether. In ammonia, either as carbonate or aromatic spirits we have as satisfactory a diffusible stimulant. Strychnin and digitalin have a better permanent effect, and in cases of collapse, atropin is greatly preferable.

Pneumonia being a germ disease, the question of treatment directed against the specific cause has to be considered. Experiments have been made and an anti-pneumococcic serum has been tried but the results so far have not been satisfactory. But of late years a method of treatment by the use of creasote or creasote carbonate has given very good results. Creasote may best be administered in enteric pills, coated so as not to dissolve in the stomach and thus avoid gastric disturbance.

The dose in this way would be from .065 gm. to .13 gm. (1 gr. to 2 gr.) every three hours. Carbonate of creasote, is a brown syrupy liquid, and may be administered in an emulsion of acacia, or in cinnamon water or other aromatic water. Given in this way it has no very disagreeable taste and children take it readily enough. The average adult dose is .6 cc. (10 m.) every three hours. It seldom produces any gastric disturbance and in most cases seems to affect the stomach rather favorably. The value of this treatment is proportionate to the earliness with which it is adopted. In cases in which the stage of complete consolidation has not been reached the temperature falls and in 48 hours the patient has become convalescent. When the stage of consolidation has been reached the symptoms are ameliorated and the temperature falls gradually instead of abruptly and a critical discharge does not occur. Some few patients are not influenced by it at all. It is important that the creasote or creasote carbonate should be continued throughout convalescence. The probable explanation of its action is that of an internal antiseptic, and we must remember that pneumonia is really a systemic disease, with a local manifestation. It seems reasonable to suppose that the creasote would follow the microorganism and its toxins throughout the circulation. But whatever the explanation of its action the evidence in favor of its beneficial effect in pneumonia is accumulating. My own experience with the drug corroborates these claims. I have here the temperature chart of a patient whom I have had under my care since I was requested to prepare this paper. Now, in estimating the effect of any treatment on any given patient, the physician must be sure that it is not a case in which spontaneous cure was likely to take place.

The patient, a man, aged 41, had been treated for alcoholism two years previously. He had had an attack of pneumonia in the same lung about 12 years previously. There was a family history of tuberculous disease, a brother and a sister, and probably also the mother, having died from pulmonary tuberculosis. When I made my first visit he had been in bed 36 hours; temperature was 104°, respirations 34, pulse 104; he was complaining of severe pain in the side, and expectorating the characteristic rusty sputum. Examination showed the right lung was involved, the disease starting in the apex and also in the apex of the middle lobe (a circumstance usually to be regarded as significant of tuberculous infection, although subsequent microscopic examination failed to show the tubercle bacillus) and already the heart was showing the stress of the illness, the pulse being irregular. Twenty-four hours later there was complete percussion dullness over the right lung from apex to base. Any one seeing this patient would have given a very guarded prognosis, and most physicians would have given an unfavorable prognosis. The patient recovered completely under the treatment as outlined above.

However, it is not so much the fact of recovery that I wish to point out, as the course of the temperature. Here was a typical case, with bad features, but note the very gradual and steady descent of the temperature so that when the time of crisis did come there was little or no reactionary depression. Were this an isolated case it would still show that typical crisis can be averted in typical cases, but I may say that since adopting this treatment I have not once seen a crisis, and all my cases in which recovery has taken place have been characterized by the same gradual and steady decline of temperature without any critical discharge.

Splenic Anemia.—J. H. Davenport and H. C. Pit§ report a case which they regard as unique in that severe anemia and wandering spleen were both present, other reported cases of the latter condition not being accompanied by marked anemia. The patient was a girl of 16, who had amenorrhea, edema, petechial hemorrhages and a large pelvic tumor. Diagnosis was in doubt but ovarian cyst seemed most probable. The tumor extended to the level of the umbilicus. Operation revealed the tumor to be the enlarged spleen which had a long, slim pedicle; it was not removed. The patient died 18 days afterward, bloody vomiting and nose-bleed having been severe. The blood count was as low as 1,176,000 reds, 2,800 leukocytes, and hemoglobin 20%.—*Yale Medical Journal*.

PRELIMINARY REPORT OF A CASE OF SPLENOMYELOGENOUS LEUKEMIA SHOWING MARKED IMPROVEMENT UNDER THE USE OF THE RÖNTGEN RAY.*

BY

CHARLES H. WEBER, M.D.,

of Philadelphia.

The patient whose case I report was admitted to the Episcopal Hospital October 19, 1903, having been referred by Dr. William A. Steel, who had made the diagnosis of splenomyelogenous leukemia.

The usual treatment with arsenic was instituted, and continued for several weeks, when the röntgen ray was substituted. This latter treatment was suggested by the favorable report of Senn upon this method as employed by him in a similar case.¹ Two additional reports have appeared, one by Brown,² the other by Bryant and Crane,³ in each of which there is noted an entire disappearance of symptoms and abnormal blood conditions. The history of the patient is as follows:

Mrs. B., a widow, aged 53, was born in Germany; occupation, housework. Her mother died of carcinoma of the stomach at the age of 72; her father died of pneumonia at 59; six sisters and two brothers are living and well. No history of tuberculosis or other disease in the family was obtainable. The patient states that she never had any of the ordinary diseases of childhood. She was healthy as a young girl, her first illness being typhoid fever at the age of 29. She recovered after having a relapse, and has been well since. Menstruation began at 16 years, and has always been regular and painless. Has three children, all living and well. Menopause occurred three years ago.

The symptoms of her present illness began about two years ago, with pain in the splenic region. It was of a sharp character, like the prick of a needle, and was increased on pressure or deep inspiration. This was diagnosed pleurisy, and treated accordingly. Shortly after this attack she noticed that her abdomen was becoming large and that deep inspiration was performed with difficulty. She felt weak and lost her appetite; complained of headache almost continually. Bowels were normal and she slept well. These symptoms have persisted or have become more severe until the present time. She complains now, in addition, of great drowsiness and vertigo, and failing vision.

Examination.—Patient appears fairly well nourished, though she has lost flesh for several months. She has a peculiar clay-colored complexion; some capillaries of the face are enlarged. Heart: Apex beat is in the fifth interspace, to the left of the midclavicular line; dullness, third rib above left border of the sternum. There is heard a systolic blowing murmur, most marked at the left of the sternum, in the third interspace; this murmur is also heard at the apex and in the vessels of the neck.

Spleen extends a finger's breadth to the right of the median line, and below, an inch above the crest of the ilium; upper boundary, eighth rib. It is hard and tender. The liver extends two inches below the costal margin. Right kidney is freely movable and can be easily palpated.

Urine: Specific gravity, 1.016; acid; marked reaction for albumin; no sugar; a few hyaline casts, epithelial cells, and leukocytes.

Blood: Red blood-corpuscles, 2,400,000; white blood-corpuscles, 328,000; hemoglobin, 30%. The differential count shows: Polymorphonuclear, 40%; myelocytes, 40.8%; eosinophiles, 13.3%; small lymphocytes, 0.74%; large lymphocytes, 4.42%; basophiles, 0.74%; nucleated reds, 24; megaloblasts, 3. There is a moderate poikilocytosis. The patient has no fever.

November 1.—The patient has been in bed since admission. The spleen has diminished slightly in size, the present boundaries being: Half an inch to the left of the median line; lower border extends to a point on a line with the umbilicus. Treatment, Fowler's solution.

November 18.—Blood-examination at this date shows: Red blood-corpuscles, 2,306,000; white blood-corpuscles, 293,600; hemoglobin, 48%.

November 20.—The patient has been in the hospital for one month on arsenic treatment. Her hemoglobin percentage has increased, but otherwise there has been no improvement in her condition. She has been encouraged to remain, by the promise of röntgen ray treatment, the delay in starting this being due to the installation of a new and improved apparatus.

December 19.—Since the last note the patient has been receiving daily applications of the röntgen ray. A low tube was used, placed 12 in. to 14 in. above the body and focused over the spleen. The applications were of 15 minutes' duration. Upon

* Read before the Section on General Medicine of the College of Physicians, of Philadelphia, April 11, 1904.

this date she left the hospital, wishing to spend Christmas with her family. She was gone nearly three weeks, during which time she came twice for treatment. Blood-examination made several days before her departure was as follows: White blood-corpuscles, 129,400. Differential count: Polymorphonuclear, 66.8%; myelocytes, 25.4%; eosinophiles, 4.2%; small lymphocytes, 1.6%; large lymphocytes, 1.6%; basophiles, 0.4%; nucleated reds, 2; megaloblasts, 2.

January 6.—Patient has returned to the hospital for readmission. Her appearance and general condition have improved during her absence. Weight at present is 111 lbs., a gain of 13 lbs. since her first admission. Daily röntgen ray treatment has been resumed. Spleen extends to left parasternal line at a point $1\frac{1}{2}$ in. above a line through the navel; lower edge $\frac{3}{4}$ in. above the middle of Poupart's ligament.

January 18.—Blood-examination. Differential count: Polymorphonuclear, 82.6%; myelocytes, 11.6%; eosinophiles, 3.4%; small lymphocytes, 0.8%; large lymphocytes, 1.6%; red blood-corpuscles, 3,448,000; white blood-corpuscles, 68,800; hemoglobin, 71%.

January 21.—Patient discharged from hospital to return three times a week for röntgen ray treatment.

February 29.—Blood-examination: Red blood-corpuscles, 4,400,000; white blood-corpuscles, 23,000; hemoglobin, 82%. Differential count: Polymorphonuclear, 80.4%; myelocytes, 7%; eosinophiles, 3%; large lymphocytes, 7.8%; small lymphocytes 1.6%; basophiles, 0.2%.

March 18.—During the past month the spleen has diminished greatly. It can be palpated at the costal margin, the edge being hard and nodular. The skin of the chest and abdomen is pigmented (mahogany color). There is some desquamation of the skin of the abdomen. The skin of the face, though rosy, has a brownish tinge. There has never been any reaction from the use of the röntgen ray, as described by Senn. Patient's weight 122 lbs.

April 10.—Blood-examination: Red blood-corpuscles, 4,720,000; white blood-corpuscles, 7,200; hemoglobin, 72%. Differential count: Polymorphonuclear, 73.6%; eosinophiles, 2.6%; large lymphocytes, 18.2%; small lymphocytes, 5.6%; no poikilocytosis; red blood-corpuscles stain uniformly; no variation in size; no myelocytes seen.

The patient has been under observation for a period of less than six months, during which time there has been a progressive improvement in her general condition, symptoms and also in the blood. For the last five months she has received no medication, only the röntgen ray. There have been no fluctuations in the blood counts, as exhibited in some cases. The myelocytes have gradually decreased, both relatively and absolutely, until at this last examination they have entirely disappeared; in fact, at present her blood is practically normal and, if she were to come under observation now for the first time, a proper diagnosis would be impossible. She herself says that she feels as well as ever, and is particularly relieved by the disappearance of the splenic tumor. This case is not reported as a recovery, but there seems to be sufficient evidence to justify the belief that the röntgen ray has been of therapeutic value in the relief of her condition.

Many cases of improvement under various methods of treatment are on record, a list of remedies too long to enumerate, of which the most popular is arsenic. The effect of an intercurrent infection has proved beneficial in some cases; other patients have improved without any treatment, but the inevitable result in all these patients is relapse and finally death. Whether in the röntgen ray we have a method which will give permanent relief, time alone will determine.

I am indebted to Dr. A. A. Ghiskey for the blood-examinations, and to Mr. Samuel Riegel for giving the röntgen ray treatments.

THE THERAPY OF ACETANILID.

BY

J. R. JOHNS, M.D.,
of Philadelphia.

Although classed with antipyretics, acetanilid is employed most frequently as an analgesic. The literature of this drug is quite as interesting as that of any in the materia medica. The circumstances attending its discovery as a therapeutic agent and its disastrous association with other remedies make the history of acetanilid unique. Notwithstanding the fact that the toxicology of this drug can be written from its early reports,

the drug is today much employed and deserving of more extended use.

The reason for the foregoing discrepancy is not difficult to find. Acetanilid is a comparatively new remedy. Its relation to antipyrin and the importance attached to antifebrile treatment, at all hazards, at the time when the latter was so favorably received everywhere, have determined the classification of acetanilid and character of its literature. But time has changed the general methods of fever treatment. The mere fact of an elevation in the body temperature is not now considered an indication for the administration of antipyretic drugs. The cause of the fever, the condition of the patient, and the suitability of the antipyretic remedy are considered as well. The result is that antipyretic drugs are less frequently employed now than twenty years ago.

Another fact in the literature of acetanilid is attributable to this same relationship, namely the too large dose quite generally stated. Antipyrin is administered in large quantities. The characteristic antipyretic effect requires full doses, as much as 1.3 gm. (20 gr.) repeated in half doses every half hour till 2.6 gr. (40 gr.) if needed, are given. Acetanilid does not require such quantities; indeed, is not safe in such doses. The Dispensatory makes two statements relative to the dose of the latter which are quite contradictory. In one place it says, "The full dose is .65 gm. (10 gr.) repeated if necessary," and subsequently adds: "The dose is .32 gm. to 1 gm. (5 gr. to 15 gr.)."

The dose of acetanilid may be said to range from .13 gm. to .52 gm. (2 gr. to 8 gr.) with a maximum for 24 hours of about 2 gm. (30 gr.) Only exceptionally, and in well-selected cases, is a dose of .65 gm. (10 gr.) justifiable, and it is probably never necessary. Effects appear after the administration of an ordinary dose, say .26 gm. to .39 gm. (4 gr. or 6 gr.) in about half an hour, reach their height in two or three hours and disappear again after about six hours. For strong analgesic or antipyretic effects a dose of .39 gm. to .52 gm. (6 gr. or 8 gr.) may be repeated in one or two hours. I have seldom, if ever, used a larger dose than .39 gm. (6 gr.) The combination with caffein is no doubt a good one, and for many uses I am partial to the formula containing also monobromated camphor, found in all tablet lists.

Acetanilid expends itself in the domain of the sympathetic nervous system and is particularly inimical to morbid reflexes in the sensory sphere. In larger doses and continued treatment it reaches the motor sphere as well; thus producing, in its fullest effects, both the analgesic and antispasmodic action. It cuts off the morbid reflexes and in so doing removes the staff of disease and tends to reestablish a feeling of well-being.

Small doses, .065 gm. to .130 gm. (1 gr. to 2 gr.) in adults and less than .065 gm. (1 gr.) in children—produce a sense of ease and quiet within; and, even in very much larger doses, such treatment is not followed by a feeling of depression. These facts determine the large range of utility and great value of this drug.

Referring to the toxicology of acetanilid we note that this drug will cause general anesthesia, but that it does not reduce a normal body temperature; which facts but emphasize my contention, namely, that acetanilid is primarily an analgesic. It also indicates that antipyresis is the result of the action of the drug upon morbid functions of the sympathetic nervous system. The result of this action is an absolute loss in the production of heat. Incidentally heat radiation is generally more or less increased by diaphoresis resulting directly or indirectly from the effects of the drug. In the same manner tissue metabolism is reduced and thus the production of heat decreased.

This increase in heat loss and decrease of heat production, though considered conjointly and in their fullest effects, can not adequately account for the full

antipyretic action of acetanilid, as is quite generally admitted. They are, as stated, incidental to the main effects of the drug—the latter quite indirectly so. Diaphoresis does not always accompany reduction of fever with acetanilid, and we know by conclusive experiments that it is not essential that it should. Again, toxic doses materially reduce the oxygen carrying and ozonizing function of the blood, thus decreasing the production of heat in the system. We may presume that this effect is *nil*, or comparatively so from medicinal doses. On the other hand the production of heat is correspondingly large in fevers. The mere reduction of the temperature reduces heat production.

To sum up, the effects of acetanilid upon the nervous system are sedative, analgesic, antispasmodic, antipyretic and antiperiodic. In addition to being beneficently palliative these effects are in a large measure also curative.

Acetanilid is our best remedy for the relief of pain not due to local inflammation, reflex pains, etc., the cries of nerve centers, the fury of nerve storms, the dyscrasias of the sensory nervous apparatus. This class of pain is more common than any other. Our best illustration is probably found in the characteristic fulgurant pains of tabes. The class embraces gastralgia, functional dysmenorrhea, sciatica, rheumatism, neuralgia, migraine, etc. When there is marked irritability the remedy may be advantageously supplemented by one of the bromids.

Acetanilid is a valuable adjunct to other major remedies, as a modifier of action. Such remedies are quinin, salicylates, opium, and calomel. In some instances it acts mainly as a correction of the effects of such remedies. In others, and I may say the majority of instances, it is effective as well, in controlling and curing the condition for which treatment is pursued.

Fifteen years ago I gradually fell into the practice of always giving acetanilid with quinin. I found the effects more pleasant to the patient and the results of treatment more satisfactory to myself. Especially is the former the case when full doses of quinin are given. Then it was considered good treatment to repeat a .52 gm. or .65 gm. (8 gr. or 10 gr.) dose of quinin to "break up," as we said. In such treatment a moderate dose of acetanilid cut off the train of reflexes resulting from the full doses of quinin.

The next step in my experience was to observe that a larger quantity of acetanilid and a smaller quantity of quinin will yield better results. I then, as a rule, gave 18 gm. (2 gr.) of the former with an equal or double quantity of the latter. The same remarks, except as to quantities, apply to the salicylates. Here, in connection with the modifying effects upon the main remedy, we have the analgesic and antipyretic effects so essential in the treatment of rheumatism.

Acetanilid is antagonistic to opium in some of its spheres of action and supplemental in others. It takes from opium that subtle soporific influence which follows its anodyne effect. I have observed, taking for instance an adult who is unused to the effects of either drug, that 16 mg. ($\frac{1}{2}$ gr.) of morphin, given at night for severe reflex pain, afforded relief and sleep, followed next day by languor; but when combined with .26 gm. or .39 gm. (4 gr. or 6 gr.) of acetanilid, I obtained relief from pain without the resulting drowsiness, sleep, and languor. Instead, there was brilliant wakefulness, with very marked mental activity for five or six hours. In another trial, 8 mg. ($\frac{1}{4}$ gr.) given alone, was inductive of sleep, but when combined with .26 gm. (4 gr.) of acetanilid, of wakefulness.

The value of acetanilid in combination with calomel in the treatment of many acute and subacute maladies in children cannot well be overestimated. I know of no condition in which small doses of calomel, with or without sodium bicarbonate, are generally used in which acetanilid could not be advantageously combined in the treatment.

The irritability so generally present calls for small doses of an anodyne, once so largely supplied in Dover's powder, but now so much better provided in small doses, .03 gm. ($\frac{1}{2}$ gr.) or less, of acetanilid.

The drug is eminently adapted to play a most important part in such treatment. It is a good intestinal antiseptic, tasteless, etc. In most conditions so treated there is some febrile action which, while not calling for direct treatment, adds much to make the patient irritable and peevish. Treatment with calomel and acetanilid in small doses every hour, followed in due time by a mild purgative, if needed, affords early relief and makes for a speedy cure.

In conclusion, let me add two other instances in which acetanilid is the best drug to employ: 1. When the indications for treatment are not clear; when you do not know what to give—give acetanilid. It will afford a measure of very acceptable relief without further masking the diagnosis of the condition or interfering with the inauguration of any other course of treatment. 2. When only the psychic features of the case demand drug treatment, give acetanilid in .13 gm. (2 gr.) doses. It is as harmless as any placebo and may be depended upon to produce a favorable mental effect.

THE MEDICAL INSPECTION OF SCHOOLS.

BY

HELEN MACMURCHY, M.D.,

of Toronto, Can.

Compulsory education, now almost the rule in civilized countries, sometimes means compulsory infection. But the medical inspector is abroad in the land, and the movement for the medical inspection of schools is making steady progress. It was needed.

"How many times, to take an almost everyday example, does not one hear the distressing complaint that 'the child had never had a day's illness until it went to school, and scarcely had it started school life before it got one infectious disease after another?' Some parents have a positive dread of sending children to school at all on this account, and one cannot wonder at it, for the control exercised in the matter by those competent to act is practically nil."—[*Medical Magazine*, Eng.]

"We have, for instance, a child suffering from diphtheria in school, not ill enough to attract special attention. He may be there a day or two before the disease is discovered, with a mild, unrecognized case, or he may be there for a much longer time in a condition for spreading the disease. During this time he may attach the infective matter to the desk, chair, books, slates, slate pencil, penholder, sponge, drinking cup, door knob, window sill, banister, wainscoting, or to anything else which he may handle or touch after using his fingers about the mouth. The fact that these things may become infected with diphtheria in this way has been conclusively shown in the laboratory by Professor Ernst.

"In kindergarten schools the danger of spreading the disease by a single case is much greater, both by direct and indirect infection, because these children by virtue of the different processes of teaching are brought into much closer contact with each other, and they use a large number of objects in common, which are very liable to become infected. One unrecognized case under such circumstances may give rise to a dozen more, and without our being able to trace one of them to its particular source.

"The following account of a kindergarten teacher may be of interest at this point: 'Regarding the contact of children with each other in the kindergarten and the interchangeable use of material, it is as follows: The chairs for seating the children are small, portable ones. These are carried from one place to another as the classes need them; no one chair is allotted to any particular child; all are used in common. The tables at which the children sit are long enough for four or five children to sit at each. It is impossible to arrange so that each child may have the same chair or the same place at the table regularly. The material used is such that it is almost impossible to let one child use any portion of it solely as his. We have but two dozen worsted balls with which to teach color, form, and direction; and we have 70 children to use the balls. It is the same with everything else. The blocks used are handled by two or three classes during the same day. The iron rings, wooden sticks, wooden planes, pasteboard tablets, wooden beads, weav-

ing needles, and worsted needles are used in common. The napkins used at lunch time are washed once a week, and taken out before then if really soiled, otherwise they are folded and returned to the drawer ready for the next day. The picture books are enjoyed by all, and the dolls are used at every recess. In playing the games the children stand holding hands on the ring, and when there is good attendance they are crowded.

"Many of the games bring them very close together, for instance: In playing the 'bird's nest,' the mother bird chooses six or more children, who kneel upon the floor in a semicircle; she twines their arms about each other to imitate weaving the nest. She then chooses three children, who are put close together, necessarily, in the nest, and then the game proceeds. This is a typical bird game, and is very pretty; but in time of epidemic of throat diseases, we do not like to play it in our kindergarten, as it brings the heads so near each other. There are other games, of course, which do not need such close proximity as the one described; but all the games are for two or more children to take part in, and they are generally in contact in some way, if only holding hands."

"Numerous instances have come under our observation in which a child has been found in school suffering from an infectious disease, by the medical inspector of schools, and sent home. This case has been followed in due time by other cases in children whose only discoverable exposure was that which occurred in the schoolroom."

"In the examination of the children in school, every facility is extended to the doctor by the teachers, and he in turn reaches a satisfactory conclusion with the least possible delay or annoyance to anyone. There being frequent need for looking into the children's throats, we provided the inspectors with something for a tongue depressor which could be used once and destroyed, and thus get rid of the danger of communicating any disease from one pupil to another, and avoid unfavorable criticism on that score. These little pieces of clean pine are made for us at a cost of one-tenth of a cent each. They are without objection in use or appearance, and will burn as easily as a match, which is the intended destiny of each after being used once. The thermometer is rarely a necessity in these examinations, and when used is treated with due care."

"The corps of inspectors has become an organized association, which meets once in two months to discuss the manifold medical questions which arise in the performance of their duties."—[Dr. S. H. Durgin, of the Boston Board of Health.]

"How little protection would come by trusting to the parents of some public school children is shown by their action in the following cases: Four children were sent home at the time of the discovery of the epidemic on the morning of May 5, 1897. They all had suspicious looking throats, and in view of the existing epidemic the diagnosis of diphtheria was warranted clinically. With each child was sent a note, stating that there had been some cases of diphtheria in the schoolroom, that the child had a sore throat that probably was diphtheric, and that the school inspector advised calling the family physician. The mother of one of the children brought him back herself in the afternoon and was abusive to the teacher for sending him home. I turned up just in season to get my share. I was informed that I did not know what I was talking about, that his nausea and vomiting and constitutional symptoms two days before were due to indiscretion in eating, that his sore throat was simply 'tonsillitis,' which he was subject to, and that the patches in the throat were of no importance. The other children might have diphtheria, but *her* boy didn't, 'because he wasn't sick enough.' She refused to let me take a culture, and was informed that the boy would not be admitted to the school until a negative culture had been obtained by myself, or if she preferred, by her family physician. She did not go to the family physician until another week had elapsed and a culture proved negative. I feel reasonably sure, however, that an earlier culture would have been positive."

"The three other children returned next morning. Two brought verbal messages that they were well enough to come to school. The third brought a note from his father, saying it was absurd to say his boy had diphtheria. *Cultures were taken from all three throats, and all proved positive; i. e., the three children had diphtheria.* The mother of one of these was not convinced even then. She called another doctor to prove that the school doctor was wrong, and discharged him when he obtained a positive culture, and she was only partially persuaded there was no trick to it when a third doctor also found a positive reply to his culture."—[H. D. Arnold, M.D., of Boston.]

HISTORY OF THE MOVEMENT FOR THE MEDICAL INSPECTION OF SCHOOLS.

On the Continent.—During the nineteenth century efforts were made in this direction in Belgium, Sweden, Switzerland, Germany, Austria, Hungary, Holland, Servia, Roumania, Russia, Portugal, Spain, and especially in France, where, in 1833, 1837, and 1842, laws were passed relating to school physicians and school hygiene. In Paris, the system was reorganized in 1878, and placed upon its present basis in 1884. In Paris each school district for medical supervision contains from 15 to 20 schoolrooms and the annual salary of the school physicians

is 800 francs. The school physician must visit each schoolroom under his charge at least once a fortnight, and oftener if necessary. The Minister of Public Instruction in France has just received the report of a Commission on Tuberculosis in Schools appointed by the government, and having regard to their report, has ordered that each scholar in an elementary or secondary school shall bring with him or her a certificate, giving his or her height, weight, and chest measurements, and that these measurements shall be kept on file by the school physician and repeated every three months.

In Germany the plan of medical inspection varies a good deal in different cities. That of Wiesbaden has been recommended by the Government for general adoption. In Wiesbaden the school physician is expected to examine the physical condition of all new pupils, to visit the classrooms under his charge from 10 a. m. to 12 a. m., once a fortnight, or oftener, if necessary. Each pupil is also weighed and measured periodically by the class teacher and a record is made on the child's health-card twice in each year.

Japan and the Argentine Republic.—Japan has had school physicians since 1893 and the Argentine Republic in South America has now medical inspection of schools.

Great Britain.—In Great Britain all the great public schools and many private schools have regularly appointed school physicians.

The School Boards of London, Edinburgh, Bradford, Leeds, Sheffield, Bristol, Hull, Birmingham, etc., have all appointed medical officers. In London, the school physicians are assisted by school nurses, a plan that has been received with great favor.

The Royal Commission on Physical Training for Scotland, as a result of its investigations, has advised that all schools should be under regular medical inspection.

In Canada, the City of Toronto appointed a medical inspector of public schools in 1903, and a very complete record with regard to diphtheria in schools is kept at the City Health Office. A law has also been passed by the Province of Ontario, providing for the medical inspection of schools where cases of diphtheria or scarlet fever have occurred.

The United States.—Philadelphia, Boston, New York, Chicago, Washington, Detroit, and a great many smaller cities and towns in the United States, have systematic medical inspection of schools. Preliminary investigations satisfied the boards as to the necessity, but in Boston, for example, although a small appropriation for this purpose was secured from the City Council in 1892, it was not till a severe epidemic of diphtheria occurred in 1894 that the system was inaugurated.

The city of Boston is divided into districts, each containing a school population of about 1,400, and a medical inspector is assigned to each district, at a salary of \$200 a year. It is the duty of the inspector "to visit each school daily, early in the morning, and to examine all children whom the teacher thinks ailing. The teachers report to the principal all pupils who appear to be ill, the physician examines them, and if any one is found too ill to remain in school, from any cause, he is sent home for the observation and care of his parents and family physician. If the illness is contagious, the child is ordered home and the case is reported to the Board of Health. It is also the duty of the inspector to visit the homes where contagious diseases exist."

"The method of medical school inspection in New York City has recently been radically changed. As it is now more complete and satisfactory than that employed in other cities, it may interest many physicians to know in just what this present method consists."

"The isolation of such children as might be sources of contagion was formerly left entirely to the judgment of the teacher. Some of these were not very observant; others, depending solely on their own diagnostic skill, neglected to send patients with contagious diseases to the medical school inspector. This was the weak point in the system. In order to obviate this defect, the inspector now visits the classroom himself once a week, and examines each pupil. This examination is not a thorough one, but, as almost all of the acute exanthema and the contagious affections of the eyes and the skin have typical manifestations on the head, face, or hands, or in the mouth and throat, the examination is sufficient to detect any such disease. The visit to the classroom also gives the inspector an opportunity to instruct the teacher and demonstrate to her those symptoms which are to be especially noted, in order that she may be able

to select those who are to be sent to the physician for examination. The teachers are aware that it is possible for them to contract a contagious disease from their pupils, and that the more thorough the inspector's examination, the less this danger is. For these various reasons the teachers observe their pupils more carefully and more intelligently.

"There are at present 80 medical school inspectors in the borough of Manhattan, each having three or four schools, with a total of 4,000 to 5,000 children to inspect. The schools are situated in one neighborhood, so that as little time as possible is lost in going from one school to another. The inspector visits his schools before 10 a.m. every morning, and examines, in a room set aside for that purpose, all pupils who have been isolated by the teachers as being possible sources of contagion. Children presenting any symptoms of measles, scarlet fever, diphtheria, mumps, whoopingcough, or chickenpox, are sent home immediately; those affected with contagious diseases of the skin or eyes leave at the next recess. Each of these children is given a card on which are stated the reason for exclusion and the date on which the child should return for re-examination, with the advice to the parents that the patient be promptly treated.

"After the day's work is finished, a report is sent to the department stating, on a separate blank for each school, the number of pupils examined, and the name, age, and address, with the reason, in each case excluded.

"At the end of each week, a list of those pupils who have been absent for three or more days on account of sickness is obtained from the school. These are visited, and the character of the disease is determined. If cases of contagious disease are found, the name, address, disease, and its duration are sent to the department. The inspectors report every Saturday morning at the central office to receive instructions.

"In the lower part of the city, where the number of children requiring treatment is much greater, nurses have been appointed by the department. They visit each school at a stated time every day, and treat in the school, children who have been sent by the inspector, with the diagnosis and an outline of the treatment to be followed. In this way, many that would otherwise be sent home (impetigo contagiosa,) ringworm of the face, acute conjunctivitis, etc.) may remain in school. The nurses also visit the homes of the pupils excluded on account of parasitic diseases of the skin and scalp, and treat these patients, also giving instructions to the mother, the object being that the child shall lose the least possible amount of time from school.

"The number of cases of trachoma in this same neighborhood being very great (due to a large Russian and Polish population), the department has opened special wards in the old Gouverneur Hospital building for the local and operative treatment of these patients. The children are given a card on which the date of each visit is stamped, so that the school inspector knows whether the patient continues under treatment. From December 17, 1902, on which date the wards were opened, until February 2, 1903, the total number of visits has been 11,968. Of these, 7,726 were in old cases, 4,242 were in new cases, and 608 were in operative cases.

"The department has power only in cases of contagious disease. However, in other affections, such as enlarged tonsils, adenoids, otitis, errors of refraction, etc., the inspector may call attention to the existence of such trouble and advise treatment. In no case, however, does he treat or prescribe drugs." [Charles Hermann, M.D., in *The New York Medical Journal*.]

IS AN EPIDEMIC NECESSARY?

Is an epidemic necessary in order to convince a community of the necessity for the medical inspection of schools? Sometimes it is. In Boston the mayor and council were persuaded to make an appropriation for this purpose in 1892, but delay after delay occurred until an epidemic of diphtheria visited the city in 1894. That settled the question. The inspectors went to work and during the first year they found within the school-rooms and sent home 73 children ill with diphtheria. How many more cases of diphtheria were prevented by these medical inspectors?

In Germany it was measles:

"Public meetings were held at Berlin after a serious epidemic of measles, in which three-fourths of the scholars of the local academy suffered because the school was not closed. These meetings resulted in the passing of resolutions as follows: 'Laymen and physicians demand that each school have a physician assigned to it, to have charge of the general hygiene of the building and be watchful over the health of scholars; to see to the proper heating, ventilation, cleanliness, and, if necessary, disinfection of the building; to order the closing of the school when the heat becomes excessive and in time of epidemic; furthermore, to examine new scholars, in short, the school physicians should protect the scholars against the dangers of school life.'"—[*The Medical Record*, January 22, 1898.]

DOES THE MEDICAL INSPECTION OF SCHOOLS PAY?

Chicago tried it first in 1900. Here is the result so far as diphtheria and scarlet fever are concerned:

In 1899 there were 3,931 cases of diphtheria with 843 deaths.

In 1900 there were 3,303 cases of diphtheria with 797 deaths.

In 1899 there were, 5800 cases of scarlet fever, 533 deaths.

In 1900 there were 3,475 cases of scarlet fever, 226 deaths.

The result—2,953 cases of illness prevented and 353 lives saved would pay well and repay many times all the money spent on medical inspection of the schools.

New York first sent medical inspectors to its schools in 1897. The first day, March 29, 1897, gave the following results:

	Cases.
Diphtheria	14
Measles	3
Scarlet fever	1
Contagious eye diseases	35
Mumps	3
Croup	1
Chickenpox	8
Skin diseases	8
Parasitic diseases	67
Children excluded	140

Cases of neglect of cleanliness were numerous.

In the last annual report of the health officer of Boston it is shown that there were found in the schools in 1902, 1,040 children having dangerous communicable diseases as follows:

Diphtheria	7
Scarlet fever	2
Measles	69
Whoopingcough	119
Mumps	50
Chickenpox	57
Tonsillitis	738
	1,040

It pays to prevent these diseases. If there are 40 or 50 children in each class it pays to prevent them carrying infection to 39 or 49 other homes beside the one already infected.

"There is no reason why this plan of school inspection should be limited to large cities. It seems to me that in smaller communities, where the number of schools is smaller, it would be even easier to execute the plan.

"In Detroit a medical inspection of schools was started in February, 1902. The method of inspection is similar to the one in vogue in Chicago and is as follows:

"A medical inspector visits each school in the morning about the same hour. Before his arrival each teacher sends to the principal's room any pupil who is suspected of having some communicable disease or who has been absent from school. The medical inspector immediately examines all pupils thus detained in the principal's room, and any child found with a communicable disease or any symptoms of such disease is at once sent home with a notice signed by the principal of the school informing the parents of the child's condition and advising them to send for a physician. In no case does the medical inspector prescribe for the child or have anything to do with it except at school. Whenever a child is excluded from school on account of a disease required to be quarantined by the Board of Health, notice is sent immediately to the health officer. The home of the child is then quarantined and the school, or at least the room from which the child came, promptly and thoroughly disinfected. For the examination of throats of the children the examiners are provided with wooden tongue depressors, each one to be destroyed immediately after it has been once used.

"This plan was adopted in Detroit in February, 1902. It was first submitted by the health officer to the Board of Health and the Board of Education. The latter body offered its cooperation in the work, and the Board of Health instructed the health officer to begin the examinations in four schools. As there were no funds at the disposal of any of the city commissions for this work, volunteer inspectors were called for and the response was very encouraging. The results obtained by this experiment in four schools were so satisfactory that on March 1, 26 schools were added to the list, making a total of 30, and on May 1 the number was increased to 50 schools, with one volunteer inspector working daily in each school. An idea of the scope of this work may be had from the following facts and figures:

"The total number of pupils examined in Detroit during the 4½ months, from February 1 to the close of the school year, was 10,554, and the total number excluded 914. The diseases for which the children were excluded, together with the number excluded for each disease, were as follow:

Scarlet fever	11
Diphtheria	1
Tonsillitis	314
Measles	78
Mumps	128
Impetigo	24
Whoopingcough	19
Chickenpox	79
Pediculosis	151
Other diseases	117

From these figures, given in detail, the value of this work can be estimated. When we consider, for example, the cases of measles and mumps that were excluded, 78 cases of the former and 128 of the latter disease, nearly all in the early stages, and when we remember that these diseases are communicable before the rash appears in the one case and before the parotitis is apparent in the other, in other words before a physician is called in either case, then we must conclude that this plan of daily inspection of schools is probably the only way in which these diseases can be discovered early and thus hundreds of other cases prevented. Again let us look at the scarlet fever column. Eleven children were found with the disease and sent home. In each instance the schoolroom was immediately disinfected and no more cases followed. There is, of course, no telling how many cases would have followed if these 11 children had remained in school, but it is safe to say that the number would have been quite large. Another condition for which we have excluded children is pediculosis (lice) and when you look at the number sent home for this cause, 151, you will, perhaps, be surprised. These children are kept home until they can no longer communicate the loathsome disease.

"These are some of the good results to be obtained from a systematic, daily, medical inspection of schools."—[Dr. Guy L. Kiefer, Medical Health Officer of Detroit.]

"The system of medical inspection of schools should be under the control of the Board of Education. It should be a department of the school system, and only related to the Board of Health as the two bodies may be of mutual benefit in performing their respective functions. It would be less liable to interfere with any other department of the school system. It would be more liable to become a factor of the school system, assisting the teacher in determining the physical condition of all defective children, thereby enlarging its sphere of usefulness.

"By daily medical inspection of the pupils, diseases are detected in their incipency, and therefore most easily dealt with, and, in cases of infectious diseases, they can be isolated. The treatment of diphtheria with antitoxin, it is well known, should be as early as possible to insure success. In November and December of 1898, in the city of Chicago, there were 219 patients with diphtheria treated with antitoxin. Of these, nine died, but there were no deaths among those treated on the first or second day. Medical inspection of schoolchildren is the best means of preventing disease. It should be the aim of the medical profession to prevent sickness as well as to cure the sick, and by doing this the profession is attaining its highest ideal. Medical inspection is truly prophylactic work, and when it is once well established our physicians will be able to broaden their field of usefulness by the more careful study of the growing body in relation to exercise and education. The field is a practical one and is worthy the ambition of the best talent of our race. It would be asking too much to expect the teacher to be able to diagnose the cases of disease which appear before her. This requires medical skill and can only be properly done by regular physicians.

"The prevention of disease and physical disorder is a public blessing, particularly the prevention of the spread of contagious diseases. It requires time, energy, and skill on the part of some one to accomplish this end. The public purse ought to pay for that which is a public benefit. Medical inspection would be a valuable benefit to a community in directing the people to sanitary measures which they would practise in their homes by reason of having their attention directed to them. It would be educative by spreading among the people more generally a knowledge of the common laws of health.

"Disease not checked or prevented in children is what makes dependents in adults. Our country is burdened with the insane, the feeble-minded, the deaf and dumb, the blind, the epileptic, orphans, and paupers. Ohio is a fair representative of the States. There was spent in Ohio in 1894 for charities \$4,175,915.47. The income of all the colleges of the State for 1896-97 amounted to about \$1,000,000. Over four times as much was spent on charities as for higher education. Education is nothing without health and a physical constitution. It is high time that we strike a blow at the root of all this defectiveness. One does not wonder at the condition of adults when he reflects on the percentage of defectives among children. Strong, robust, healthful childhood would prevent much of this inability in adult life. The cost of medical inspection is but a bagatelle compared to the good it would accomplish in mitigating suffering and making those self-supporting who otherwise would probably be objects of charity. We spend millions in taking care of these dependents. Would it not be true economy and equally just and appropriate to care alike for all children, who show beginnings of spinal curvature, defective vision or hearing, signs of pulmonary tuberculosis, or symptoms of nervous diseases of every kind? These diseases detected in their incipency could generally be cured, but they are of such a nature as to require medical skill for their detection.

"Chronic diseases of all kinds often have their beginnings in environment. It requires a bacteriologist to detect the germs of disease. The State which provides a place for the assembling of children and does not provide for the prevention of contagious or any other disease, the germs of which could be detected by a competent expert, is morally responsible.

"Compulsory attendance at school is fast becoming the law of the various States. We are thereby often requiring a child

to attend school when he possesses some physical defect of sight, hearing, or other bodily ailment, of which he is not aware, but which makes school life distasteful and a burden, and which might be easily detected and cured by a skillful physician. The State should demand attendance at school on the part of those for whom the schools exist, but it should also see to it that no child blindly suffers from a defect that could be cured.

"A child physically defective so that he cannot succeed well with his studies and gets behind his class grows to dislike school, and if his moral training is not of the highest standard he becomes a truant. It would be better to prevent dislike for school and truancy than to have truant officers and reformatories. It is better to lead the child in the right way by skillfully correcting all physical or mental defects and surrounding him with the proper environment than to build walls of prohibition and costly State penitentiaries. Do not wait till a criminal is made to reform him. Train him so he cannot become one. Truly much is being done for the education of children, but much more can be done. The cost of a system of medical inspection would be more than saved in the lessened cost of the care of adult criminals and dependents.—[H. W. Tickle, of the University of Colorado.]

THE DUTIES OF MEDICAL INSPECTORS OF SCHOOLS.

In his report of the Committee on Medical Inspection of Schools in New Jersey, Dr. Walter B. Johnson, chairman, made some wise suggestions to the State Board of Education which may be of service to other inspectors and boards. They were as follow:

1. The educational boards, to whom the inspector is responsible under the law, shall assume full control, and health boards or health officers shall only be called upon to assist in the work when the duties of one overlap the duties of the other, or when requested to act in an advisory capacity.

2. The medical inspector should keep all of the records, which the law directs, in suitable books or cards of a uniform character specially prepared for use throughout the State. Each pupil should be examined at least once in every school year, for the detection of physical defects or diseases of the organs of special sense, especially of sight and hearing, for the presence of spinal curvature or other bodily deformity. There should also be notes of the record of each pupil, as kept from year to year, indicating the growth and development of such pupil.

3. The duties of the medical inspectors in relation to lectures of instruction to teachers are of great importance and should not be neglected. The teachers should be thoroughly conversant with the methods to be employed in the detection of the first signs of communicable disease. Their instruction should include also, under the head of the "Recognized Measures for the Promotion of Health and Prevention of Disease," a complete understanding of the essentials for a perfect hygienic condition of the schoolrooms. The use and operation of the mechanical appliances used for heating and ventilation should be appreciated. If a ventilating apparatus is not used, instruction in relation to the best methods of admitting fresh air through the natural channels when opportunity occurs, without exposure of the pupils to drafts, must be considered. Attention should also be given to the adjustment of school desks and seats to the bodily requirements of the pupils, to the admission of sufficient light from the proper direction, and to such other matters as pertain to the physical well-being of the pupils. The fact that the complete success of the operation of the law depends upon the teachers, who are in reality executive officers constantly present in the schoolroom, is an indication of the importance of the thorough instruction advised.

Your committee feels that it is possible under the present law to secure very satisfactory results, providing that the educational board of the State will undertake to secure the uniformity of method in the administration of the law suggested in every community where medical inspectors have been or may be appointed.

"There is obviously room for the development of systematic inspection of schoolchildren in this country, but we see no reason whatever why such inspection should be limited to infectious diseases. We should prefer to see it embrace an examination for all morbid conditions likely to diminish the child's chances in the struggle for survival or which would be likely, by passing unrecognized and untreated, to render the child a charge upon the national funds."—[*Lancet*.]

"The function of the school doctor in relation to the children in the schools is often mistaken even by medical men, who should know better. It is no part of his duty to prescribe for or treat any individual. His work is preventive, and in individual cases only applies to matters involving educational questions. He may call attention to the need of glasses, but has nothing to do with prescribing them. He may notice the presence of adenoids, but takes no part in their removal. On the other hand, his work should extend far beyond mere investigation of the sanitary state of buildings, or the excluding of unhealthy or diseased children. The methods of education, requirements of physical exercise, avoidance, particularly in

the very young, of overstrain from prolonged fatigue or from improper tasks, are all matters in which improvement can only be obtained by the school doctor acting, not as an authority to shut or close, to disturb or interrupt the proper work of the school, but as a counselor and advisor with knowledge of school routine and of the requirements for health to assist and collaborate with the teacher and administrator, and it is with this in mind that he should enter any school."—[Dr. James Kerr, Medical Officer of the London School Board.]

What the medical inspectors of schools should do:

1. Prevent children, as far as possible, from being exposed to communicable disease at school.

2. Help children with defective sight or hearing to profit by the education the State is giving them.

Sight.—In London, England, in 1902, the newly-appointed school physicians examined 17,245 children, and found that 8% of the boys and 11% of the girls had serious visual defects.

Hearing.—Dr. Barr examined 600 children in Glasgow, Scotland. Their ages ranged from 7 to 14 and there was an equal number of boys and girls. He found 166 defective in hearing. After his tests were made, Dr. Barr asked the teachers to select 70 bright pupils and 70 backward ones. He found 14 of the bright and 28 of the backward defective in hearing.

Of 5,000 schoolchildren in Stuttgart 30% were found by Weil to be defective in hearing.

Dr. Sexton examined 570 children in the schools of New York City and found 76 had defective hearing. Of all these 76 pupils only one was known by the teacher to be defective, and only 10 knew themselves to be deficient in this sense.

3. Pay proper attention to the physical condition of the children. What is the sense of promoting growing children to a higher grade when their bodies are unfit for that grade?

6. The Army Medical Department, II. A Historic Sketch. (Continued.)

1.—Acute Ascending Paralysis and Landry's Paralysis.—L. H. Mettler thinks the term Landry's paralysis should be confined to describe simply one phase of a wellknown disease. It once stood for a definite clinical entity, but now is applied to conditions diametrically opposite. Both the above terms describe simply phases of a specific intoxication of probably bacterial origin, producing first functional and later inflammatory and degenerative changes in various parts of the central and peripheral nervous apparatus, thus accounting for the variability of the clinical symptoms. Postmortem findings may be nil, or suggestive of diffuse myelitis, acute anterior poliomyelitis, or peripheral multiple neuritis. The paralysis may descend or even skip about from arm to leg, and from side to side. The point in which the different types agree is in apparent limitation to the lower or peripheral neurons. There is frequent association in modern cases of pronounced sensory symptoms with the motor symptoms. This disease has developed whether etiologically or not after malaria, diphtheria, typhoid, variola, anthrax, influenza, pneumonia, pertussis, septicemia, gonorrhea, and the puerperium. Once it occurred after Pasteur treatment for rabies, and sometimes has been attributed to syphilis and alcohol. In some cases the changes of interstitial and parenchymatous neuritis have been found, in others the changes were in the spinal nerve roots, more frequently in the anterior than posterior, a third class was characterized by spinal cord involvement, a fourth by a diffuse process involving all parts of the lower motor neuron, peripheral nerve, spinal root, and ganglion cell. The indications for treatment are support and elimination. [H.M.]

2.—Surgery of the Stomach.—W. H. Wathen believes that many cases diagnosed as chronic dyspepsia are due to

interference with the normal physics of the stomach and duodenum, because of organic and mechanical changes in these organs. Of postmortem cases, 5% have or have had gastric ulcer. In 50% of these there are perigastric adhesions, and from 1% to 3.5% of all deaths are caused by gastric cancer and 40% of all cancers occur in the stomach. We can prevent these results by early diagnosis and timely operation. We must learn to make pathologic and surgical diagnosis as in pelvic disease. The writer discusses the question of diagnosis in detail, together with the proper surgical treatment in cases of hemorrhage from ulcer, perforation, chronic ulcer, benign pyloric stenosis and retention, perigastric adhesions and contracted stomach, and gastric cancer. [H.M.]

3.—Prevention of Tetanus.—D. N. Eisendrath emphasizes the following points: Early and thorough exposure of every part of the tract which has been infected by the blank cartridge or instrument which caused the punctured wound, retracting the edges so the disinfection and removal of the infected tissue can be done under the guidance of the eye. Prophylactic injections of tetanus antitoxin. Thorough disinfection can be carried out only under anesthesia, either local or general, and when the parts are rendered bloodless by a constrictor. Such radical measures are our only hope for reducing mortality. [H.M.]

4.—Suprapubic Prostatectomy under Nitrous Oxid Anesthesia.—J. Wiener, Jr., has found that suprapubic prostatectomy can be rapidly and safely performed under laughing gas. Any patient who can stand this for 10 or 12 minutes can have this operation performed. Old age, diabetes and cystitis are no contraindication. All of the contraindications usually mentioned are contraindications not for the operation but for the administration of ether and chloroform. [H.M.]

5.—The Medical Profession.—C. A. L. Reed points out that professional service rendered the government is the most conspicuous that can be offered to society, and if efficient the science which it represents is advanced in public esteem, therefore we should approve of the severity of examinations and should object to lower compensation than that paid to other professions invested with similar responsibilities, the precedent tending to cheapen the profession in private life. The same holds true when one profession is denied rank, position, or social prerogatives accorded to other professions. Life tenure takes away the stimulus of necessity, but long public service unfits for private practice. The greatest loss a professional man can sustain is loss of enthusiasm. Those in authority should give their subordinates the fullest opportunity for the development of individualism consistent with discipline. Promotion should be for cause. Special postgraduate instruction is important for military and naval service and clinical hospitals should be provided in connection with the special medical school. The writer advocates the creation of a reserve corps for emergencies, appointed on examination, and discusses the duties of the profession in private life to those who by reason of government regulations are prohibited from attempts to influence legislation in their own behalf. 1. Contribution to the Etiology of Idiocy and Imbecility. WILLIAM N. BULLARD.
2. A Sigmoid Band of Unusual Origin: Operation: Relief. AETHUR L. CHUTE.

1.—Etiology of Idiocy and Imbecility.—W. N. Bullard presents a study of 258 cases, of which 113 were congenital, 63 acquired, and the remainder uncertain. Of the acquired cases 13% to 19% were due to trauma and the rest to diseases including encephalitis and meningitis, hemorrhage, cerebrospinal meningitis, measles, scarlet fever, pertussis, pneumonia, sunstroke, rheumatic fever, diphtheria, etc. The majority of congenital cases are due to prenatal causes, although the large proportion of unusual circumstances in labor may be an exciting cause, but a depression or fracture at birth does not prove that the cerebral condition was not preexistent. The occurrence of unconsciousness, convulsions, or other acute cerebral symptoms immediately on birth suggests intranatal lesion. The

affection is as liable to be caused by prolonged pressure on the head during delivery as by injury from forceps. Prenatal causes may include worry, fright, falls, or illness during pregnancy. Heredity is a potent factor. The feeble-minded and epileptics are liable to imbecile offspring. Syphilis and alcoholism are important causes. The latter acts only through excess or through the fright or worry that it causes the mother. Enough stress has not been laid on maternal uterine disease. Attempted abortion undoubtedly also plays a part in causation. In the 258 cases there were 11 of hydrocephalus. [H.M.]

2.—Sigmoid Bands.—Arthur L. Chute reports the case. From December, 1899, until February, 1902, a female patient did not have a single natural defecation. In February, 1902, she was sent into a hospital for observation. At first she was fed large quantities of bulky food and given neither cathartics nor enemas. Two or three attempts of this sort showed its futility, as at the end of 48 hours she would have a violent headache and begin to vomit. Various cathartics in small doses produced no effect; in larger doses they caused vomiting and griping abdominal pain. Nothing but an enema would bring about a defecation. Not all of the enema was returned, and after each enema the patient would pass for an hour or more a greatly increased quantity of colorless urine. It was found that an enema of a few ounces acted quite as well as a larger one. Laparotomy revealed bands across the sigmoid; the latter was distended and thin above the obstruction. Removal of the bands resulted in complete relief. The fact that the symptoms of chronic obstruction arose after a difficult labor, led the author to believe that some injury occurring during the labor was responsible for the adhesions. [A.B.C.]

5. A Case of Hodgkin's Disease Treated by Röntgen Rays. EDWARD B. FINCH.
6. Local Applications in Pneumonia. W. F. CHURCH.

1.—Stegomyia Fasciata.—H. R. Carter thinks that other species may possibly be hosts for yellow fever. Its distribution is generally between latitudes 43° N. and 43° S. on the coasts and low plains of Africa, Asia, and the adjacent islands, Australia, and the Mediterranean basin of Europe. On the east coast of America it is general from 38° N. to 35° S. latitude. On the west it is found at Panama and Guayaquil, and its existence is implied from Guayaquil to Acapulco. It is conveyed by vessels indefinite distances, more often by sail than steam vessels. It lives a long time—154 days being recorded, power of transmitting yellow fever being retained as long as it lives. It propagates preferably in artificial containers, or in pools, if these are not available. In America it has been reported only near dwellings, and war against it should be waged about houses, cisterns; and water jars should be abolished, and covered drains be introduced to carry off rain water and prevent pools. Cess-pools are not breeding places. It hibernates, but a larger proportion of the adults or of the infecting parasite must generally die. It is inclined to stay where it has fed, hence the greater danger of the residence portion of an infected city. It does not feed in the dark or in bright sunlight, but will do so in artificial light. Prior to 14 days of development in the mosquito the germ cannot be transmitted to man. This mosquito is usually conveyed aerially less than 100 yards. Twelve hundred feet from the Havana shore has always been considered a safe distance for vessels. The direction of the prevailing wind during the day influences its aerial flight. [H.M.]

2.—The Unclassified Troubles of Women.—E. C. Savidge believes that there are certain important matters connected with the "feminine element" which make for woman's longevity, and determine her resistance to many of the inevitables involved by her sex. He refers to a frequently met condition which he calls the "self obliterated feminine element," occurring either in young girls as the result of overexpenditure

of vitality in intellectual and emotional pursuits and leading to a shortened life when life is most valuable, or in women from 25 to 40 whose increasing lithemia, growing obesity, conscious hebetude and diminishing menstruation show a strangling out in function of important selective principles. The gynecologist should study these conditions and the medical profession must look to the specialist for light on this subject. Savidge believes also that many effective years may be added to the life of a woman after the menopause, if we learn to keep patients at this period from becoming uric acid machines, to keep their arteries soft, to abolish the toxic headache and the loose flesh folds which are simply human sewers. In these unclassified troubles the psychologic condition aggravates enormously the physical condition. The woman too often feels that she is losing her usefulness to her husband and family and spends her time waiting for the end. These influences all conspire to rob her of what should be the best years of her life and the most useful to the community. The gynecologist must learn to call up the power for life and healing in the human mind, an underlying force of which the eddyte avails himself, and which medical men have too long neglected. [W.K.]

3.—Diagnostic Syndrome for Intracranial Syphilis.—William B. Pritchard states that in his experience covering a period of 16 years' special work syphilis was the dominant factor in the histories of more than 40% of all organic cerebrospinal lesions. Syphilis may simulate almost any other disease and may therefore lead to much confusion in diagnosis. The author gives the following formula, as his chief guide: Given a patient between the ages of 25 and 45, affected with any form of intracranial paralysis, which was preceded by headaches, of nocturnal onset or exacerbation, associated with vertigo and with insomnia, the insomnia occurring during the first half of the night, the paralysis developing during sleep, both headache and insomnia appearing upon the onset of the paralysis; the cause is syphilis. The average age among 160 carefully recorded cases of cerebral syphilis was 37; the youngest was 22; the oldest 72. The average interval in years between the primary syphilis and the metasyphilitic nervous accident was 7½ years; the shortest interval was 7 months; the longest interval was 28 years. Mercury and the iodids are the only drugs of value, the latter being the chief reliance. Iodism is rare if the drug is given properly. Beginning with 20 drops (never less) after meals, the dose is increased 3, 5 or 10 drops daily, according to the urgency or gravity of conditions. The vehicle is changed every third day, the first 2 days water, the next 2 milk, the next vichy, then apollinaris, then back and through the same cycle again. Should iodism develop to an annoying or extreme degree, stop for 2 days and then start just where you stopped, doubling the ratio of daily increase. [A.B.C.]

4.—Claudius' Catgut.—A. V. Moschcowitz says catgut prepared by this method has been in use almost uninterrupted during the past 17 months at Mount Sinai Hospital for all purposes for which formerly catgut prepared by other methods had been used, and it has stood the test well. The preparation of this catgut by this method is very simple. Catgut, just as it is bought from the dealer, is wound, preferably in a single layer, on to the spool, and tied at both ends, in order to prevent unraveling. It is then immersed for eight days in a solution of iodine, one part; potassium iodide one part; distilled water, 100 parts. The solution is prepared by dissolving the potassium iodide in a small quantity of the water, to which the iodine previously finely pulverized, is added, and the whole diluted up to 100 parts. It has been found that even anthrax spores were killed after the catgut was placed for 30 minutes in this solution; still for absolute safety eight days is recommended. The catgut can be kept indefinitely in this solution, and when simply rinsed off in sterile water is ready for use. [A.B.C.]

5.—Hodgkin's Disease Treated by Röntgen Rays and Quinin.—Edward B. Finch reports that a youth of 18 presented himself, having enlarged lymph-glands in the neck, axillas, and groin. The spleen was enlarged. Over the cartilage of the second rib was a soft tumor 5 cm. (2 in.) in diameter. An incision was made into this tumor, and while it could not be removed, a portion taken for microscopic study showed

evidence of lymphosarcoma. The peculiarity of this tumor, together with the general glandular involvement and the blood-examination, led to a diagnosis of Hodgkin's disease. Quinin in 3 gr. doses, given three times daily, and röntgen ray treatment was resorted to. Exposures to the röntgen rays lasted for from 40 to 90 minutes, the position of the tube being altered every 10 minutes so as to subject the whole body to a "shower" of röntgen rays. During a period of 5½ months, 62 röntgen ray sittings were had, after which time all tumor and glandular enlargement had entirely disappeared, and the patient was dismissed. Two months later the patient returned for treatment, the presternal tumor showing rapid recurrence. The former treatment was again employed and the growth was rapidly receding at the time of writing. The use of quinin as an adjuvant to the röntgen ray, on Morton's theory of its fluorescence in the blood, undoubtedly hastened the favorable result in this case, several cases of Hodgkin's disease having been reported as unsuccessfully treated with the röntgen ray when quinin was not used. [A.B.C.]

6.—Local Applications in Pneumonia.—W. F. Church thinks the status of local applications would have been settled long ago were there not so many differing modes of internal treatment. Transmission of blood from the lungs to the muscles and integument of the chest through the pleura must be very slight. In order to modify the supply to the lungs, the agent must act on the heart itself or the vessels connecting the two organs. It is claimed that cold, and possibly other agents, reflexly affect the cardiac and respiratory centers. Dilating the cutaneous vessels and anesthetizing the nerve twigs may relieve pleuritic pain, but the small amount of blood taken from the general circulation does not relieve the lung any more than were it drawn to other parts of the body. The addition of appreciable weight to the chest must result in loss of strength. By baths with friction, rubefacients, etc., more blood can be drawn to the extremities to relieve internal congestion than would be possible by producing hyperemia of the chest wall. [H.M.]

1.—Parenchymatous Change in the Kidney.—H. A. Tomlinson discusses this subject at some length. The conclusions arrived at from clinical experience, which have been largely verified by the study of similar conditions, both experimentally and clinically, in the lower animals, are: That there is as much difference in the kidney capacity of different individuals as there is in the capacity of their other vital organs and the nervous system; that some individuals are born with defective kidneys, not necessarily anatomically incomplete, but functionally incapable; that in these individuals a chronic degenerative process is set up early in life; that they are always, to some extent, the victims of chronic autointoxication, because of imperfect elimination; and that in them the irritation resulting from the retention of the waste products of retrograde metabolism, keeps up a chronic congestion in the kidneys, so that from causes which do not seriously affect the ordinary individual, there may arise, and does arise, acute involvement of the parenchyma of these organs, checking elimination, and resulting in more or less explosive outbreaks involving the general organism, and especially the nervous system. [C.A.O.]

2.—Juvenile Tabes.—The case reported in detail by Alfred Gordon is that of a girl of 17, who presents a rare example of tabetic manifestations developed in a patient who shows symptoms of an acute anterior poliomyelitis of infancy. All the cases known are those of progressive muscular atrophy with a rare involvement of the pyramidal tract (amyotrophic lateral

sclerosis). It also shows that hereditary syphilitic tabes and acquired syphilitic tabes are identical in their symptomatology. [C.A.O.]

4.—Arteriosclerosis.—Theodore Diller reports five cases. The first is that of a man of 66, who for four months had been frequently subject to curious attacks which came on toward morning, just before the arising time. In these attacks he kicked and sprawled about the bed. Various muscles were irregularly involved. They lasted from a few minutes to half an hour; during them he was conscious or semiconscious. Beside these "attacks" for two weeks his speech upon waking was thick, slurring, difficult to understand. His legs were ataxic. Upon attempting to arise he staggered and sprawled about the room in a very helpless fashion and was dizzy. Soon after arising the patient's various symptoms, including the speech defect disappeared. The condition is believed to be one of temporary deficiency of blood-supply to the brain and cord, for which three possible explanations are given: 1. Insufficient heart force. 2. Arteriosclerosis. 3. Vasomotor spasm. Diller says that probably all three factors were operative; certainly two of them, either the first or second, or first and third. The disappearance of the symptoms soon after arising he looked upon as due to the increased cardiac activity accompanying the efforts in arising and dressing, which forced increased amounts of blood, through partly occluded vessels. The patient was put on large and frequently repeated doses of nitroglycerin. In less than a month all his symptoms had disappeared. The diagnosis of spinal arteriosclerosis in four other cases was made on the consideration of the following facts: A marked weakness and unsteadiness of the legs in all cases suggestive of the gait of the very old man; a senile appearance; the presence of sclerotic arteries; an uncertainty in gait which bore only a superficial resemblance to that of tabes; the altered knee-jerks (in three of the four cases the knee-jerks were feeble or absent, in the other cases they were active); the absence of specific history; the absence of muscular atrophy; the absence of sensory symptoms (subjective or objective); the absence of involvement of the sphincters; the failure of the symptoms to conform to those of any of the wellknown organic diseases of the cord. [C.A.O.]

5.—Diabetic Glycosuria.—A. C. Croftan submits a preliminary note concerning the reduction of diabetic glycosuria with pancreas-hemoglobin-muscle extracts prepared by him. The preparation has been given in six cases so far, and in each case a marked decrease in the sugar excretion followed within 24 hours. [C.A.O.]

6.—Diabetes in Childhood.—Two cases are reported by H. N. Rowell to illustrate the influence of the nervous system upon this condition. The patients were brother and sister and death occurred in each instance. The members of the father's side of the family all exhibited neurotic tendencies. The father himself, while apparently free from organic disease, is an unusually nervous, irritable man, and is considered eccentric by his fellows. An uncle is confined at present in a hospital for the insane. An aunt died recently of goiter and diabetes. The father's father died of chronic alcoholism, and the father's mother is alive, but partially mentally unbalanced. [C.A.O.]

1.—Intraspinal Injections of Lysol in the Treatment of Cerebrospinal Meningitis.—Morris Manges reviews the litera

ture, and reports three cases treated successfully by Seager's method, except that Manges did not wash out the spinal canal with an artificial serum. Seager's treatment consists of lumbar puncture and the withdrawal by aspiration of varying quantities of cerebrospinal fluid from the spinal canal, frequently amounting to 50 cc. Normal salt solution is then injected with the same syringe by means of a canula placed between the twelfth dorsal and second lumbar vertebrae and injecting the solution through the upper canula and allowing it to flow out the lower; lastly, a quantity (from 9 cc. to 12 cc.) of a 1% solution of lysol is injected through the syringe and the needle withdrawn. The temperature falls immediately, but rises again after one to three days, when the puncture and injections are repeated, and so on until only quite clear and limpid fluid is withdrawn after puncture, when the injection of lysol is stopped. Afterward a few punctures are made to see if the fluid continues clear. Of the 31 patients whom Seager treated by this method 13 died and 18 made complete recoveries, there being no after-complications. Manges' patients likewise recovered completely. [A.B.C.]

2.—Carcinoma of Retained Testis.—Sinclair Tousey reports the case. The patient was a man of 33, with both tuberculosis and cancer in his family history. He was born with a number of malformations. Among these were claw-like deformities of the hands and feet, some of the phalanges being absent. Both testes were completely within the abdominal cavity, and neither could be felt. There was an inguinal hernia; and an exaggerated hypospadias with apparent absence of the penis. The penis was buried in a sulcus, the glans pointing back. There was practically no corpus spongiosum. Some years ago a plastic operation for the formation of a penis was successfully performed. Four years ago the patient began to complain of fainting spells, pain in the lumbar region, and later a tumor presented in entire lower portion of the abdomen. In 1903 Tousey did a laparotomy, and removed a very large cystic malignant mass from the abdomen, which had its origin in malignant degeneration of the retained right testis. The man recovered from the operation, and was apparently well for some months, but pain in the lumbar region recurred, and death followed. Necropsy showed the lumbar vertebrae attacked by malignant diseases—as were also several other parts of the body. [A.B.C.]

3.—Modification of Mattoli in the Operation of Von Hacker for Gastroenterostomy.—Carlo Savini reviews the operations of Roux, Braun-Jaboulay, and Von Hacker, and then describes Mattoli's modification of the last. This modification consists in transforming the modified Von Hacker into an operation offering the practical advantages of a Roux, by closing with sutures the efferent or duodenal portions of the intestine between the two anastomoses. According to Mattoli the operation should be performed in three steps: 1. The jejunum is anastomosed to the posterior wall of the stomach as in the Von Hacker. 2. The two branches of the jejunum are united and anastomosed about three inches from the gastroenterostomy as in the Braun-Jaboulay. 3. The afferent branch of the jejunum between the two anastomoses is held between the thumb and middle finger of the left hand, placing the fingers longitudinally. The pressure forms a groove and the two resulting ridges are sewed together by a number of stitches. The section of the intestine is here changed into a solid cord. The vicious circle is thus absolutely prevented, and the bile and pancreatic juice flow into the stomach and thus entirely empty the jejunum. Illustrations accompany the article. [A.B.C.]

5.—Treatment of Tuberculosis of the Testis.—Joseph A. Blake has operated on eight patients by castration, with removal of the entire vas deferens in all, and in two with simultaneous removal of the seminal vesicle. In one case double castration was performed. He has never performed epididymectomy alone. In all cases the disease was restricted, as far as could be ascertained, to the genital apparatus, with the exception of one previously reported, in which in three successive operations the kidney, ureter, left testicle, both seminal vesicles and most of the prostate were removed. It is now nearly three years since the last operation, and this patient is practically a

sound man. Blake discusses the various operative procedures, his preference being castration, unless both testicles are involved. He doubts whether sexual vigor is retained long after epididymectomy. The seminal vesicles should be removed in all cases in which they are affected if the disease is limited to the genitourinary tract. [A.B.C.]

6.—Tuberculosis of the Urinary Bladder.—Alex. B. Johnson discusses this subject at some length, and concludes as follows: (1) If other tuberculous lesions of the genitourinary tract exist, their operative removal is sometimes followed by improvement and even cure of the process in the bladder, provided the patients are placed under the most favorable hygienic surroundings; (2) operative treatment of the bladder alone in the presence of tuberculous lesions of other portions of the urinary tract, is usually harmful rather than beneficial; (3) the local treatment of the tuberculous bladder by means of injections or applications through the urethra is generally useless, and often very deleterious; (4) the internal administration of the drugs known as urinary antiseptics is generally useless; (5) palliative operations, such as suprapubic drainage, may be useful in advanced cases; (6) the general or hygienic treatment, suitable climate, out-of-door life, etc., offer these patients the best hope of recovery; (7) such hygienic measures should be preceded by the operative removal of tuberculous foci in the kidney, the epididymis, the prostate, and the seminal vesicles, if such exist, and the patient is still in sufficiently good condition to bear the operative procedure; (8) in those rare cases where the bladder alone is affected over a moderate area only, the operative removal or destruction of the diseased tissue may be followed by improvement and even cure. [A.B.C.]

7.—Developing Mental Disorder.—W. K. Walker notes that, while we cannot always correlate nervous and mental phenomena with cell changes or their metabolic activities, we are beginning to understand how they may have their origin in nutritive changes, which interfere with the cellular mechanism upon which "associative memory" depends, that is, the mechanism of mental states, whatever their character. Previous happenings in the individual's mental life are here of equal significance as those of his physical organization in relation to bodily diseases. In dissociative or disorganizing processes we look to the sphere of sensation (with its psychic equivalent idea) or the earliest indications of mental disorder. Every idea results either in movement or in inhibition of movement. Fixation of attention necessary for performance can in health be transferred to a variety of objects. Emotions through repetition, long duration, or intensity may attract all the forces, and with no conflicting ideas interposed, be translated into action with clear, blurred, or no consciousness whatever (epilepsy). Exhaustion narrows the field of consciousness by interfering with associative memory. Emotion narrows it by attracting ideas which harmonize with the particular emotion. It is through attention that higher development is possible. Fixed ideas and obsessions are merely the morbid manifestation of this faculty and are apt to be the earliest signs of abnormality, but it rarely happens the medical adviser is made acquainted with these until the underlying emotional element is more clearly shown as translated into appropriate deed. In the early stage we may do much through removal of the exciting cause, whether this be overwork or defect of the organs of special sense, excessive expenditure of energy, emotional stress, or toxins. [H.M.]

8.—Ammonium Sulfate Method of Sterilizing Catgut.—Weller Van Hook is not favorably impressed with the method of Claudius for sterilizing catgut, claiming it is not agreeable for handling and is brittle. He prefers the ammonium sulfate method of Elsberg. Van Hook has slightly modified Elsberg's method, and as used by him, consists of the following: Select raw, rough, unbleached material of good quality. Soak for a week in pure ether or a mixture of chloroform 1 part and ether 2 parts. Wind on glass spools in single layers. Soak for 3 days in aqueous solution of chromic acid, 1 to 1,000. Boil for 20 minutes in water, to which, while boiling, chemically pure ammonium sulfate has been added until the crystals cease to dissolve. Wash the catgut for a half hour in cold sterile water. Store as desired. Van Hook places the spools in a solu-

tion of corrosive sublimate, 1 part in 95% alcohol, 1,000 parts. Should the material become infected, it may be reboiled. [A.B.C.]

9.—**Major Hysteria.**—T. Diller reports a case interesting from its high and subnormal temperature, greatly accelerated respiration, and practically normal pulse, with recurrence of symptoms after a second accident, in neither of which were there grounds for damage suits. At one time the respirations were 60, the pulse 66, and the temperature 107°. The temperature ranged from 96° to 109°. The permanent stigmas consisted in contracture and sensory changes, including restricted visual fields. [H.M.]

EDITORIAL COMMENT

Something about Catalysis.—The scientific conception of the process, or processes, designated by catalysis has, in the light of modern research, undergone a change. The process may be termed a physicochemic one, and the only explanation of the same that scientists up to a comparatively recent period were in a position to offer was that of mere action by contact, in which the introduction of certain agents produced a change or reaction in the original substance to which it was added. This theory, however, no longer holds good, as it fails to explain the phenomenon of certain original substances remaining apparently unchanged, in spite of the distinctly traceable catalytic process. Modern scientists have, therefore come to the conclusion that the formation of intermediate compounds must be assumed, and, in doing so, they have differentiated between the action of catalytic agents which are the actual causers of the process, such as the solidification of an oversaturated solution brought about by the introduction of a crystal, and that catalytic action which only accelerates reactions which already ensued before the introduction of the catalytic agent, such as occur in the catalysis of all, or almost all, chemic bodies.

Catalysis in oversaturated substances takes place when such substances do not possess the highest possible degree of stability under the prevailing conditions of pressure and temperature. A small quantity of substances which possess a higher degree of stability, coming in contact with the former, impart a new phase to it which will go on increasing until a state of equipoise shall have been reached. Thus, an oversaturated solution of carbonate of soda will be reduced to solidification by the introduction of the smallest possible weighable particle of solid carbonate of soda. It is, indeed, a matter of importance for the formation of the new substance that the catalytic agent should consist of the same substance as the possible solid result. Foreign substances exercise no influence upon it.

Isomorphic substances, however, produce certain effects, but in this connection extensive research is still required. It may be assumed that isomorphic substances produce their effects by the formation of fixed solutions, but it is questionable whether nonisomorphic solid substances which can form fixed solutions with the original substance produce any catalytic effect. There are other cases where solid bodies react on the original substance which are neither isomorphic nor capable of forming fixed solutions. This will sometimes happen, for instance, when silicic acid is rendered insoluble in the presence of the crystals, and the latter are removed by means of suitable solvents. A solution may be simultaneously oversaturated with regard to several different phases. Thus, acetate and thiosulfate of soda can be combined into one fluid, which, however, will react in a different way upon germs of each one of the respective salts by excreting its own special substance, while the

rest remains in a solvent state. This would explain the formation of the various substances of the animal body from the blood, if it were permissible to regard the latter as a fluid surcharged with the germs of all these substances.

Homogeneous Catalysis.—While in the cases above described contact with a substance of greater stability was required to produce catalytic effects, such a condition is excluded in the case of catalysis in homogeneous substances, as the term implies. Catalytic action is only possible with nonstable bodies, and homogeneous nonstable formations can only exist in a state of transmutation. A fluid which is capable of producing, without extraneous influence, other substances which remain in solution cannot exist without forming such products. The degree of rapidity with which such transmutation takes place is of no consequence. The catalytic agent, however, increases that speed, and that is the only effect it has on homogeneous substances. The measurement of this influence on the speed of transformation in connection with the various substances is another important point to which research should give its attention.

Heterogeneous Catalysis.—The most important process illustrating the catalytic effect of heterogeneous substances is the combustion of sulfur dioxide into trioxide. These are likewise cases of increased speed in the transmutation of substances, and the regularity of such increase, as the temperature rises leads one to assume that some transmutation, however small, takes place even at normal temperature. The slowness of the process is explained by the fact that gases always react slowly. This is best shown by experimenting with the same substance in a fluid state and in a gaseous state; in the latter case its reacting power is very considerably lessened. If we assume that by catalytic action part of a gaseous substance becomes fluid or assumes the density of a fluid, then that part will display a more active reaction and be transformed into the final product with increased speed, and if the catalytic agent is such as to constantly renew its condensing influence, the result throughout the process is accelerated reaction. The effect of platinum upon combustible gases would find a ready explanation by the adoption of this assumption.

Enzymic Catalysis.—We have to look upon enzymes as catalytic factors which are generated in the organism during the life of the cells, and to assume that by their action living beings perform the greatest portion of their chemic task. The production of chemic energy by combustion at the expense of the oxygen of the atmosphere, and therefore life itself, would be impossible without the decisive cooperation of enzymic catalysis. Oxygen, unaided, would be too slow in action to sustain life and is dependent upon the accelerating effect of reactions. Such acceleration may be accomplished by temperature, concentrations or catalysis. Animal life, however, cannot control temperature at will, while concentrations frequently depend upon the solubility of substances. There remains as the only reliable means the employment of enzymosis as catalytic agent, and this is fully equal to the task.

REVIEW OF LITERATURE

Corset Cancer.—Clement Lucas¹ reports two cases, and concludes that he has demonstrated a site of origin of cancer dependent upon the friction of the upper edge of a corset where it crosses the anterior fold of the axilla. The disease, he believes, was due to a chronic irritation, but supposing cancer to be of germ origin introduced from without, the rubbing in of such an organism at this point might aptly be compared to the rubbing in of staphylococci by the collar in the production of boils and carbuncles. Allusion is made to other recognized

¹ The Lancet, April 2, 1904.

sites of origin associated with irritation, and especially with the points of junction of mucous membrane with skin. He then essays to show how syphilis producing injurious effects in numerous situations often proves the forerunner of cancer. Inoculation and contagion are considered; also the proved inoculability of cancer in animals of the same species; the self-inoculation in the human subjects in parts in contact but not continuous; and the probable communication of the disease in certain cases from wife to husband. The recent observations of Farmer, Moore, and Walker as to the resemblance of the myototic changes of cancer cells to those normal in the reproductive cells of plants and animals, are alluded to as of interest, showing why in both cancer and sarcoma there exists such an intense power of multiplication of cells. [A.B.C.]

The Lymph-glands in Typhoid Fever.—D. L. Edsall¹ has observed the behavior of the lymph-glands in 60 cases of typhoid fever; in 36 of these satisfactory notes were obtained and are made the basis of the paper. Of the 36, glandular involvement during the course of the disease occurred in 25; in 4 the conditions were doubtful; in 7 there were no determinable changes in the glands. The regions observed were the groin, axilla, anterior and posterior portions of the neck. As a rule the occurrence of glandular involvement could be detected only by painstaking and deliberate examination; occasionally it was prominent enough to be apparent on rather hasty palpation. Several factors must be taken into account in these cases to prevent too high estimation of their occurrence; chief among them is that emaciation of typhoid patients makes prominent the glands and the taking on of flesh after the disease has run its course obscures them. Edsall finds in this involvement of the glands but little that is of value from a diagnostic standpoint; the principal conclusion drawn is that glandular enlargement, unless very marked, cannot be considered a point against typhoid fever. As to prognosis, the condition apparently has no important bearing; enlargement of the glands is followed by relapse and is usually more prominent in the relapse. Further study may reveal some prognostic value. The fact that all the patients recovered and that glandular enlargement was more marked as convalescence was established, suggests that the lymphatic tissues were active in establishing immunity. [A.G.E.]

Albuminuria in the Apparently Healthy.—S. West² believes that albuminuria is always pathologic, except when the albumin is obtained from a residue of cells extracted after evaporation. He classifies cases into (1) postrenal or accidental, due to contamination from the genitourinary tract; (2) renal (a) with obvious cause as kidney disease, (b) without obvious cause; (3) prerenal (a) with obvious cause, as in fevers or heart disease, (b) with no obvious cause. A tiny calculus in the kidney or oxalic acid gravel or strongly acid urine might lead to transient albuminuria. The frequency of the condition has been put at 10%; in quite young infants the figure has been placed at 40%; in boys at school at 20%. These boys should be under medical supervision. The presence of albumin is a risk which the insurance office is justified in declining to take. The gravity of the condition increases with every year. When accompanied by arterial thickening, it is an indication of granular change in the kidney. It is advisable for life insurance companies to reject all cases of albuminuria above 40, to load heavily those between 35 and 40, to add considerably between 25 and 30, and to postpone and watch those cases occurring from 18 to 25. If arterial thickening is present one should reject at all ages. [H.M.]

Transplantation of the Thyroid Gland in Man.—H. Cristiani³ had the opportunity of experimenting with thyroid transplantation in three patients who were subjected to operations on the neck. He found that new thyroid glands could be produced in man by this process. The results are excellent when normal thyroid tissue is used, and are even successful when tissue is used that is slightly altered by pathologic changes. The new glands thus obtained are practically normal. If markedly pathologic thyroid tissue is used, the results are nega-

tive, the transplanted tissue being disintegrated and absorbed. From a clinical point of view, the transplantation is shown to be of great service in cases where the entire thyroid gland has been removed on account of disease, and also in cases of myxedema due to deficiency in the thyroid gland. The chief difficulty, from a practical point of view, is in obtaining fresh human thyroid tissue for transplantation. This may be met in the future by devising some preservative medium, such as artificial serum or the blood-serum of certain animals. An open operation may possibly be avoided by devising a method of injecting an emulsion of the thyroid tissue into one of the body cavities. [B.K.]

EDITORIAL COMMENT

Fat as a Cause of Painful Knee-joint.—Abnormal deposits of fat in the knee-joint have been described by pathologists since the days of Virchow's eminent teacher, Johannes Müller, who gave the name *lipoma arborescens* to such accumulations. Until recently the condition has attracted little attention from surgeons, but during the past few months two important contributions have appeared on this subject. Painter and Ewing¹ report in detail seven cases of *lipoma arborescens* under observation during the year preceding their publication, and Hoffa² also reports a series of seven cases of similar nature which he operated upon during the year. The earlier pathologists believed that the condition was almost always associated with tuberculosis or arthritis deformans, but later writers are not inclined to attach much importance to these diseases as a cause for such abnormal deposits of fat. Hoffa believes that the condition is usually of traumatic origin, though he does not agree with König that it arises by an ingrowth of fat through the break in the synovial membrane caused by injury, but rather it is a condition of hypertrophy of the normal folds of synovial membrane; the so-called *plicae alares* and *plica synovialis patellaris*. Quite possibly he is indebted to Painter and Ewing for this suggestion, for their valuable paper antedates his almost a year, and so far as we are aware, they were first to suggest that *lipoma arborescens* is not really a fatty new-growth, but only a condition of hypertrophy of the normal synovial folds with fatty degeneration. The usual course of the affection as described by Hoffa is: Severe pain in the knee following some injury which may not be considered of very great importance at the time; there is, however, permanent pain on moving the joint, the pain, as a rule, being located on the inner side of the joint; the knee cannot be fully flexed; there is usually more or less atrophy of the quadriceps tendon, and sooner or later a typical swelling appears just below and on either side of the patella, which makes the patellar ligament seem prominent; the subquadriceps bursa is usually free, as are the sides of the joint capsule; the swelling below and on the sides of the patellar tendon have a doughy consistence and quite a characteristic appearance. In the later development of the case the movability of the joint may be normal, or there may be some joint crepitation on motion. Hoffa considers the picture so characteristic that a diagnosis can be made with absolute certainty. In the differential diagnosis, foreign body in the knee-joint or separation of a semilunar cartilage has to be considered, but with the latter we have the typical point of pain and swelling exactly in the fissure between the ends of the bone, while with foreign body within the joint the röntgen ray photograph is of aid. He claims to have made the diagnosis in all of his cases, the accuracy of the diagnosis being confirmed by operation at which the hypertrophied fatty

¹ American Journal of the Medical Sciences, April, 1904.

² Deutsche medizinische Wochenschrift, 1904, Vol. xxx, p. 837.

masses were excised. In the after-treatment, Hoffa advises gauze drainage for the first 24 hours, removal of the stitches on the tenth day, after which active movements are begun, and the patient is allowed to be out of bed on the tenth to the fourteenth day. With massage and suitable gymnastics a perfect functional result is usually obtained in from six to eight weeks. Painter and Ewing find that the symptoms are usually those of a foreign body in the knee-joint, and they believe that a positive diagnosis is usually impossible until the joint is opened. Modern, septic exploration of the knee-joint is not attended by any more danger than is the opening of any other cavity of the body, and it seems indicated in cases in which it seems likely that this is the cause of the trouble. The favorable results which have been obtained in such cases certainly would encourage the removal of hypertrophied and fatty tissues. The condition has attracted very little attention in surgical textbooks, and we venture to be unrecognized by many surgeons of considerable experience. The writers quoted seem to believe that the condition is a relatively frequent one, and their opportunities for the examination and exploration of numerous cases of joint diseases give their opinion great value. Probably many persons now suffering from painful affections of the knee-joint will find relief in years to come from the simple operation suggested.

REVIEW OF LITERATURE

Treatment of Anterior Dislocation of the Shoulder.—

George Tulley Vaughan,¹ in discussing the treatment of luxation at the shoulder-joint, states that the method of direct reposition should be first tried; when it fails the method of extension and counterextension should be employed. Reference is made to an article by Stimson, in which he advocates placing the patient on a canvas cot with a hole cut through sufficiently large to permit the arm of the affected side to pass; the patient lies on the cot with a weight of some 10 lb. suspended from the wrist of the projecting arm. In 10 cases reported by Stimson, in no instance was it necessary to continue extension longer than six minutes. Vaughan's method of employing extension and counterextension is similar in principle, but it consists in placing a sheet around the patient's body below the axilla of the affected side, crossing anteriorly and posteriorly the shoulder of the opposite side, traction being made by an assistant. The surgeon then makes traction upon the affected arm first in the line of the displacement, and as the traction increases the arm is carried away from the side to an angle of 45 degrees. Traction is continued, not too strongly, but just enough to make the muscles tense. An assistant should be ready to relieve the surgeon when he becomes tired and the change is made without relaxing the traction. In from one to six minutes the steady traction overcomes the muscular spasm, contraction ceases, and the head of the bone slips into place. The importance of using traction with gentleness and persistence without force is insisted upon. The Kocher method is discussed in some detail, while in old cases the method of arthrotomy is applicable. [A.B.C.]

Suppuration of the Bursa of the Great Trochanter Simulating Hip Disease.—T. Pridgin Teale² quotes from a paper which he published more than 30 years ago, calling attention to two cases of suppuration of the bursa overlying the great trochanter, wherein the patients complained of symptoms which strongly simulated hip-joint disease. In the present paper he calls attention to another case coming under his own observation and to one or two others which have come to his notice, and says that very little in reference to this troublesome, though rare condition, is to be found in the textbooks. The recent case reported was that of a man of 51 who, when 14 years of age, was kicked in the region of the great trochanter; 16 years later a lump the size of a walnut appeared 1½ inches below the great trochanter; this was opened a year later and fluid escaped, a sinus persisting for 3 years, and then healing; 15 years later

the sinus opened, and has now been discharging for 4 or 5 years. Three years ago a second sinus opened in front of the trochanter; 9 months ago a third below the buttock. The sinus behind the trochanter was enlarged, the finger introduced, and the bursa was laid open by direct incision, dividing the aponeurosis of the great gluteal muscles. The points upon which he lays stress are: (1) A *prima facie* suspicion of hip disease; (2) either no marked muscular rigidity of fixity of the hip-joint, or if such exist, their disappearance under an anesthetic; (3) absence of tenderness on pressure of the head of the femoral against the acetabulum; (4) the frequency of the history of a fall or blow on the trochanter; (5) the effect of the flap tendon of the gluteus maximus as a factor in keeping up the diseased condition of the bursa and the importance of the division of this tendon in the surgical treatment of the disease. [A.B.C.]

Traumatic Rupture of the Small Intestine.—Lawford Knaggs¹ reports two cases of rupture of the small intestine, one of the patients recovering after operation and the other dying. The author states that the symptoms produced by abdominal contusions when the bowel has been ruptured are frequently insidious in their onset; in some cases the presence of the collapse and the urgency of symptoms leaves no room for doubt; in others, the immediate effect of the accident is recovered from and the patient subsequently develops symptoms of peritonitis, which justify an exploratory operation. It is the time that is lost in this way that is responsible for the want of success in the treatment of ruptured intestine, yet it is impossible to prevent it unless a rule be formulated that every severe abdominal contusion be subjected to immediate laparotomy, and this, of course, all surgeons will not accede to. Increased rapidity of the pulse as an indication for operation is a most valuable sign, but as it also indicates the absorption of toxins from the peritoneum, it shows that valuable time has been lost. The author appears to place more importance upon vomiting as an early symptom of intestinal rupture; it is not always present until unsatisfactory conditions are far advanced, but should it occur early it points to probable implication of the peritoneum, and may be the first sign of intestinal rupture. All cases of severe abdominal contusion if not operated upon at once should be watched with extreme care for the first signs of any complication. [A.B.C.]

Experimental Nephritis and Renal Decapsulation.—

Hall and Herxheimer¹ experimented on 35 rabbits, doing a decapsulation as a primary experiment, and neither by ordinary nor by serial section of the kidneys was there any marked formation of new blood channels between the kidneys and the adherent tissues. Their experiments agreed with those of Johnson, who found that the capsule, when removed from healthy kidney is reformed at the end of about 21 days and is represented by fibrous covering thicker than the original capsule. After their preliminary experiments they then undertook a series in which they produced an acute degenerative nephritis in rabbits by injecting ammonium chromate; following this, after degeneration had time to ensue, with decapsulation of the kidney, in order to more nearly approach the condition under which the operation has its practical application in man. The experiments are enumerated in detail. They state that from the anatomic standpoint decapsulation does not appear to offer any advantages, and if there exists no anatomic basis for the operation in acute degenerative nephritis it is impossible that in chronic nephritis the capsular change will be less marked. Clinically it is true that increased excretion of urea, disappearance of albumin and casts have been observed to follow renal decapsulation. Some ascribe this to the relief of congestion, others suggest that it is the result upon the sympathetic ganglia. The latter, they believe, the correct explanation. This being true they question the necessity of removing the entire capsule and assert that renipuncture or one longitudinally and several transverse incisions would avoid the main anatomic disadvantages and yield equally beneficial results. According to the compiled statistics of Guiteras, who collected 120 cases operated upon for chronic nephritis, there were 16% of cures, 43% improved, 11% unimproved, and 33% followed by immediate death.

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

REVIEW OF LITERATURE

Ventrofixation of the Uterus.—The operation of ventrofixation appears to W. J. Sinclair¹ to be the best for the treatment of chronic retroflexion of the uterus in women at the childbearing time of life. The ideal ventrofixation is that which results from cesarean section, when the wound is longitudinal, involving about the middle third of the uterus, and complete adhesion takes place between the uterine and abdominal wounds. In these cases, when pregnancy occurs again, there are absolutely no abnormal symptoms, either functional or mechanical, and the operation may be repeated again almost or altogether without opening the peritoneum. Sinclair condemns the introduction of sutures through the posterior surface of the uterus as practised by Kelly. That is ventral suspension, not fixation, and is faulty in many respects. In performing ventrofixation he uses only catgut and the finest silk thread. In closing the vesicouterine fold he introduces only two catgut sutures, one on each side, well below the lowest point of the abdominal wound, while the uterus is firmly pulled upward by means of an ordinary volsella inserted in the center of the fundus and manipulated by an assistant. Then fine silk sutures are introduced from the outside surface of the parietal peritoneum, passed through the peritoneum, and after taking a good hold of the uterus low down and near its margin, they are brought back through the peritoneum and firmly tied. The knot is thus always extraperitoneal. Two of such sutures are, as a rule, introduced on each side. The same process is now continued, the sutures including the fascia, as well as the peritoneum on each side. The transverse sutures are next introduced. These are two or three in number, consist of fine silk, and include fascia and peritoneum at the sides, and each takes a fairly extensive hold of the anterior surface of the uterus. The highest of the sutures is placed about half way up from the isthmus to the fundus. After suturing the abdominal wound in the usual way, the last step in every case is the introduction of a glycerin-pessary into the vagina to press forward and support the uterus during the formation of adhesions. The patients are kept in bed for a month or six weeks, and are advised to lead invalid lives for several months. This operation has stood the test of efficiency in nearly 100 cases. [W.K.]

Leukocytosis in Pelvic Disease in the Female.—E. S. Carmichael² believes that in 75% of cases quantitative gives as trustworthy results as qualitative examinations. Toward the end of pregnancy and during parturition, leukocytes increase, while during the puerperium there is a steady decrease, and if a marked leukocytosis is found, toxemia must be suspected. There is a strange independence of temperature and leukocytosis. Pelvic exudation or abscess may be looked for. In chronic exudations the leukocytosis is lower than in acute forms. Streptococci cause the highest degree, and *B. coli communis* the next, gonococci only a moderate degree, and the tubercle bacillus not any. More than 10,000 in tuberculous conditions indicates a mixed infection. In ovarian tumor much increase in the white cells indicates an inflammatory, rather than malignant cause. One cannot lay down a hard and fast rule as to the number indicating operation, but suppuration should be suspected after three counts of 20,000 or above. A rise after operation is a sign of bad drainage. With high leukocytosis and tubal swelling, palliative methods as drainage by the vagina are indicated. In ulcerative cancer of the cervix the leukocyte count should be reduced by cauterization before extirpation. In puerperal fever with marked toxemia and no leukocytosis the result is inevitably fatal. Leukocyte decrease with eclampsia is grave, increase is favorable. The qualitative count in a few cases gives more information than the quantitative, but it also often fails. The count should be made when digestive leukocytosis is absent, and also that from drugs and hemorrhages. It should never be relied on exclusively as a means of diagnosis. [H.M.]

Ruptured Ovarian Cyst and Sarcoma.—R. Alcock³ reports a case of multilocular cystadenoma of the left ovary in a woman of 34. Operation was not performed until one week after rupture of the cyst had occurred. The cyst contained no evidence of malignancy and the right ovary was normal. Improvement of the patient was marked for a time, but general decline then began, and death occurred nine months after the operation. Autopsy showed the entire abdominal cavity to be occupied by a white, friable tumor mass; there was also a tumor of the right ovary, the size of an orange, that could barely be differentiated from the former. The whole mass was a round-cell sarcoma. The writer believes there was a causal relation between the contents of the cyst that escaped into the abdominal cavity and the sarcoma of the contained structures. There is a possibility that the tumor of the right ovary was independent of the general tumor mass in which it was embedded, and that the latter was secondary to it. The general distribution was against this view, and Alcock considers it very important that no cystic fluid be allowed to escape into the peritoneal cavity during operation on ovarian cysts. [A.G.E.]

The Coagulation Time of the Blood in Pregnant and Puerperal Women with Albuminuria and Eclampsia.—According to Carstairs Douglas,² in general terms, it may be said that the total quantity of blood is raised in pregnancy; that the leukocytes, fibrin, and probably the hemoglobin are increased in amount, while the red cells are if anything diminished. A study is made of the question of the alleged tendency of the blood in eclampsia to form thrombi readily by examining the blood as to the time of coagulation, several hundred observations being made upon these groups: Cases of albuminuria, of eclampsia, of healthy puerperas, of healthy pregnant women, of healthy nonparous women. The only class of cases in which the time of coagulation was shortened was that of albuminuria in pregnancy, in which the average was 5.6 minutes, in all the other classes the average being 7 to 7.75 minutes, but none of these cases of albuminuria developed convulsions. He concludes that there is little difference in the coagulation time of healthy pregnant and puerperal women and of women having eclampsia before or after delivery, and that there is nothing as far as the coagulability of the blood goes, to support the contention that the thrombi found in certain organs in fatal cases of eclampsia are due to an increased coagulability in these cases. [W.K.]

Treatment of Dysmenorrhea and Sterility, Due to Stenosis of the Cervix, by Incision.—Bedford Fenwick³ contends that dysmenorrhea due to stenosis of the cervix or to a conical cervix, can only be permanently cured by incision of the cervix, and the separation of the edges of the wound until healing is complete. Other methods, such as dilation of cervical canal by bougies or other means, or incision of the internal os, only give temporary relief. Fenwick prevents union of the incised lips as follows: After an incision of a half to three-fourths inch is made on each side, the posterior lip falls back and the anterior lip is drawn forward with a hook. A small needle threaded with strong catgut is passed through the left side of the anterior lip close to the upper angle of incision, and then across and through the corresponding point on the right side. The catgut is cut sufficiently short, and a similar stitch is inserted about midway between the former and the tip of the cervix. The anterior lip is sponged clean of blood, and first the upper and then the lower stitch is tied. The result is that the anterior lip of the cervix is indrawn together—the raw surface being closed completely, while the posterior lip is flat and open. Two or three wool plugs are then applied tightly against the cervix to check hemorrhage. At the end of 10 days the catgut stitches are removed, and then the anterior lip flattens out and lies nearly in its normal position, but both the opposed surfaces being covered with mucous membrane, they cannot adhere. He has performed this operation in 87 cases, and in 91% the relief from pain has been permanent. Out of 41 cases of sterility he has heard from 24, in 18 of whom pregnancy has resulted. [W.K.]

TREATMENT

SOLOMON SOLIS COHEN

L. F. APPLEMAN

E. LINDAUER

REVIEW OF LITERATURE

Treatment of Insomnia.—C. J. Aldrich¹ first makes emphatic that the treatment of sleeplessness does not resolve itself into a choice of drugs. He then considers the condition under five forms—irritative, toxic, psychic, degenerative, and that due to changes in mode of living. In the first the cause of irritation should be removed and stimulants and opiates sedulously shunned. Of the toxic variety, hydrotherapy is of special value in the insomnia of alcoholism, a condition from which many die because of poor treatment. Chloral, morphin, and hyoscin should rarely be used; they are not necessary, and frequently cause death. Aldrich uses bromids in large doses, combined with a small amount of chloral, tincture of capsicum, infusion of digitalis, and whisky or brandy. Many trials of digitalis have convinced him of its safety and usefulness. Strychnin hypodermically is a necessary adjunct of such treatment. The use of hypnotics in pneumonia is reprehensible; strychnin and stimulants with free catharsis is more serviceable and less dangerous. For the insomnia of the gouty individual with high arterial tension, commercial potassium nitrate combined with small amounts of potassium iodid makes an ideal eliminant. Aldrich believes that the seriousness of insomnia is, as a rule, overrated, and the condition therefore overtreated. He closes by stating that there is no absolutely safe hypnotic. [A.G.E.]

Digestion and Absorption of Hemoglobin.—W. D. Halliburton² gives the results of his series of experiments carried out along physiologic lines to determine the question of digestion and absorption of hemoglobin in the general system. His conclusions are: 1. The administration of iron in the form of powdered hemoglobin, leads in rats to an increase in the number of red corpuscles and the amount of hemoglobin in the blood. 2. There appears every reason to suppose that the hemoglobin is actually absorbed; the intensity of ammonium sulfid reaction is much greater than in animals kept on a diet poor in iron; the main situation for absorption, as judged by this reaction, both to the naked eye and to the microscope, is the extreme pyloric end of the stomach and the first few inches of the abdomen. The spleen appears to be the principal organ for storage. 3. Hemoglobin in the stomach is converted into acid hematin. This is the pigment of what clinical observers call "coffee grounds" in the vomitus in hematemesis. Acid hematin after it is formed is slowly precipitated and is indiffusible through parchment paper. It therefore seems unlikely that much of it is absorbed. 4. By the pancreatic juice, however, it is rapidly dissolved and forms alkaline hematin, which diffuses through parchment paper. This accounts for absorption in the first part of the duodenum, lower down where the reaction no more becomes acid, absorption ceases. It is well known that in many animals the reaction of the intestinal contents becomes alkaline, owing to ammonia formation in the large bowel, but in rats Halliburton found the contents of the cecum and first part of the colon still acid. [A.B.C.]

Enemas of Blood of Benefit in Chlorosis.—Juan Manuel Mariani³ reported to the Fourteenth International Congress of Medicine at Madrid his results in chlorosis treated by enemas of blood. He now gives the details of seven cases, with his conclusions, as follows: 1. The blood so injected is quite well absorbed—it would seem entirely. 2. Tests made confirm the belief that the patient is rapidly and surely benefited, while the clinical appearances are satisfactory. 3. This treatment is good in cases of chloranemia, but of little value in anemia the result of cachectic morbid processes. [T.H.E.]

Treatment with Antituberculous Serum.—Alexander Marmorek⁴ reports results obtained in several patients treated by his antituberculous serum. He began with a series, having advanced tuberculous lesions, holding that if these could be

cured it was then time to begin with lesions of less advanced character. His results were sufficiently encouraging to warrant his continuing the treatment and applying it in less advanced cases. The more acute the lesion the sooner may good results be expected from the serum, though in the most acute form, tuberculous meningitis, Marmorek was not able to effect a cure. He states that in a large number of well-advanced cases he succeeded in reducing the hectic fever; many of these patients had previously been treated in sanatoriums and elsewhere without success. In mixed infection he suggests the alternate use of antituberculous and antistreptococcal serum. Many of his patients are doing well under treatment, but the time has not been sufficient for a cure to have taken place; however the physical signs have changed so much for the better that final complete cure is anticipated. [A.B.C.]

Injections of Thiosinamin in the Treatment of Keloid.—Presno y Bastiony¹ gives the following formula:

Water	} of each 45 gm.
Glycerin	
Thiosinamin	

This is given subcutaneously or even intramuscularly, though its administration is very disagreeable and painful. Bastiony believes thiosinamin to have a special value as a tissue-builder and regenerator. Hebra and Richter use the drug in the form of a plaster. [T.H.E.]

Serumtherapy of Tetanus.—Blumenthal² reports the cases of two women operated on the same day; on the eighth day one of them complained of slight soreness of the jaws. Considering tetanus a possibility, both patients were injected with curative doses of serum; tetanus convulsions developed in spite of the treatment and ultimately both died. The inefficacy of these injections, he explains through the fact that the serum, although capable of neutralizing the toxin within the circulatory stream, cannot do this within the peripheral and central nervous system, and hypodermic injections must therefore always be associated with subdural and intravenous injections. The wound must be thoroughly cleansed but amputations are not approved of by him. Morphin and chloral should be exhibited in large doses as they only can inhibit the convulsions. Whenever possible prophylactic injections should be employed. During the height of the disease no nourishment should be given by mouth on account of danger from aspiration pneumonia. [E.L.]

Treatment of Lumbago in Women.—Toledo³ offers the following as an excellent remedy for lumbago in women:

	Gm.—Dec.
Ferric phosphate	0 050
Ext. of belladonna	} of each 0 006
Ext. of nux vomica	
Ext. of cascara sagrada	

M. To make one pill. [T.H.E.]

Suggestion Treatment in Alcoholics.—Since the end of 1899, Stegmann⁴ has treated 28 drunkards of different types with hypnotic suggestion. Of these, five forsook treatment during the first week, although he was able to produce hypnotic sleep in all of them; seven others were treated for some time, but relapsed into old habits soon after discharge. The other 16 have been sober since treatment was commenced; seven have had short recurrences since discharge. Of the nine persons apparently cured, two have had no relapse for over two years, four for one year, and three for shorter periods. The treatment was conducted in the following manner: Patients who wished to be treated had intense suggestions made to them for weeks, in some cases for months, still while awake, later in the hypnotic state; after discharge they returned to the institution once or twice weekly for further suggestions. Most of the patients were asked to join temperance societies after discharge. With grave psychic disturbances the treatment is more difficult and the prognosis not so good. Long duration of the disease does not preclude a cure, but makes a longer stay in the sanatorium imperative. [E.L.]

Three Methods of Promoting Scientific Discovery.—The older method adopted by endowers and scientific societies was to offer prizes for manuscripts chronicling the discovery, their publication to be later and under the control of the prize-givers. The evils of this plan early became evident and as a consequence there is much competition now, among the prize-givers, not among the seekers, for contributions. What may be called the second method is that adopted by the Carnegie Institution, of grants to investigators, and this is a better plan; but it has already drawn upon itself the severe criticisms of many scientific men. The most telling of these relates to the impossibility of any group of human beings finding out in what direction, and especially by what particular workers, discovery is to come. There is a strange waywardness and obstinacy in the law of discovery, which often makes the official and recognized investigation resultless. The real resolution of the mystery so frequently comes by some unknown delver, who at first may even be sneered at by the official judges and leaders. The history of almost all great discoveries and progressive steps is that the recognized authorities ignored or scorned the great innovation and left the genuine discoverer to the inevitable and pathetic reward of his temerity. The third method is that adopted by Nobel: Reward the true discoverer and innovator as soon as the genuineness and value of his thought has been demonstrated.

Health Boards in towns and small cities often need organizing and reorganizing. We are too prone to pay attention to those of large cities only, forgetting that the country is often as unhealthy or more so than cities, and that the people by no means all live in cities. For their neglect of the manifest duty and the commands of the law, the executive officers are partly responsible, but upon the local medical profession must always rest the burden of the actual work. Only medical men can put the requisite zeal and science into actual reductions of the deathrate by practical efficiency. In many places there is no organization whatever, and in many more there is no life to the nominal organization. One is pleased to note that the thoroughgoing and scientific character of the work of health boards in some towns is often of as high an order as in the large cities. Serving without salaries, and often doing most needed

work, unrecognized perhaps by their fellow citizens, frequently perhaps making enemies by the very nature of their labors, these unknown presidents and members of the local boards have a thankless task. In one place, Warren, Pa., the review of the year's work for 1903, the methods employed to lessen the deathrate to an enviable figure are admirably set forth by Dr. Ball. The deaths from cancer are noteworthy—11% of the whole number. Next in order come organic diseases of the heart, 7.1%; chronic Bright's disease, 7.1%; pneumonia, 6.2%; debility in the aged, 6.2%; apoplexy, 5.3%; tuberculosis, 4.4%. The true spirit is shown in these words:

If we have succeeded in preventing one untimely death we have saved more than triple the amount of our appropriation. Money spent in guarding the health of a community and preventing disease is money well invested. To say nothing of the mental and physical suffering disease produces, the injury done to the business interests by any well-marked epidemic is not inconsiderable.

Picture Books.—In a laudable endeavor to attract the attention of the charitable there has lately grown up an interesting custom of hospitals, which consists in spending a large amount of the money contributed in making beautiful pictures. The annual reports of some of these institutions are veritable works of art and in a little pamphlet will be found on nearly each alternate leaf a full-page illustration of sylvan scenes, landscapes, rural, and architectural views, glimpses of chambers and sitting-rooms which are possible only to private citizens of wealth and leisure. It is well, indeed, that the sick and the crippled in life's battles should have precisely these peaceful and delightful places in which to regain health, or at least to pass the remnant of failed lives; but there seems to be an over-accentuated satisfaction in these conditions and a trend toward considering them ends in themselves. There remains, at least, the critical question as to the expense of the illustrations of the reports. The full-page reproductions on plate paper of exquisite photographs with tissue paper interleaving, as all book makers know, cost a deal of money. Did the almsgiving donors endow for this purpose? and is not the competition to get into these "havens of repose" sufficiently keen already? What relation do they bear to therapeutics? Could not the money be more wisely expended?

The American Red Cross controversy is by no means ended with the resignation of Miss Clara Barton. There has been no investigation and publication of the deplorable financial and other conditions of the society in the past, nor what they are today. There is no reputable and trustworthy new organization to guarantee that "the more it changes the more it [does not] remain the same." For example, the Red Cross report for 1903 stated as the balance of cash on hand \$124; whereas Miss Barton, in her letter announcing her retirement from the presidency, says: "It is a pride as well as a pleasure to hand you an organization . . . with no debts, and a sum from \$12,000 to \$14,000 available to our treasury as a working fund." It will be of interest to know how the meager balance of 1903 swelled one hundred fold or more in a single year. It is a great misfortune that during the long recess of Congress nobody representing the original aims, spirit, and organization of the Red Cross should be in a position to act promptly in concert for the relief of sufferers from an epidemic or other great disaster. At the outbreak of the war between Russia and Japan both Ambassador Cassini and Minister Takahiri declined in behalf of their governments the assistance of what now purports to be the American Red Cross. There can be little doubt that the motive for their refusal was a desire to keep out of the disagreeable muddle in which the wreck of the old society is now involved. A new charter was prepared during the last Congressional session, and it is expected that it will be authorized by the next Congress, but in the meantime much "investigation" is imperatively demanded if the organization is to be supported and to be of service in future emergencies. And also in the interim the talents of the ex-president can be usefully devoted to the encouragement of quack nursing schools and patent medicine vendors.

The Italian immigrant is the subject of a capital special number of that excellent periodical, *Charities*, and the *Revista Commerciale* has published the results of a statistical investigation of the Italians of New York City. One is astonished to learn that there are in that city 382,775 Italians, the great majority below 45 years of age, and nearly 50,000 are being added each year. Although 48% are utterly illiterate, the fact remains that they are "most valuable additions to our population." For instance, from the investigation made by the Committee of Fifty, of nearly 30,000 cases in the records of organized charity, it was shown that in 20% of the German cases, 24% of the American cases, 25% of the English cases, and 38% of the Irish cases, the principal cause of distress was intemperance; in only 3½% of the Italian cases was intemperance the cause. American city life is having a bad effect upon them. The sudden change of diet is responsible for an increase of certain diseases. The change from the stone cottage in the open fields to the dark and unventilated tenement of Mulberry and Mott streets has resulted in an alarming spread of tuberculosis. Dr. Stella, in his practice in New York, has known as many as 25 cases of pulmonary tuberculosis in one year in a single tenement house. The danger is sufficiently shown in

the fact that the mortality is greater among the second than the first generation. Dr. Stella says that in New York in the mortality from pulmonary tuberculosis among the different nationalities between the ages of 15 and 45, the Italians occupy only the tenth place in the list, losing but 149.9 per 10,000 population, as against 548.4 and 428.0 lost, respectively, by the negroes and the Irish, who lead the way. On the contrary, Italians come second in the table where the mortality is considered below the fifteenth year of life (children generally being allowed to die here); and the same high percentage would certainly be found for the adult generation, were the statistics arranged not according to the deathrate, but according to the infection-rate, which is simply appalling.

Comparative Per Capita Expenditure for Health Purposes of American Cities.—In his 1904 annual message the Mayor of Chicago thus epitomizes the health expenditures of different American cities for the year 1900:

Cities.	Deathrate per 1,000 of population.	Per capita expenditure for health purposes.
Chicago.....	16.2	\$0.10
Cleveland.....	17.1	.16
St. Louis.....	17.9	.22
Buffalo.....	18.4	.14
Cincinnati.....	19.1	.12
Pittsburg.....	20.1	.25
San Francisco.....	20.5	.64
Baltimore.....	21.0	.15
Philadelphia.....	21.2	.23
Boston.....	23.4	.30
New York.....	25.4	.30

These figures show Chicago's deathrate to be 20% lower than the average of the other 10 cities, 23% lower than that of Baltimore, 24% lower than Philadelphia, 32% lower than Boston, and 36% lower than New York. They show its per capita expenditure for health purposes to be 58% lower than the average, and 66.6% lower than that of Boston and New York. These results are traced to supervision of the milk-supply, to measures restricting the prevalence of infectious diseases, to the antitoxin treatment of diphtheria, to daily examinations and warnings as to the water-supply, etc.

In 1894 the city paid the penalty of previous years of neglected vaccination through an epidemic of smallpox, which cost 1,190 lives and an enormous loss in money. The practice of vaccination has been completely modernized and persistently pushed. At the close of last year there had been but 61 deaths from smallpox since 1895. In October, 1895, the department promoted the antitoxin treatment of diphtheria and assumed its treatment among the poor and destitute. In that year the deaths from this disease amounted to 11.66 per 10,000 of population. Last year they were only 3.44 per 10,000—a decrease of 70%. During the three years previous to the first appointment of the present Commissioner there were 4,494 deaths from typhoid fever—an average annual rate of 12.86 per 10,000 of population. During the last three years, 1901-1903, there were only 1,898 such deaths—an average annual rate of 3.46 per 10,000, and a decrease of nearly three-fourths (73.1%) in the typhoid mortality.

The Prevention of Ankylostomiasis.—One of the most thorough and generally valuable contributions to the subject of ankylostomiasis is that of Boycott and

Haldane,¹ who present a general discussion of the disease from the point of view of its prevention, particularly in mines. As the prevention of the spread of the disease depends largely upon the knowledge of the life-history of the parasite, that point is first considered by the writers. They find the longevity of adult worms to be such that individuals who in the past have been in contact with infected places, can be proved free from infection only by the absence of eggs in their stools. As to the resistance of larval worms, it has been quite conclusively shown that they are susceptible to the action of reagents, particularly corrosive sublimate, to such a degree as to encourage the practical use of disinfectants; this is true even of the "encapsuled" larva, which appears to be the infective stage of the ankylostoma. In considering the paths of infection, the writers call attention to a phase of the question not hitherto generally known, namely, the importance of infection through the skin. In a previous paper they gave an account of the very troublesome skin eruptions associated with cases of ankylostomiasis among the miners at Dolcoath mine, in Cornwall. Inquiry has failed to show that such eruptions were specially associated with cases of the disease among workers in other mines in England, and personal experiments, in which cultures of larvas were bandaged on the arm for as long as twelve hours, have repeatedly yielded negative results. Notwithstanding these facts, the association of the skin disease known in Assam as "water-itch" or "ground-itch" with the prevalence of ankylostomiasis, and the experiments of Looss on puppies and on man, in addition to the Cornwall cases, seem to the authors to render it all but certain that infection with ankylostomas may occur quite readily through the skin. If this is true, precautions against infection through the mouth will not effectually prevent the disease among ground workers, although there seems to be no doubt that this is the chief path of infection in man. Among the means of actually preventing the disease in mines, the following are mentioned: The drinking of clear water, the adoption of cleanly habits in eating, the rigid exclusion of all persons whose feces contain ova, prevention of fecal pollution of mines. Many of these prohibitions mean considerable expense to mine owners, but when contrasted with the loss from the presence of the disease, the monetary significance of medical supervision, etc., necessary to enforce them becomes markedly lessened.

Leprosy; Mr. Hutchinson's "Fish Hypothesis."

—The "fish hypothesis" of the origin of leprosy is still being advocated by Mr. Jonathan Hutchinson, of London, with zeal. All the world knows that Mr. Hutchinson's hypothesis is that the cause of leprosy in man is a (ill-conditioned) fish diet. Accordingly, this malady is not transmissible by the methods of contagion, and segregation means unnecessary and useless expenditure of pains and trouble. One must see at a glance that in order to establish this hypothesis it is necessary to prove that every subject of leprosy has partaken of such diet, and that every person who never partakes of the same remains always free from the disease. Before the fish

hypothesis of the origin of leprosy is admitted, it must be proved that every leper has been a partaker of such fish diet. And it must be proved that nonlepers have been—at least—less addicted to its use than the victims of the disease. From both these aspects the foundation of Mr. Hutchinson's hypothesis still remains in an unsatisfactory condition. It is well known that in numerous tribes of Kashmere and of Southern Africa, leprosy is of frequent occurrence, although the touch—far more the taste—of fish is treated as a religious sacrilege, punishable with tribal excommunication. Still Mr. Hutchinson, by the most laborious investigation, thinks that he has gathered evidence sufficient to prove the possibility of the affected individuals of these localities having at some date ingested some smuggled preparation of ill-cooked or ill-preserved fish. Such evidence, of course, involves no sort of explanation of the infinitely greater susceptibility of the members of the tribes in question. With regard to Europe, he explains the greater frequency of leprosy in some countries by their adhesion to the older form of the Christian faith; and the definite proportion of fish dietary to which its inhabitants adhere, in conformity with their religious regime. Accordingly, the disappearance of leprosy from England and Scotland is readily explained; as a consequence of their adoption of the reformed faith and its dietic methods. But—according to the metaphoric derivation of *lucus a non lucendo*—the omission of a reference to Ireland in this connection is somewhat suggestive of a Hibernicism. The great body of the Irish peasantry has always remained *unreformed*; and along the coast line, especially in the South and West, the poorest of the inhabitants partakes largely of a fish diet all the year round. In some of those parts fuel is so scarce that the cooking is often done by the help of dried twigs and leaves, and cow dung. It is hardly necessary to add that the cooking often hardly deserves the name, while the hygiene of such districts is of the most primitive description, and admits the consumption of the fish in almost every conceivable condition. Yet the occurrence of a case of leprosy is never heard of, far less seen.

Capitalizing Mystery.—The charm of the mysterious is inexhaustible, as the South Sea Bubble and all of Mrs. Eddy's children have exemplified. With the inevitable logic of a commercial world, we shall perhaps soon have million dollar syndicates for securing the miraculous vibrations of health, success, and happiness straight and fresh from the creator, purity and genuineness guaranteed, together with 25% dividends, payable quarterly at the company's office, located anywhere and everywhere. A noteworthy indication of the trend is shown by a bulky periodical, "The New York Magazine of Mysteries." No. 3 of Volume VI is now lying before us. It is "a magazine of health, happiness, and prosperity." It deals in palmistry, prophecy, dreams, psychometry, new civilizations, wisdom, metaphysics, etc., but its greatest things for sale are prayer, healing vibrations, religiosity, and success. The Mystic Healing Circle costs patients \$1.00 a month, and the testimonials are delightful in writing of the miracles

¹ Journal of Hygiene, January, 1904.

performed by "Mystic Adept No. 12" in their bodies through his healing vibrations, which cure tuberculosis, estrangement, bowel troubles, insomnia, out-of-work, weakness, sickness, melancholy, and all the rest. It is entered as second-class matter at the New York Post-office. The advertisements offer cures of spinal curvature, deafness, stammering, rheumatism, biliousness, kidneys, heart, neuralgia, cascades, etc. Sexology is, of course, to be had, hair-growers, and hair-removers, and hair-stainers, diamonds on credit, spectacles at wholesale, astrology, and gold watches free.

An Oculist's Division of the Spoils.—The following letter is being received by the citizens of Philadelphia, and deserves the serious attention of the profession:

In the early part of September last, I outlined a plan of mutual advantage on a 20% basis to you for all eye work sent me, together with the prescription work. That the plan has proved a signal success is attested by the 17 opticians who have so far responded.

In the four months in which the system has been in operation I have distributed commissions to the amount of \$198, averaging over \$2.50 to each patient sent me, and at the same time have kept my fee for services under an average of \$10 per case. One optician alone received \$42 in commissions in nine weeks, together with 14 prescriptions for glasses, from which he made a nice profit. He acknowledges that the work has proved entirely satisfactory and that he would not have made half this amount had he refracted the patients himself or sent them elsewhere.

My practice is limited to eye, ear, nose, and throat work. I have had large experience as resident surgeon and assistant in the leading hospitals of this city, and my offices are fully equipped to do the work right.

I ask you to use my card with your endorsement when an opportunity for recommending a specialist arises, and for which

1. You receive 20% commission for all cases sent me.
2. You receive the commission and prescription for glasses promptly by mail.
3. You receive both from any case coming to me through a patient, sent by you. Further, I direct patients from my personal following to opticians, who cooperate with me, and which will average more than an equal exchange, and for which I ask nothing.

My fees are extremely low, and for the really poor, nominal only. I am reaching out for more business, and I have the ability and facility to care for it satisfactorily. Will you join me? Thanking you for your attention, and wishing you a happy and prosperous New Year, etc.,

I am, very truly yours,

The letter of this physician for revenue is here reproduced to call the attention to a hundred schemes to fleece the patient suffering from eyestrain. There is no part of medical practice so abused as that of the specialist in diseases of the eye. The profession seems to have made up its mind that nonprofessionalism as to the eye does not count. The druggist may not prescribe for typhoid fever or stomach-ache, but spectacle peddlers fill the land, and a host of quack colleges, schools, and institutions manufacture "ophthalmotricians," and every sort of "eye-doctors" that may be imagined, and as many that cannot. There is a big penalty to pay for this professional neglect to protect the community from the malpractice of ignorance and greed.

BOOK REVIEWS

The International Medical Annual.—A Year Book of Treatment and Practitioner's Index. Twenty-second year. 1904. New York: E. B. Treat & Co. Price \$3.

An extended review of this wellknown publication is unnecessary. The present number is fully up to the former standard, which is that of one of the best summaries of current medical and surgical literature. With but two exceptions, the contributors are English physicians; all are men of eminence in the profession. The volume contains 742 pages of text; to this is added a list of the principal medical books published during 1903. Illustrations include 34 plates and 38 diagrams. A new departure is the introduction of stereoscopic views, illustrating the anatomy of the ear. All articles have been thoroughly condensed, which allows of a very large number of really valuable references.

Immune Serums.—By PROFESSOR A. WASSERMANN, M.D. Authorized translation by CHARLES BOLDUAN, M.D. New York: John Wiley & Sons. 1904.

This little monograph of 77 pages supplies a distinct need for concise and definite information regarding a subject that is at present of paramount importance in experimental medicine. Under the three titles of Hemolysins, Cytotoxins, and Precipitins is given the gist of modern ideas concerning immunity, special attention being paid to Ehrlich's side-chain theory. This necessarily complicated subject is set forth so simply and intelligently that its principles, all that can be given in a work of such size, may readily be grasped by any careful reader. Every physician ought to read this book, and it should prove invaluable to students of medicine.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences.—Edited by HOBART AMORY HARE, M.D., assisted by H. R. M. LANDIS, M.D. Vol. vi, No. 1, March, 1904. Lea Brothers & Co., Philadelphia and New York.

This volume comprises a critical digest of recent literature on the surgery of the head, neck, and thorax, by Dr. Charles H. Frazier; on the infectious diseases, including acute rheumatism, croupous pneumonia, and influenza, by Dr. Robert B. Preble; on the diseases of children, by Dr. Floyd M. Crandall; on laryngology and rhinology, by Dr. Charles P. Grayson; and on otology, by Dr. Robert L. Randolph. The recent literature on each of these branches of medicine is very well covered, there is an excellent assortment of the wheat from the chaff; and in its new dress the volume sustains the reputation attained by its more dressed-up predecessors.

Medical Epitome Series: Pediatrics.—By HENRY ENOS TULEY, A.B., M.D. Lea Brothers & Co., Philadelphia and New York.

This number of the series edited by Pedersen is a very successful condensation of accepted knowledge regarding pediatrics. Unusual ability to state things concisely is shown by the distinguished author, hence the book is exactly what it purports to be and contains a very great amount of information in small compass. We think, however, that the true nature of the book would be better indicated if the subtitle was changed from a "A Manual for Students and Practitioners" to "A Manual for Students." For those who from inclination or necessity wish rapidly to review the essentials of the subject the book will prove very valuable; we cannot believe that the practising physician will often refer to it in preference to larger treatises.

Physiology and Pathology of the Urine, with Methods for its Examination.—By J. DIXON MANN, M.D., F.R.C.P. Charles Griffith & Co., London; J. B. Lippincott Company, Philadelphia, 1904.

The author intends this volume to serve as a clinical guide in the diagnosis and treatment of disease. He describes the constituents of the urine, its physical properties, its chemical reactions and the methods to be followed in its examination. While strictly clinical methods are allotted the chief place, many processes are described that are best carried out in the

laboratory of pathologic chemistry. The first 234 pages of the book deal with the urine and its examination; the remaining 32 pages are devoted to a discussion of the urine in its pathologic relations or its characters in various diseases. References to many of the original articles mentioned are furnished. The book is well written and is up to date. It can be recommended as a very convenient guide to urine examination.

Manual of Clinical Microscopy and Chemistry.—By Dr. HERMANN LENHARTZ. Authorized translation from the fourth and last German edition, with notes and additions by Henry T. Brooks, M.D.

Lenhartz has succeeded very well in his attempt to furnish students and physicians a book that will not only instruct them in microscopic and chemie methods of examination, but also aid them in interpreting the diagnostic significance of their results. The accomplishment of this difficult task forms the chief recommendation of this work among the many laboratory guides now offered to the profession. The emphasis placed upon diagnostic features has led to the necessary abridgment of certain parts of the technical side of the book. The translator has very happily supplied this want where it existed by inserting descriptive notes of instruments and technic that are so essential to the untrained or partially trained investigator. The book thus rounded out is a very complete one, and can be unhesitatingly recommended to physicians. The contents of the 395 pages are grouped in six divisions: 1. Vegetable and Animal Parasites. 2. The Blood. 3. The Sputum. 4. Secretions of the Mouth and the Gastric and Intestinal Contents. 5. The Urine. 6. Aspirated fluids.

BOOKS RECEIVED.

[Prompt acknowledgment of books received will be made in this column, and from time to time critical reviews will be made of those of interest to our readers.]

International Clinics. Vol. I, Fourteenth Series, 1904: A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otolaryngology, Rhinology, Laryngology, Hygiene, and other topics of interest to students and practitioners by leading members of the medical profession throughout the world.—Edited by A. O. J. KELLY, A.M., M.D., Philadelphia, U. S. A. With the collaboration of William Osler, M.D.; John H. Musser, M.D.; James Stewart, M.D.; J. B. Murphy, M.D.; A. McPhedran, M.D.; Thomas M. Rotch, M.D.; John G. Clark, M.D.; James J. Walsh, M.D.; J. W. Balantyne, M.D.; John Harold, M.D.; Edmund Landolt, M.D.; Richard Kretz, M.D. J. B. Lippincott Company, Philadelphia, 1904.

The Therapeutics of Mineral Springs and Climates.—By I. BURNEY YEO, M.D., F.R.C.P., Emeritus Professor of Medicine in King's College, London; Consulting Physician to King's College Hospital; Honorary Fellow of King's College; formerly Professor of Principles and Practice of Medicine and of Clinical Therapeutics in King's College, and Examiner in Medicine at the Royal College of Physicians. W. T. Keener & Co., Chicago, 1904. Price, \$3.50 net.

Digest of Researches.—By Laboratory Workers of the Smith, Kline & French Company of Philadelphia, 1904. Volume I, comprising abstracts of papers published from 1898-1904.

A Manual of Fever Nursing.—By REYNOLD WEBB WILCOX, M.A., M.D., LL.D., Professor of Medicine in the New York Postgraduate Medical School and Hospital; Consulting Physician to the Nassau Hospital; Visiting Physician to St. Mark's Hospital; Fellow of the American Academy of Medicine; Member of the American Therapeutic Society, etc. Illustrated. P. Blakiston's Son & Co., Philadelphia, 1904.

Lea's Series of Medical Epitomes. Epitome of Pediatrics: A Manual for Students and Practitioners.—By HENRY ENOS TULEY, A.B., M.D., Professor of Obstetrics in the Medical Department of Kentucky University, Louisville, Ky. In one volume of 266 pages, with 33 engravings. Cloth, \$1.00 net. Lea Brothers & Co., Publishers, Philadelphia and New York, 1903.

The Practical Medicine Series of Year Books.—Comprising 10 volumes on the year's progress in medicine and surgery. Issued monthly under the general editorial charge of GUSTAVUS P. HEAD, M.D., Professor of Laryngology and Rhinology, Chicago Postgraduate Medical School. Vol. III. The Eye, Ear, Nose and Throat. Edited by CASEY A. WOOD, C.M., M.D. D.C.L.; ALBERT H. ANDREWS, M.D.; GUSTAVUS P. HEAD, M.D. December, 1903. The Year Book Publishers, Chicago.

Physiology and Pathology of the Urine: With Methods for its Examination.—By J. DIXON MANN, M.D., F.R.C.P., Physician to the Salford Royal Hospital; Professor of Forensic Medicine in the Victoria University of Manchester. With illustrations. J. B. Lippincott Company, Philadelphia, 1904. Price, \$3.00.

A Textbook of Physiology.—By ISAAC OTT, A.M., M.D., Professor of Physiology in the Medico-Chirurgical College of Philadelphia. With 137 illustrations. Royal octavo, 568 pages. Bound in extra cloth. Price, \$3.00 net. F. A. Davis Company, Philadelphia, Pa.

Röntgen Ray Diagnosis and Therapy.—By CARL BECK, M.D., Professor of Surgery in the New York Postgraduate Medical School and Hospital; Visiting Surgeon to St. Mark's Hospital and the German Poliklinik. With 222 illustrations in the text. D. Appleton & Co., New York and London, 1904.

AMERICAN NEWS AND NOTES

GENERAL.

The American Medical Temperance Association.—The thirteenth annual meeting will be held in the parlors of the Hotel Dennis, at Atlantic City, June 8 and 9, 1904, at 9 a.m. The object of this Association is to encourage and promote the clinical, therapeutic, pharmacologic and chemie study of alcohol in health and disease. It also aims to gather, compile, and make available the studies and experiences of medical men in all parts of the country, concerning the use of alcohol, and to formulate such definite facts as can be utilized and made available in the practice of medicine. For particulars address T. D. Crothers, Secretary, Hartford, Conn.

Miscellaneous.—Maine: The Maine Medical Association will hold its fifty-second annual meeting in Portland, Maine, June 1, 2 and 3, 1904. Dr. Frederick C. Shattuck will deliver the annual oration, his subject being "The Anomalies of Thyroid Secretion, General." **New Organization to be Formed to Combat Tuberculosis:** A number of wellknown physicians in the United States, among whom are Drs. Trudeau, Biggs, Flick, Sternberg, Osler, Welch and Jacobs, and others, will convene at the public school building in Atlantic City, June 6, at 8 p.m., for the purpose of organizing the National Association for the Study and Prevention of Tuberculosis. **New York:** The Manhattan Eye, Ear and Throat Hospital is the recipient from Edward R. Thomas of \$40,000. The amount is given as a memorial to General Samuel Thomas, father of the donor. This secures conditional gifts of \$125,000, and makes possible the erection of a new hospital. **The American Surgical Association** will hold its annual meeting in St. Louis, June 14 to 17, 1904.

Liable for Appendicitis.—An interesting point of law was determined by the full bench of the Supreme Court recently when it held that the Boston Elevated Railway Company was liable for an attack of appendicitis which James J. Sullivan suffered two years and three months after an injury he sustained by reason of the negligence of the road. The company had strenuously urged that the attack of appendicitis was too remote and that the accident was not the proximate cause of it. It contended, further, that damages by reason of that contention could not be recovered against the road. The accident happened August 8, 1900, in Main street, Charlestown, as a result of a car running into a brewery wagon which Sullivan was driving. With Sullivan was John J. Knox, who also was injured. Sullivan had been in good health up to the time of the accident, and was operated on for appendicitis in November, 1902. The operating surgeon testified that the accident was a sufficient cause for the appendicitis. Sullivan received a verdict of \$4,000, but subsequently agreed to abate \$1,000 from it. Knox was awarded \$2,250.

Poison in Canned Foods.—News from Washington states that a series of experiments have been carried out by Dr. Wylie since January last, have demonstrated that certain poisons are found in canned goods. Experiments were carried out by a number of persons who volunteered their services for the purpose, being fed on the canned foods. Some of the so-called poison squad, of a dozen men, have suffered in the course of the experiments. The ill-effects of eating drugs used in preserving articles of food are said to be visible on all members of the squad, and one or two of them are on the verge of breaking down. Two of the young men are from Georgetown University. One is from the Columbian. The others are employees of the chemie laboratory of the Department of Agriculture. The experiment was made to ascertain exactly what are the effects on the human system of preservatives used by food packers, both domestic and foreign. The results show the preservatives are injurious to the digestive tract. The experiment tends to explain away many poison mysteries following the eating, by people in various parts of the country, of canned goods and preserved foods generally.

Pneumonia vs. Tuberculosis in Chicago and New York.—The Bulletin of Chicago's Health Department for the week ended May 7, says: The excessive mortality that has obtained from the two specified diseases since the first of last November still keeps up, and all previous records, both in this city and in New York, have been far distanced this season. At the close of office hours on Saturday, May 7, the reported deaths from all causes, from tuberculosis and from pneumonia in each city, since November 1, 1903, were as follows:

	New York	Chicago
Total deaths, all causes	42,249	15,829
Deaths from tuberculosis	4,706	1,686
Deaths from pneumonia	9,119	3,448
Proportion percent of all deaths:		
From tuberculosis	11.1	10.6
From pneumonia	21.5	22.4

These figures show that, while New York has had a 4.7% excess of tuberculosis mortality as compared with Chicago, the latter city has had a 4.2% excess of pneumonia mortality.

The War on Mosquitos.—An exchange calls attention to the war which is being waged this spring in various parts of the country and states that: The chief center of operations is New Jersey, where plans are already on foot for an antimosquito crusade. Ponds where the insects breed will be drained and filled up, and the mosquito will be attacked in the larva stage. Suggestive communications were recently sent by New Jersey's State entomologist to Long Branch and to Cape May relative to the work of extermination of these infested points. At Long Branch the mosquito-breeding areas have been located and about 7,300 feet of ditching will be constructed. It is said that the whole of Cape May's mosquito supply is bred within its own haunts, which will be drained at once. When it is understood that a mosquito can reproduce itself nearly 400 times a week under favorable conditions and that the progeny of one mosquito will number over 60,000,000 in a season, the immensity of the task of extermination is apprehended. It is apropos to note that the proposition to form a national antimosquito organization is under consideration. It is proposed through a national society to distribute literature dealing with the subject, describing the breeding places of the mosquito and the easiest way of doing away with them.

The Red Cross in the United States.—Clara Barton's recent resignation from the head of the Red Cross Society in the United States paves the way for a complete reorganization of the society. The parent organization, it appears, was not in complete harmony with various too loosely affiliated local organizations in the several States. These latter held themselves not responsible to, nor subject to the central organization in Washington; this, together with the lax business methods on the part of the central organization, form the basis for contentions, investigations, and dissensions. The latter reached such a crisis that Clara Barton, for many years the head of the central organization has resigned, and it now remains for a complete reorganization to effect a unification of the parent society and the affiliated societies into one complete whole, whose central head and supreme authority will probably be vested in the head of the central organization in Washington, D. C. Only in some such manner can the Red Cross in the United States hope to equal in effectiveness and utility the Red Cross organization in the more progressive and enlightened European countries.

The Etiology of Scarlet Fever.—Dr. Mallory, of Boston, claims to have discovered a protozoon which is the cause of scarlet fever. Concerning this discovery, Dr. Mallory is credited with the following quotation: "These protozoon bodies which I have found resemble the well-recognized protozoa or microorganisms which are the cause of malaria. They are, however, about a third larger. The bodies are of two types. One is a granular form which varies in size from one to seven or eight microns in diameter, a blood-corpuscle being seven microns in diameter. The other type of body is radiate in structure and resembles the segmenting forms of rosetts found in malaria. These rosetts break up and each segment forms a small granular body. In other words, we have a cycle of development corresponding to that of the malarial organisms. It is not possible at the present time to prove that these bodies in scarlet fever are live organisms and that they are the cause of the disease, but from their morphology, the development cycle which can be traced in them and their staining reaction, it seems possible that they may be. In four cases during the stage of the eruption, three times in the skin and once in the tongue. They are found both in the protoplasm of epithelial cells and also in the superficial lymphatics of the skin. They bear no resemblance whatever to the bodies found in cases of smallpox and vaccinia, the disease which comes from vaccination. In the six other cases under study the protozoa were not found, but only small bits of skin were available in those instances for study. In their morphology and in their staining reaction they do not resemble in any way leukocytes or degenerating cells. It is a subject of difficult pathologic research because fresh material cannot be easily obtained from living cases of scarlet fever, and there is no way in which the parts of the body over which the protozoa may be distributed can be ascertained."

NEW YORK.

Fewer Cases of Pneumonia in New York.—For the first time since January 1, officials of the Health Department have been able to report a let up in new cases of pneumonia. There have been in greater New York more than 200 deaths each week in this year—double the average of the preceding year—the greatest number reported being 311 for the week ended March 5. A campaign of education will at once be put under way in the hope of preventing a recurrence of the scourge.

Reception Hospital for the Insane.—It is announced that Governor Odell has approved a bill authorizing the city of New York to acquire a site for the establishment thereon of a reception hospital for the insane, and authorizing the State Commission in Lunacy to erect such a building. The need of such a hospital has long been urged. New York has no such reception pavilion. Advocates of the bill have pointed out that the difference between a speedy recovery and permanent mental derangement can oftentimes be laid to the first place of detention to which an insane person is taken.

To Fight Spotted Fever.—That there is an epidemic of cerebrospinal meningitis among children of the city is shown by the daily reports of hospitals, dispensaries and clinics of Manhattan and the Bronx, and that the mortality is considerable is evidenced by weekly statistics of the Health Department. That the epidemic is the greatest the city has ever known in this disease or that the mortality from it has broken records is not denied by the authorities as well as by physicians, both in private practice and public work. Territorially every part of the city may be said to be affected at this time. Cerebrospinal meningitis is at present a baffling disease to physicians generally, because its symptoms are so irregular that no definite diagnosis can be laid down, and a course of treatment which may be effective in one case may have the opposite result in another. But that the profession is learning fast how to conquer the malady there is no reason to doubt.

Vaccination Frauds.—Health Department officials have discovered a system of swindling for small amounts ignorant people of the East Side, by the sale of bogus certificates of vaccination. Many of the certificates, it is said, have been issued by dispensaries, and evidence has been secured to the effect that some physicians have been peddling the certificates at 10 cents each. Dr. Darlington, the Health Commissioner, said that he wished not only to warn purchasers of the certificates that the documents would not be received at the public schools, but that he wished to advise people that they were throwing away any money by the purchase of certificates which have been and are issued free by the Health Department. Certificates given by reputable physicians to the effect that examinations of scars have been made and found satisfactory are accepted without question, but none of these contains a "guarantee." The sale of the certificates has been extensive, the buyers believing that possession will permit children to attend school without any other formality. All certificates are issued gratis by the Health Department for all children submitting to examination of scars or to new vaccination.

Loomis Sanatorium for the Tuberculous.—The seventh annual report of the superintendent of the Loomis Sanatorium for the tuberculous, situated at Liberty, Sullivan county, New York, has lately been issued. This report states that the treatment remains practically the same as that which has been in vogue for several years, no "specific treatment" being employed. The clinical work has been along the lines of exhaustive studies of the blood of patients suffering with tuberculosis, chemic and microscopic investigation of the stomach contents of such patients as presented digestive disturbances, and more thorough and exhaustive study of the excretions, both physiologic and pathologic. To summarize briefly the most important results of the year's work then, of the 119 patients, in all stages of the disease, discharged from the main sanatorium during the year, whose term of residence was a month or more, there were apparently cured 23, or over 19.3%, and with disease arrested 24, or over 20%. Thus a total of 47 patients, or over 39%, were enabled to return to their homes and resume in part, or whole, their several occupations. In the annex, of the 58 patients reported upon, 9, or 15.5%, were discharged apparently cured, while 16, or 27.5%, were discharged with disease arrested. In other words, 25, or 43%, were enabled to return to their homes and occupations.

PHILADELPHIA, PENNSYLVANIA, ETC.

Resident Physicians Elected.—At the regular meeting of the Board of Trustees of the Polyclinic Hospital, held May 19, the following were elected resident physicians to fill the vacancies occurring in the resident staff during the coming year: James K. Hall, John Decker Butzner, Edward D. Lovejoy, George Eaton Adams, and John Read.

To Combat Tuberculosis.—The White League, an association for the treatment of tuberculosis, applied for a charter recently to Common Pleas Court. The object of the league is to treat the disease by modern scientific methods, including open-air camps and hospitals. It proposes to provide for the suitable employment and maintenance of those suffering from the disease.

Faculty Reorganization, University of Pennsylvania.—A plan for the reorganization of the faculty has just been approved by the Board of Trustees, whereby the faculty membership has been extended to the clinical, associated and assistant professors, to the associates and lecturers and to limited representation from the subordinate staff. The scheme provides for an executive body or council, to be composed of the heads of the departments in the fundamental subjects and two representatives of the specialties. The plan will be put into effect September 1, 1904.

Vaccination against Tuberculosis.—At a meeting of the State Live Stock Sanitary Board, at Harrisburg, a report was made on the general progress of the work for the past year. An investigation which is being conducted in relation to the protection of cattle against tuberculosis by vaccination, shows that

vaccinated cattle exposed for a year to daily contact with tuberculous animals remained free from disease, while unvaccinated cattle exposed in the same way, become extensively affected. In connection with these experiments, calves of tuberculous cows are being vaccinated and are then left with their diseased mothers and are allowed to use their milk, with the view of discovering whether vaccination will be effective under such conditions. Unvaccinated calves raised in this way, it was reported, almost invariably contract disease.

Rule for Requirements in Physical Examination of Teachers Defeated.—The proposed rule requiring all candidates for certificates of qualification to teach in the public schools to pass a physical examination was defeated in the Board of Education recently by one vote. The rule is suggested to be applied to prospective students in the Normal School and the School of Pedagogy at the time of applying for admittance. As amended, it provides that candidates shall answer the following questions: "Have you had any severe illness within the last year? If so, what was it? How much time have you lost from your studies, attendance at school, or vocation, through illness in the last two years? Have you any disease of the throat, eye or ear? Have you been successfully vaccinated within three years? What is your age?" It provides also that a certificate shall be signed by a physician in the following form: Name and address of applicant examined. Has the applicant pulmonary tuberculosis? Has the applicant any contagious disease of the skin or mucous membrane? Has the applicant any defect in hearing? If so, describe its extent. Has the applicant any irremediable defect in vision? Has the applicant any defect or disease which will disqualify him or her from performing regularly the duties of a teacher? It is expected that the matter will be again taken up in June.

Convicted for Illegal Practice of Medicine.—A correspondent sends us the following interesting item: "E. E. Leifer, alias Doctor Leifer, came to Chambersburg, Pa., in March, and commenced treating (?) diseases, using a small electric battery and some sort of decoction for medicine. A warrant was sworn out against him for obtaining money upon false pretenses. He was arrested as he was making an effort to leave the county. The count upon which he was arrested failed at the hearing before a justice. He was at once rearrested for practising medicine illegally, and practising as an itinerant. For this he was held for court. At the April term of court he was tried and convicted. The prosecution was brought by the District Attorney and by the Attorney of the Medical Society of Franklin county. Judge Stewart, in charging the jury, said that the law was designed to protect the health of the people of the Commonwealth, and not to protect the physicians as a body of men. May 1, Leifer was sentenced. The sentence imposed was very mild, as he had a wife and child in dependent circumstances. He was directed to pay the costs and to quit the county. In sentencing Leifer, Judge Stewart told him just why the sentence was light and intimated that he had better not attempt to practise again in Franklin county. He told the man that he was an impostor and not a physician, and could not cure people as he pretended to do."

WESTERN STATES.

Pneumonia and Tuberculosis.—The Bulletin of Chicago's Health Department for the week ended May 14, says: "What was styled, in one of last October's Bulletins, the 'murderous' pneumonia season is drawing to a close, but still has a tale of deaths double those of pulmonary tuberculosis, or consumption. Since the beginning of the current season, November 1, 1903, there have been reported 3,565 deaths from pneumonia and 1,696 from consumption in this city. In the city of New York, during the same period, the figures are 9,460 and 4,878 respectively. These two diseases, pneumonia and consumption, are responsible for one-third the total deaths from all causes in the two cities within the last six months and of the two, pneumonia has been twice as destructive of human life as consumption."

FOREIGN NEWS AND NOTES

GENERAL.

Would Require Hospital Training for Unmarried Girls.—A Zurich woman doctor is advocating a scheme under which all unmarried girls of the well-to-do classes are to be compelled by the State to devote one year to unpaid hospital work. She claims that not only would the hospitals benefit, but the girls would gain a training which would be of great value to them after marriage.

Doctors Poorly Paid.—Correspondence just printed in the newspapers call attention to the smallness of the salaries paid to house physicians in London hospitals. Out of 20 examples selected, the average salary is about £870 a year, in addition to board and lodging. At St. Bartholomew's Hospital, one of the largest in London, not only is no salary paid, but the

hospital doctors have to pay their own living expenses. The result in all cases is the selection of physicians according to the money they have and not through fitness, as only men possessing private resources are able to take hospital posts. There are many instances where excellent men have thus been excluded from appointments which are filled by less skilled young doctors who happen to be wealthier.

Blue Light in the Treatment of Neuralgia.—From a statement in the London *Daily Graphic*, it appears that the blue-glass cure is used in Italy for neuralgia. The apparatus used consists of a bell-shaped reflector, large enough to converge all the light from a lamp of 30-candle power, covered with blue glass. The patient sits about a foot from the lamp, and the light is directed over the neuralgic area. The doctor who uses this appliance is satisfied from the results obtained that the blue rays have marked anesthetic and pain-soothing properties on all types of neuralgia, not only giving relief when superficial structures are affected, but penetrating to the deeper tissue and even the abdominal organs. The action, he considers, is due to changes in the circulation, as well as a specific action in the blue light. Unlike the röntgen and ultraviolet rays, simple blue electric light is not possessed of any dangerous properties, so that the new treatment is one which might safely be tried by any sufferer from one of the most distressing "ills that flesh is heir to."

Sanitation and the Canal.—Colonel W. C. Gorgas and Major L. A. LaGarde of the medical department, and Medical Director J. W. Ross of the navy are hard at work on their plans for the redemption of Panama. Their visit to the isthmus disclosed the fact that those experts will have the biggest job of its kind which the profession has ever been called upon to consider. Practically nothing was ever done in Panama in the way of sanitation, and the indifference of the people who have been there, and who are there now, to the ordinary comforts of life as we know them is nothing short of appalling. The "palaces" where members of the commission stayed during their visit to the isthmus were barren of the conveniences of civilization and they found only one bath-tub in a country where such a feature was more a necessity, one would think, than a luxury. It will be necessary to furnish a water-supply for the cities of Panama and Colon, as well as along the line of the canal, where now water is delivered in barrels, each a receptacle for the breeding of millions of disease bearing mosquitos. Then, there will have to be a sewerage system at both towns, and Colon, to meet the sanitary demands in that locality, will have to be raised four feet. There will have to be hospital accommodations provided for 30,000 people and the establishment of strict rules for the government of the people, native and foreign, who live within the zone of canal administration. The army and navy surgeons are enthusiastic over their work, mainly because it is such a gigantic task and presents to them a field practically virgin. They have a professional curiosity in comparing the vital statistics of old conditions on the isthmus with those which will prevail under the new order of things.—[*Army and Navy Register*.]

OBITUARIES.

Julius A. Freeman, was killed in a runaway accident near his home in Millington, Ill., May 8, aged 76; a graduate of the American Medical College, Cincinnati, in 1850; member of the American Medical Association; ex-president of the North Central Illinois Medical Association; surgeon in the Federal army during the Civil war.

Joseph D. Titcomb, from pneumonia, at his home near Duluth, May 6, aged 45; a graduate of the Medical School of Maine, at Bowdoin College, Brunswick, in 1881; member of the American Medical Association and various State and county Associations. He was one of the most prominent ophthalmologists of the Northwest.

C. S. Priestley, from pneumonia, at his home in Des Moines, May 13; a graduate of the University of Pennsylvania in 1894; member of the American Medical Association, Iowa State Medical Society, and various local societies; professor of dermatology in the Drake University Medical College, Des Moines.

Truman B. Ellis, at his home in Bethany, Harrison county, Mo., April 28, aged 48; a graduate of the State University of Iowa, College of Medicine in 1881; member of the American Medical Association and various local organizations.

Andrew J. Leitch, from paralysis, at his home in Niles, Ohio, May 6, aged 56; a graduate of the Medical Department of Western Reserve University, Cleveland, in 1871. He retired from practice in 1898.

John E. Miller, at his home in Darbyville, Ohio, May 8, aged 43; a graduate of the Starling Medical College, Columbus, Ohio, in 1889; one time member of the Ohio State Legislature.

A. J. Campbell, at his home in Knoxville, May 4, aged 74. A surgeon in the Confederate army during the Civil war and for more than fifty years a practitioner of medicine.

Henry A. Wise, of Williamsburg, at St. Luke's Hospital, Richmond, Va., May 5, aged 80; a graduate of University College of Medicine, Richmond, Va., in 1896.

Henry Levy, at his home in Perth Amboy, N. J., May 5, aged 47; a graduate of the New York University in 1878; member of the American Medical Association.

Jacob C. Lee, shot and killed himself, at his home in Lees Summit, Mo., May 8, aged 46; a graduate of Hospital College of Maryland, Louisville, in 1877.

J. M. Woodward, at his home in Montmorenci, S. C., April 30, aged 55; a graduate of the Medical College of the State of South Carolina in 1878.

Martin L. Shanks, from Bright's disease, at his home in Casselton, N. D., May 5, aged 55; a graduate of Columbus (Ohio) Medical College in 1882.

Josephus Jordan, at his home in Zanesville, Ohio, May 2, aged 81; a graduate of the medical department of the University of Cincinnati in 1848.

John W. Brown, of Reading, Pa., at the Pennsylvania State Hospital, May 1, aged 69; a graduate of the University of Pennsylvania in 1870.

Leroy M. Nifong, from heart disease, at his home in Modesto, Ill., April 30; a graduate of Barnes Medical College, St. Louis, Mo., in 1897.

George P. Jeffers, at his home in Bangor, Me., May 9, aged 88; a graduate of the Medical School of Maine, Brunswick, in 1844.

Harper Tickle, at his home in Charleston, W. Va., May 5, aged 41; a graduate of the Baltimore Medical College in 1894.

William F. Miller, at his home in Louisville, May 10, aged 88; a graduate of the University of Louisville in 1843.

D. C. Phillips, of Millerstown, from paralysis, near White Mills, Ky., April 22, aged 80.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended May 21, 1904:

SMALLPOX—UNITED STATES.		Cases	Deaths
California:	Los Angeles.....Apr. 30-May 7.....	1	
	San Francisco.....Apr. 24-May 1.....	1

Changes in the Medical Corps of the U. S. Army for the week ended May 21, 1904:

HOGUE, GUSTAVUS I., contract surgeon, is granted leave for one month, with permission to apply for an extension of one month.

CHASE, ALPHA M., contract surgeon, is granted leave for three months, from June 1, or as soon thereafter as his services can be spared.

MILLER, First Lieutenant REUBEN B., assistant surgeon, leave granted March 19 is extended one month.

McMILLAN, CLEMENS M., contract surgeon, now temporarily at Fort Ethan Allen, will proceed to Fort Niagara for temporary duty during the target practice at that post, and upon the completion of this duty will rejoin his proper station—Fort Myer.

GWINN, ARTHUR C., sergeant first class, Fort Sheridan, is transferred to Fort Myer for duty.

KELLOGG, WILLIAM V., contract surgeon, is granted leave for two months, on surgeon's certificate.

MUNSON, Captain EDWARD L., assistant surgeon, now at San Francisco, Cal., is relieved from further duty in the Philippines Division, and will proceed to Fort Bayard and report at the United States General Hospital for duty.

HAISELL, JOHN T., contract surgeon, is granted leave for one month, with permission to apply for an extension of one month.

DAVIS, WILLIAM R., contract surgeon, now at San Francisco, Cal., will report for duty as surgeon on the transport Sheridan, to relieve First Lieutenant Alexander Murray, assistant surgeon, who will proceed to Fort Bayard and report at the United States General Hospital for duty.

KENNEDY, JAMES S., contract surgeon, is relieved from duty at the depot of recruits and casuals, Fort McDowell, and will proceed to Fort Grant for duty, relieving First Lieutenant Robert N. Winn, assistant surgeon, who will proceed to Fort McDowell for duty at the depot of recruits and casuals.

Changes in the Medical Corps of the U. S. Navy for the week ended May 21, 1904:

SNYDER, J. J., passed assistant surgeon, detached from the Kearsarge and ordered to the Maine—May 17.

BUCHER, W. H., surgeon, detached from the Naval Station, Cavite, P. I., and ordered to the Naval Hospital, Yokohama, Japan—May 17.

THOMPSON, E., surgeon, commissioned surgeon, with the rank of lieutenant-commander, from March 3, 1903—May 18.

FURLONG, F. M., passed assistant surgeon, detached from duty with the marine battalion on the Dixie, and ordered home to await orders—May 19.

BUTLER, C. ST. J., passed assistant surgeon, commissioned passed assistant surgeon, with the rank of lieutenant, from October 26, 1903—May 19.

MARCOUR, R. O., assistant surgeon, detached from duty with the marine battalion on the Dixie and ordered to the Hancock—May 19.

ROSSITER, P. S., assistant surgeon, detached from the Naval Recruiting Station, Baltimore, Md., and ordered to the Naval Station, Honolulu, H. I., sailing from San Francisco, Cal., via steamer Abarenda, June 4—May 19.

OWENS, W. D., assistant surgeon, appointed assistant surgeon, with rank of lieutenant, junior grade, from May 17, 1904—May 19.

SELLERS, F. E., acting assistant surgeon, appointed acting assistant surgeon from May 17, 1904—May 19.

Changes in the Public Health and Marine-Hospital Service for the week ended May 19, 1904:

CARTER, H. R., surgeon, to report at Washington, D. C., for special temporary duty—May 13, 1904.

* Report for Apr. 3-10 returned for correction. Report from Apr. 10-17 will be found in Health Reports, May 7.

WOODWARD, R. M., surgeon, granted leave of absence for three months from June 14—May 13, 1904.
 EAGER, J. M., passed assistant surgeon, reassigned to duty at the port of Naples, Italy, effective March 25—May 14, 1904.
 FRANCIS, EDWARD, assistant surgeon, to proceed to Martinsburg, W. Va., for special temporary duty—May 11, 1904.
 BURKHALTER, J. T., assistant surgeon, ten days' extension of leave of absence, granted by Bureau telegram of May 9, 1904, revoked—May 17, 1904.
 ALEXANDER, E., acting assistant surgeon, granted leave of absence for seven days from May 19—May 17, 1904.
 KENNARD, K. S., acting assistant surgeon, granted leave of absence for fourteen days from May 22—May 17, 1904.
 WALKER, R. T., acting assistant surgeon, granted leave of absence for four days from May 31—May 19, 1904.
 WALKLEY, W. S., acting assistant surgeon, granted leave of absence for nine days from May 24—May 19, 1904.
 RODMAN, J. C., acting assistant surgeon, granted leave of absence for four days from May 24—May 18, 1904.
 CARLTON, C. G., pharmacist, granted leave of absence for thirty days from June 1—May 12, 1904.
 BIERMAN, C. H., pharmacist, granted leave of absence, on account of sickness, for one day (May 9)—May 13, 1904.
 VANNESS, G. I., Jr., pharmacist, granted leave of absence for thirty days from June 1—May 17, 1904.

Boards Convened.

Board convened to meet at Baltimore, Md., May 18, 1904, for the physical examination of cadets in the Revenue Cutter Service. Detail for the Board: Surgeon H. R. Carter, chairman; Assistant Surgeon C. W. Wille, recorder.

Board convened to meet at Stapleton, N. Y., May 18, 1904, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Surgeon Preston H. Bailhache, chairman; Passed Assistant Surgeon A. C. Smith, recorder.

Board convened to meet at Washington, D. C., May 18, 1904, for the physical examination of applicants for appointment in the Revenue Cutter Service. Detail for the Board: Assistant Surgeon-General L. L. Williams, chairman; Assistant Surgeon-General W. J. Pettus, recorder.

SOCIETY REPORTS

ASSOCIATION OF AMERICAN PHYSICIANS.

Nineteenth Annual Meeting, Held at Washington, D. C.,
May 10, 1904.

[Specially reported for *American Medicine*.]

[Concluded from page 809.]

A Supposed Cause of High Tension Pulse in Nephritis.

—W. H. THOMSON offered the following conclusions: 1. High tension pulse occurs too early in nephritis to be due to any other cause than the presence in the blood of a general vasoconstricting agent, similar in its properties to adrenalin. 2. Such an agent would also produce constriction of the renal vessels and general shrinkage of the kidneys, causing interference with the excretion of urea. 3. Prolonged presence of such an agent in the blood would lead ultimately to endarteritis with degeneration of the vascular walls and to cardiac changes. 4. Acute cardiac dilation may occur from the effects of such a general vasoconstricting agent in the circulation before extensive alterations in the bloodvessels have taken place. 5. Aconite is the best vasodilator in nephritis, much more effective than the nitrites. Reports of marked increase in the excretion of urea follow its administration.

Discussion.—PEABODY said that experience had taught him that aconite would materially increase the urea output, even in cases in which the arterial tension is abnormally low. The reason for this he could not give.

Poisoning by Illuminating Gas.—W. G. THOMPSON'S investigation was undertaken to determine the cause of death and of certain symptoms that are characteristic of poisoning by illuminating gas. The series of cases included 90, of which 17 were fatal. In New York there were 288 fatal cases in 1901 and probably 2,000 cases of gas poisoning occur there annually. This is due to the prevalent use of the gas stove and to the ignorance of the foreign population coming into the city. He described the effects upon the blood and looked on carbon monoxid as the particularly poisonous element. He believed its action upon the nervous system is more important than the changes produced in the blood. A leukocytosis that lasts for many days is one of the features. The character of the fever is varied. A subnormal temperature may exist for hours and then be followed by a fever that persists high for a week or more. One case of hyperpyrexia—110°—reported. The nervous symptoms are varied and inconsistent. They consist of tremors, anesthesia, rigidity, opisthotonos, headache, coma, mental disturbance, etc. Peripheral neurosis, sclerosis and changes in the brain and cord may follow as sequels. The most satisfactory form of treatment had been phlebotomy and infusion of salt solution.

Discussion.—STENGEL called attention to some experimental work that had shown that the transfusion of defibrinated blood had saved animals poisoned by coal gas, even when venesection and infusion with salt solution had failed. S.

WEIR MITCHELL and SOLIS COHEN each called attention to the varying composition of illuminating gas in different cities, and even in a given city at different times. The last named speaker and PEABODY spoke of the difficulties in the way of procuring and using defibrinated blood. THOMPSON said, in conclusion, that these patients must be treated promptly, and salt solution is more convenient than defibrinated blood.

An Antitoxin for Snake Venom.—A personal communication from Noguchi to Mitchell. S. WEIR MITCHELL read to the society a letter just received from Noguchi, detailing the results of experimental work which he had been conducting under the auspices of the Carnegie Institute, in the laboratories at Copenhagen. Mitchell explained that Noguchi had engaged upon this work with Flexner, at the University of Pennsylvania, two years ago, and having demonstrated his fitness to conduct such a scientific investigation, and having outlined his plan of work, the Institute had, at Mitchell's request, decided to provide him with the means. The report of his studies was eminently satisfactory. He believes he has succeeded in preparing a certain antidote to the venom of the rattlesnake. The antitoxin will not operate against the toxins of other varieties of snakes, and he questions the work of others who have claimed to have discovered a universal antitoxin.

Abdominal Pain from Unsuspected Irritation of the Internal Inguinal Ring.—CHARLES G. STOCKTON. This paper will be published in a future issue of *American Medicine*.

The Mechanism of Exophthalmos.—W. G. MACCALLUM and W. B. CORNELL. An effort was made to determine experimentally the mechanism of exophthalmos by arranging an apparatus that would mark upon the smoked drum any movement of the eye and then proceeding to alter the normal vascular and muscular conditions. It was shown that obstruction to the outflow of blood from the veins of the orbit produces at once exophthalmos, which is relieved by the establishment of collateral circulation. This process is completed, however, so slowly that in the meantime the orbital tissue as well as the tissue of the face becomes very edematous, thus adding to the exophthalmos. Furthermore, entirely independent of any circulatory changes, there is an exophthalmos produced directly by the stimulation of the cervical sympathetic nerve. This protrusion is due to the peristaltic contraction of the orbital muscle tissue. From these experiments no conclusions could be drawn as to the mechanism of exophthalmos in Grave's disease, but the possibilities are more closely defined.

Diabetes Insipidus.—THOMAS B. FUTCHER called attention to the fact that animal experiments have shown that polyuria follows lesions of a point in the floor of the fourth ventricle a little in front of the glycosuria center; also after injuries to various portions of the middle lobe of the cerebellum; and, after injuries to the posterior portion of the pons and the anterior part of the medulla. He divided the cases of diabetes insipidus clinically into two groups, the idiopathic cases, or those without evident cause and the secondary or symptomatic cases, those referable to some organic lesion or some known cause. Tumors of the medulla and floor of the fourth ventricle, basilar meningitis and cerebral hemorrhage are the commonest organic lesions causing the disease. He believed that cerebral syphilis is a cause in a much larger percentage of cases than has been generally suspected. A basilar syphilitic meningitis he considered to be frequently the lesion and looked upon a transitory bitemporal hemianopsia in a case of diabetes insipidus as strong evidence in favor of the disease being due to syphilis. He stated that diabetes insipidus belongs to the rarest of the medical diseases. In 15 years there have been but seven cases recorded in the Johns Hopkins Hospital and Dispensary out of a total of 403,535 patients. Five of these cases belonged to the symptomatic group and of these four were undoubtedly syphilitic in origin. Thirst appeared to be the first symptom complained of in the majority of cases. In considering the treatment, Fletcher stated that while it is very unsatisfactory as a rule, the cases which appear to do best are those of luetic origin; antiluetic treatment almost invariably relieves the cerebral symptoms and occasionally causes a reduction in the thirst and polyuria.

Discussion.—BAUMGARTEN asked if Fletcher had observed any connection between diabetes insipidus and saccharin diabetes. He related the history of a case which first came under his observation 20 years ago. The patient was a young man with diabetes insipidus. A year or two later the disease took on the attributes of saccharin diabetes. There was never any suspicion or evidence of syphilis or cerebral disease in this case and the patient eventually died of tuberculosis. THOMPSON related a case which was hereditary in character and in the treatment of which he had made careful estimations of the food and water taken and the amount of polyuria and had shown that actually more fluid was excreted than was ingested. TYSON said that he had only seen six or seven cases in the whole course of his practice, but that in these he had been impressed by the fact that the symptoms were largely relieved by potassium iodid. DOCK spoke of the prognostic differences of these cases and of the satisfaction with which he elicited the history of syphilis in any case, because he felt that the syphilitic cases were more favorable for treatment. JACOBI thought that the frequency of diabetes insipidus is very much greater than hospital records would seem to imply and gave as his reason the belief that the disease is quite frequent in childhood. He had seen it

follow chorea minor, whoopingcough, falls upon the occiput and probably cerebral tumors. FUTCHER said that he did not wish to give the impression that the vast majority of cases of diabetes insipidus is due to lues, but merely that there are a greater number of cases due to that disease than has been generally supposed.

A Case of Prolonged Male Hysteria: with Autopsy.—S. WEIR MITCHELL and W. G. SPILLER. Mitchell related in detail the clinical history of a hysteric man who had been under his observation more or less constantly for 30 years. He had watched it from the appearance of the first nervous symptoms to the development of peculiar muscular movements that were constant in character and uncontrollable by the patient except by the greatest effort on his part, or under the influence of hypnotism. The patient requested that after his death an autopsy should be performed under Mitchell's direction, and this was done, Spiller making a most careful examination of the brain and cord. Absolutely no lesion could be found.

Discussion.—PRINCE related the history of a similar case. PUTNAM expressed the feeling that these continuous movements which hysteric patients sometimes carry on, and the fact that they are carried on by dissociated centers and without signs of fatigue on the part of the patient, are important, and that the so-called professional neuroses cause effects from much less motion than these hysteric patients are accustomed to carry out. WOOD said that in order to account for this thing it would seem reasonable to suppose that the nerve centers of organic life may take on some of the functions of the centers of inorganic life. He referred to the fact that the heart, beats constantly for a period of many years, but leaves no record of its contractions, and suggested that perhaps after all it is not the muscular movement that leaves a cerebral record, but the volition thereto. MITCHELL thought that we might have expected to find some marked pathologic evidence resulting from such long continued muscular actions, and in support of this view referred to the work of Hodges on the effects of fatigue on the nerve cells.

Some Unusual Forms of Acute Myelitis.—B. SACHS defined the term "acute myelitis" as a disease process, causing a more or less rapid or a more or less complete destruction of the substance of the spinal cord at any given level, excluding, however, those forms which are due to large hemorrhages and to the breaking down of neoplasms. The clinical histories of two very unusual cases were given, the first being a senile form of myelitis, which had the characteristics of a spinal counterpart of the cerebral apoplexies, which occur at that time of life, and the second was the record of a sudden development of myelitis in a young girl, who presented the complication of multiple streptococcus abscesses.

Infectious Neuritis: with Report of a Case.—J. J. PUTNAM reported, in behalf of WATERMANN and himself, a series of cases, illustrating different sorts of reaction of the nervous system to infectious processes. A possible bond between certain of these cases lay in the fact that they had occurred during the same period—namely, in the winter of 1902 and 1903. The most important case was that of a man of 30, who suffered from an unusual, gradually progressive form of "myelitis," which spread slowly upward through the whole length of the spinal cord, the entire illness covering a period of about two months. All the functions of the cord were involved, and the paralysis was associated with constant fever, leukocytosis, gradually increasing pyelitis, and, eventually, with bloody dejecta. The post-mortem examination showed a disintegration of the nerve elements, accompanied with but few signs of active vascular change or of exudation processes and no evidence of antecedent anemia as due to arteriosclerosis or thrombosis. The other cases were of the following sort: Meningoencephalitis, possibly due in part to alcoholic excess; progressive paralysis, eventually involving certain cranial nerves, but ending in complete or incomplete recovery; infectious neuritis, followed by encephalitis; cases of the type of poliomyelitis, but coming on slowly; and myelitis during typhoid. He called attention to the complex results of infections of the nervous system and the impossibility at present of making sharp divisions.

The Clinical Features, Prognosis, and Treatment of Cerebrospinal Meningitis in Infants and Children.—HENRY KOPLIK studied 89 cases, of which 39 were absolutely confirmed by lumbar puncture; 35 were tuberculous, 1 staphylococcus, 1 streptococcus, and 2 pseudoinfluenza cases. Sixty percent of the cases were below two years of age. The mode of onset was, as a rule, sudden, except in the tuberculous cases. Rigidity of the neck was present in all cases at some time. Babinski's reflex was present in 77%, while Konig's reflex was of little value in the patients under two years of age. In the tuberculous cases, Macewen's sign was present in the majority of instances. Optic neuritis was more common in the tuberculous type than in any other class of cases. Koplik considered the disease to be self-limited, and scarcely influenced by any mode of treatment. He did not consider lumbar puncture as curative, nor had it in his cases relieved the symptoms of pressure.

A Case of Spasmodic Stricture of the Esophagus with Sacculation; Treated by Dilation, and Later by Gastrotomy.—JAMES TYSON, EDWARD MARTIN, and JOSEPH EVANS. Tyson read this paper, which opened with a review of the literature upon the subject of diverticula and dilations of the esophagus, their etiology, treatment, and diagnosis. Then followed the detailed clinical history of

two extremely interesting cases of spasm of the cardiac orifice with resulting dilation of the esophagus. The first patient was a man aged 33 years, who had been suffering from dysphagia from the time he was 12 years old, his first attack coming on suddenly while he was at his supper and compelling the immediate regurgitation of all that he had eaten. As he described his symptoms, "while in the act of swallowing solid food he was suddenly seized with a sensation of the material sticking in the esophagus at a point posterior to the middle of the sternum." For a moment he felt as if his heart had stopped beating, and then, without any nausea, he threw off the food and was relieved. He made several successive attempts to swallow more food, but without success. After four or five days he discovered that by drinking very hurriedly a large amount of liquid immediately after the taking of solid food he was able to overcome the stoppage in the esophagus, and could feel the material enter the stomach; in addition to the drinking of the liquid it was necessary for him, however, to exert considerable effort. For fifteen years he continued this method of feeding, but at times the dysphagia would increase and he could not force the food into the stomach. At such times, and whenever any remnants were left in the esophagus, the food was immediately regurgitated or would be a few hours later. If any food remained at the time he was asleep it would run out of his mouth and be discovered by him the next morning. If he assumed the horizontal position immediately after eating, an irritating cough would start in, and he could secure relief only by regurgitating the food. Tyson attempted dilation with all sorts of tubes, but without much success. Attempts to measure the capacity of the dilated esophagus showed that he could drink 34 ounces of fluid without any unpleasant sensation, and apparently without any of it reaching his stomach. The second case was in a woman aged 33, who had been suffering in much the same way for a period of eight months. A special instrument was devised by Martin for dilation in this case, the principle of the instrument being the same as that of the Kollmann urethral dilator. It was felt that its continued use would have given satisfactory results through the production of a partial paralysis of the muscular ring at the cardiac opening, but in order to put the esophagus at rest and to force the patient's nourishment it became necessary to do a gastrotomy.

Idiopathic Dilation of the Esophagus: Cardiospasm.—B. W. SIPPY reported a case in all essentials like that described above by TYSON. He exhibited the specimens from this case, the patient having died shortly after a gastroenterostomy performed for the relief of what was at the time believed to be a pyloric obstruction. At autopsy it was found that there was no anatomic narrowing of the cardia, but a hypertrophy of the circular fibers of the esophagus wall so that it was fully a quarter of an inch in thickness.

Dilation of the Esophagus and Stomach.—FRANCIS P. KINNICUTT described another case of the same general character, and the pathologic specimens were shown. The esophagus from this patient had a capacity of 1,800 cc. of fluid, and was, so far as could be determined, the most enormously dilated stomach and esophagus recorded.

Discussion.—JANEWAY reported a case like TYSON's, except that it was complicated by hemoptysis. This patient could take 800 cc. of fluid into the esophagus without difficulty and a photograph was exhibited showing the condition with this amount of dilation. Janeway spoke of two mistakes often made in these cases, i. e., considering them as hysteric, and, as tuberculosis. MELTZER, having been called upon to say something of this condition, described his discovery of and first description of it in 1888. At that time he saw a patient that had been suffering from it for 19 years and presenting the symptoms given above. Previous to that time they had all been described as idiopathic or hysteric dilations. Meltzer was the first to determine the true condition and ascribe to it the proper cause and mode of action. His patient was operated upon by a gynecologist five years later for a supposed malignant growth and when, later, an autopsy was done it was found that the anatomic condition was precisely what he had described from the theoretic standpoint.

At the opening of the morning session the following named gentlemen were elected to membership: P. K. Brown, San Francisco; Joseph Collins, New York; David L. Edsall, Philadelphia; Frederick E. Finley, Montreal; H. C. Gordinier, Troy; Richard M. Pearce, Albany; Mark W. Richardson, Boston; and, Richard P. Strong, Manila, P. I.

Honorary Members.—Beverly Robinson; Starling Lov- ing, and, Henry G. Walcott.

The Relation of Cells with Eosinophile Granulation to Bacterial Infection.—EUGENE L. OPIE presents a most elaborate study of the action of eosinophile cells when micro-organisms are introduced into the body. He reviews the literature of the subject at length, quotes from his own published work and then relates in detail the behavior of these leukocytes during the course of fatal and of nonfatal bacterial infection. He worked with a variety of organisms and offers the following conclusions: Certain bacteria (*B. tuberculosis*, *B. cholerae suis*) producing somewhat chronic, fatal infection in guinea pigs, cause the eosinophiles to disappear from the circulating blood. After death a few can be found in those tissues in which they are usually found in abundance. During more active and acute infections produced by inoculating bacteria into the peritoneal

cavity eosinophile leukocytes disappear almost completely from the peripheral circulation within a few hours. After the inoculation of an organism producing an infection from which the animal is capable of recovering they disappear from the peripheral circulation so that their proportion may fall from 5% or 10% to less than 1%. The number then gradually increases until in four or five days it exceeds the normal proportion, and then slowly falls back to normal. When the number of eosinophiles is at the lowest point in the peripheral circulation they are found in great numbers in the vessels of the inflamed mesentery and omentum near the site of inoculation. Unlike the polynuclear leukocytes they rarely if ever act as phagocytes. In the region of the bacterial poison they undergo degenerative changes of which nuclear fragmentation is the most characteristic. Under the influence of severe bacterial infection eosinophile myelocytes together with other elements, usually regarded as characteristic of the bone marrow, accumulate in the spleen and may be found in the circulating blood. The occurrence of this phenomena within two to four hours demonstrates that the elements are derived from the bone marrow and are not formed in the spleen. Bacteria exert a chemotactic influence upon cells with eosinophile granulation, attracting them from the circulating blood to the site of inoculation and from the bone marrow into the blood. Eosinophile leukocytes, like the finely granular polynuclears accumulate in the neighborhood of bacteria injected into the body and though they rarely act as phagocytes, have a part in the series of changes which follow bacterial invasion.

A New Case of Chloroma with Leukemia, with a Study of the Cases Reported since 1893.—GEO. DOCK and A. S. WARTHIN. Dock presented these conclusions: 1. Chloroma is a tumor-like hyperplasia of the parent cells of the leukocytes, primary in the red marrow, the periosteum being involved only secondarily. The possibility of a primary chloroma in any part of the body in which white cells are formed must be considered. 2. As a result of this leukoblastic hyperplasia, atypical leukocytes may appear in the circulating blood in varying number. Chloroma is therefore to be classed with the leukemias. 3. The white cells resulting from the atypical proliferation may in different cases attain different stages of differentiation. In some cases they may be of the large lymphocyte type, in others of the type of neutrophile or eosinophile myelocytes. 4. It is evident, therefore, as in the case of other leukemias, that the blood picture in chloroma may be very varied, and if this be used for a basis of classification it is possible to designate different varieties of chloroma. 5. The essential difference between chloroma and other forms of leukemia is the more marked neoplastic character of the former and the formation of the green infiltrations and metastases. 6. Chloroma is probably to be regarded as a more malignant form of leukemia. This malignancy of chloroma depends chiefly upon the replacement of the red marrow and erythroblastic elements by the proliferating white cells and the consequent diminished red-cell formation. 7. The cause of the green color remains unknown.

Types of Splenic Anemia or Splenomegaly.—ALFRED STENGEL reported a series of cases that had been carefully studied clinically and microscopically. The first case was that of a child 3 years old, that had, at the age of 2, shown an increase in the size of the abdomen and marked pallor. Physical examination showed an enlarged spleen and the blood-examination gave 30% of hemoglobin, 2,900,000 red cells and 7,600 white cells. A general dropsical condition appeared and at the same time a leukocytosis of about 20,000. Autopsy revealed a general splenic enlargement with infarcts of the spleen and kidneys, a bronchopneumonia, vegetative endocarditis of the mitral valve and miliary tuberculosis of the lungs, liver and spleen. The lymphatic glands showed a marked hyperplasia and necrosis of the endothelial cells. The second case was in an adult showing splenic anemia with cirrhosis of the liver. There was a generally stunted growth, club fingers and pigment changes in the skin. Autopsy examination disclosed hyperplastic changes in the spleen, cirrhosis of the liver and fibroid changes in the lungs and other organs. The third case was in a young woman of 25, whose condition was diagnosed as primitive splenomegaly. The spleen was removed by operation and the patient recovered. Microscopic sections of the spleen showed a very marked hyperplasia with extensive fibroid growth.

Discussion.—OSLER thought that these cases illustrate the extreme complexity of the subject and said that while the third case belonged to a very definite group it was doubtful if they could often be recognized clinically. He had seen such a case operated upon by Mikulicz some years ago and the patient was afterward exhibited before the German Surgical Congress. Since Osler's last report on this subject he has seen 9 cases of great enlargement of the spleen associated with anemia. One was a case of so-called primitive splenomegaly; 4 were cases of chronic splenic enlargement with pigmentation of the skin; 2 belonged to that group which resembles Hanneaux disease, and 2 were cases of splenic anemia subsequently becoming pernicious anemia. SIPPY related a case which he had seen since the report he published in 1899. The patient was a woman with a movable spleen that came down below the umbilicus and readily moved about in the abdominal cavity. She presented the picture of a gradually developing anemia. The spleen was removed by operation and she made a complete and satisfactory

recovery. He raised the question whether the splenic anemia in these cases might be due to poisonous substances secreted by the enlarged spleen or whether it be due to malnutrition. CABOT replied to this point that there is no evidence, clinical or experimental, that splenic anemia is ever due to malnutrition.

The Agglutination and Filtration of Trypanosomes.—The main features presented in this work by F. G. NOVY and his associates, MCNEAL and HARE, may be briefly summed up as follows: 1. The trypanosome present in the Philippine surra can be cultivated artificially. 2. Attenuated cultures of this organism can be obtained, as in the case of *Trypanosoma brucei*. 3. This trypanosome is differentiated by its cultural characteristics from *Trypanosoma brucei* and *Trypanosoma lewisi*. 4. The Philippine surra is therefore a distinct disease, different from nagana, and this observation confirms the work of Laveran and Mesnil on the nonidentity of nagana and the surra of Mauritius. 5. The morphologic differences between the Mauritian and Philippine trypanosomes suggests the probability that these organisms are distinct species, and hence that the term surra covers a group of closely allied diseases.

Zonal Necrosis of the Liver.—E. L. OPIE reviewed the vascular and other anatomic features peculiar to the liver structure to show the varying facility with which necrosis occurs in different zones of that organ. He referred at length to the experimental work which has heretofore been done on this subject, and then considered in sections the conditions associated with zonal necrosis of the liver in various diseases, dividing the subject into central necrosis, peripheral necrosis, and midzonal necrosis, and followed that with a special consideration of the relation of midzonal necrosis to acute yellow atrophy of the liver. He related the clinical and anatomic histories of cases in each class. The paper is an extremely interesting one, not susceptible of satisfactory abstraction, and can be profitably read in full by those who are interested in the subject.

Experimental Arthritis and Endocarditis Produced by a Streptococcus Isolated from the Blood of a Case of Rheumatism, Endocarditis, and Chorea.—M. J. LEWIS and W. P. LONGCOPE. In a fatal case of rheumatism, endocarditis, and chorea a streptococcus was isolated from the blood before death. This organism did not differ materially from the common varieties of *Streptococcus pyogenes* in cultural properties, but produced very characteristic lesions in rabbits when injected intravenously. Such inoculations were always followed after a few days' incubation period by a multiple arthritis, which usually started in the ankles. In one rabbit extensive vegetations were found on the mitral valve, while typical infarctions were seen in the spleen and kidneys. This organism was believed to be the same as that described by Wassermann, Meyer, Poynton and Paine, and Ainley Walker, and considered by them to be the specific cause of rheumatic fever.

Serum Treatment for Hay-fever.—Harper's Weekly states that in a list of 285 patients to which serum treatment had been given under different circumstances and in different countries, recently compiled in Germany, 60% are reported as completely relieved, 29% partly cured, and 11% failures. "Hay-fever," says the Weekly, "is supposed to result from the pollen of various plants, and the serum was prepared by inoculating horses with this pollen. It may be used in liquid or powdered form, and is applied locally, no attempts having been made as yet at subcutaneous injection. There is strong evidence to believe in the efficacy of the serum, and in the majority of cases it was found possible to relieve the patient and to shorten materially the seizure. Although it does not, however, prevent a recurrence of the attack, it has great value as a prophylactic."

Ceylon's Battle with the Plague.—A correspondent to an exchange states that the last governor of Ceylon, fearful that the bubonic plague might gain a footing in this island as in the adjacent mainland, left no means of prevention and no precaution untied. The railway stations are posted over with regulations and instructions in case of plague patients being apprehended on a train, and no one with a rash, a high temperature, a glassy eye, or a swelling near the glands of the throat need present himself at a ticket office and expect to go on. Despite the hordes of coolies traveling back and forth between southern India and the Ceylon tea estates, the plague has never been established on the island. There is strict quarantine against Madras, and tourists coming down by Tanjore and the temple towns of southern India are obliged to keep themselves under inspection and record for 10 days. A permit is given them and they are free to travel in Ceylon if they report themselves daily to the government medical officer, who stamps the paper day by day. This mysterious black death is almost as far from being understood as in the middle ages. A Japanese bacteriologist discovered the bacillus 10 years ago, and since then all means of battling with it have been experimental. It rages in Madras, Calcutta, and Bombay, in all of which ports the most elaborate sanitary regulations have been in force for years; and it only exists at times, instances in which it has been directly brought from other places, in Colombo and Singapore. If the high temperature of Colombo is the reason for its not being domiciled there permanently the cooler hill country should invite the black plague of Yunnan to whatever temperature it prefers.

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

A CLINICAL METHOD OF DETERMINING THE VASOMOTOR FACTOR IN BLOOD-PRESSURE.

BY

ALBERT ABRAMS, A.M., M.D.,
of San Francisco, Cal.

Dr. L. F. Bishop, in a contribution on "The Importance of Considering the Element of Vasomotor Instability in Estimating the Significance of Irregularity of Cardiac Rhythm," published in *American Medicine*, April 23, 1904, directs attention to a significant clinical paradox, viz., the discrepancy often existing between the heart-sounds and the pulse—in other words, the vigor of the one cannot be gauged by the strength of the other. My own observations tally with those of Bishop. I have frequently noted among arteriosclerotics and others, that a high blood-pressure is often coupled with the local evidence of cardiac incompensation. When the heart tones are weak, increased blood-pressure can never indicate a vigorous heart action, and in estimating the vigor of the latter, blood-pressure is of subsidiary value only. When high blood-pressure coexists with cardiac enfeeblement, a vasomotor factor is concerned in the maintenance of the former, this increase in the peripheral resistance of the bloodvessels acting as a prop to the enfeebled heart. In other words, the arterial system serving the objects of compensation acts as a subsidiary heart, which in turn facilitates the circulation of blood. In this way, as I view it, the nervous system through the vasomotor nerves, may compensate an impaired myocardium. I have accumulated sufficient data to warrant recommending the following method for determining the vasomotor factor in the clinical measurement of blood-pressure. In my observations, the Riva-Rocci instrument was employed. After determining blood-pressure according to the conventional method, the patient is instructed to inhale amyl nitrite from a bottle, after which procedure the blood-pressure is again estimated, and the difference noted. The arm piece of the instrument need not be removed until the investigations are completed. The patient must be instructed not to practise forced breathing while inhaling amyl nitrite, as observation has taught me that this physiologic act alone will reduce blood-pressure, and thus negative the clinical findings. Sufficient amyl nitrite must be inhaled to induce its physiologic action, viz., slight duskeness of the face, fulness in the head and relaxation of the bloodvessels. The average effect of inhalation of the drug in the normal subject is to cause a slight increase of blood-pressure, varying from 2 mm. to 20 mm. The primary effect is to depress slightly the blood-pressure, but it rises at once. I am inclined to conclude that in the average healthy individual, inhalation of amyl nitrite relaxes the arterial walls by eliminating the vasomotor influence, thus bringing into play the veritable cardiac pressure. My observations, extending over a period of one year, permit me to formulate the following conclusions:

1. Blood-pressure is an expression of action of two chief factors, ventricular force and vasoconstriction.

2. Inhalation of amyl nitrite dissipates the vasoconstrictor factor and brings into play the ventricular force which is the real factor to be encouraged in a failing heart.

3. The vasoconstrictor factor may and does compensate myocardial inadequacy, for it is essential in most cardio-arterial diseases for the blood-pressure to be maintained to afford better nutrition for the heart and to augment arterial elasticity as a means of establishing the blood circulation.

4. The recognition of the myocardial and vasomotor factors in blood-pressure guides us correctly in the administration of cardiotonics.

5. In the individual endowed with cardiac health, the removal of the vasomotor factor by inhalation of amyl nitrite causes an increase in blood-pressure, whereas the converse condition causes the latter to fall and the degree of reduction is proportionate to the degree of cardiac enfeeblement. In other

words, the high blood-pressure in myocardial disease, is maintained by an augmented tonus of the vasomotor center. Thus the blood-pressure may fall from 240 mm. before, to 180 mm. after inhalation of amyl nitrite in arteriosclerotics with enfeebled hearts. Even this reduction in blood-pressure is not low enough to correspond with the tones of the feeble acting heart, hence one is constrained to conclude that the action of the amyl nitrite does not suffice wholly to eliminate the vasomotor factor.

6. The execution of the foregoing maneuvers in estimating heart vigor is by no means comparable to a correct method of cardiac auscultation, although the latter method does not indicate how much of the cardiac force may be attributed to increased peripheral resistance; cardiac auscultation in conjunction with the sphygmomanometer and the inhalation of amyl nitrite, constitute the ideal methods for eliciting the real condition of things.

7. In estimating blood-pressure, the sphygmomanometer only gauges the force of the left ventricle, and to determine the sufficiency of the right ventricle, auscultation of the pulmonic sounds and a physical examination of the lungs are alone adequate.

I have encountered a number of individuals with very high blood-pressure and who demonstrated no cardiac anomaly, yet the blood-pressure remained the same after as before the inhalation of amyl nitrite. In about half of these individuals, the urine was light in color, of low specific gravity, contained a trace of albumin, and was excreted in increased quantities. Albumin often disappeared when the blood-pressure was spontaneously lowered, to reappear when the pressure rose, hence the albuminuria in such instances could be correctly designated as the albuminuria of high blood-pressure.

Miners' Pulmonary Tuberculosis in the Transvaal.—Mr. R. B. Haldane, the wellknown British author and Liberal M. P., directs attention in a published letter to the ravages committed by miners' pulmonary tuberculosis in the mines of the Witwatersrand. It seems that the quartzite of the gold-bearing beds of the Witwatersrand is very hard, and the mines very dry; consequently, when the rock is drilled and blasting takes place, the atmosphere becomes filled with minute particles of hard rock dust, which are inhaled. The result is a deplorable loss of life, and great economic wastage. Mr. Haldane estimates that the deathrate among the white rock-drill miners of the average age of 35 is over 70 per 1,000. Among English coal miners of this age the mortality is only 6.3 per 1,000; among English ironstone miners, 6; and among English tin miners, 8.1. The figures appear to indicate that among the native rock-drill miners the mortality is less. It is given as 42.03 per 1,000. Mr. Haldane insists that the loss of life is unnecessary. All of it, or nearly all of it, could be obviated by the substitution of wet for dry mining. But this, owing to the scarcity of water, would be a costly operation.

Scheme for Measuring Great Britain's Population.—There is a likelihood that the committee which is at present investigating the alleged decline of the national physique will recommend a scheme for measuring and weighing the population of the United Kingdom. The desirability of adopting such a scheme has been strongly urged upon the committee by doctors and anthropologists. The development of a project of such magnitude will necessarily occupy considerable time, but it is understood that it has so far advanced that a schedule based upon measurements and tests prepared by Dr. Cunningham of the Edinburgh University is now being drawn up by a section of the British Association. A copy of this schedule, it is suggested, should be sent to every householder with a request that he state therein the age, height, weight, chest measurement, and other facts respecting the physical condition of himself and each member of his family. Anthropologists are anxious that the measurements should include those of the skull. They argue that as the population of these islands has become so cosmopolitan an effort should be made to determine the native counties of its constituent members. Skilled anthropologists can tell from the conformation of a man's head not only of what nationality he is, but in the case of an Englishman what county gave him birth. Mr. James Gray of the Anthropologic Institute, who is taking an active part in the present scheme, recently addressed a meeting at the Tynbee Hall. His audience included a large number of foreigners, whose heads he measured with an instrument invented by himself. Mr. Gray then correctly informed 50 of them in what countries they were born. For these and other reasons anthropologists urge that the size and shape of heads should be noted when the other proposed measurements are taken.—[*London Mail*.]

ORIGINAL ARTICLES

EMPYEMA.¹

BY

DE FOREST WILLARD, M.D.,
of Philadelphia.

Empyema is a condition so frequently unrecognized until the changes in the pleura are positive and destructive, that the results are exceedingly detrimental, not only to the immediate health of the patient, but to the subsequent symmetry of the chest. Many cases of lateral curvature of the spine are directly traceable to empyema as a cause of the commencement of the deviation. Collapse of the lung and contraction of one side of the thorax must necessarily distort the ribs and spine. The extreme degree to which the trunk may be twisted is well illustrated in the following case:

A girl of 14 had pleurisy at four years of age; her left chest was drained by a good surgeon for several months through two openings. One cicatrix is near the second costal cartilage, the other near the nipple. At the present time, 10 years later, her body is so tilted to the right that the line of the internatal fissure crosses her left shoulder, and a plummet line dropped from her right shoulder falls three inches outside her right hip. The anteroposterior diameter of the left chest varies from 3 inches to 4½ inches, while the right is 5 inches to 8 inches. The left thorax is greatly flattened and collapsed, and resonance and the vesicular murmur are heard only over the upper third. The right chest is very prominent, and the spinal curve with dorsal convexity to the right is most marked. The rotation is very great in the right thoracic region; moderate to the left in the lumbar. (Figs. 1 and 2.)

In many cases, in which drainage is instituted early, no deformity of the chest or body results. Only recently I had the opportunity of examining a lady upon whom I had operated 30 years ago when she was a child of five. She bore two large scars on the lateroposterior aspect of the right thorax, but her spine was perfectly straight, her right chest but slightly flattened, and even when stripped, asymmetry of the trunk could only be detected by close observation.

Many cases of pleurisy with effusion are subtle and insidious in their progress, patients even walking about with a large quantity of unrecognized fluid in their chests. In other cases the lack of recognition is due to the severity of the symptoms, especially when complicated with pneumonia, the effusion being masked until pus is thoroughly formed. No practitioner can afford to be other than an expert in percussion and auscultatory signs that mark an accumulation of fluid in the chest. With a flat percussion note, absence of respiratory murmur, of vocal fremitus and of vocal resonance, there need be but little doubt. A small locally walled-up accumulation may, however, cause a temporary uncertainty.

Errors of diagnosis are however not uncommon. I frequently have cases sent to me as spine disease or as lateral curvature, because the patient is tilting the body to one side and is carrying himself cautiously. When such a patient is stripped, it is plainly noted that the side toward which his body is inclined is sensitive to pressure, that movements in the opposite direction cause distress, while auscultation and percussion give speedy assurance of the existence of pleural accumulation.

On the other hand, pus in a case of dorsal spinal caries may make its way into the pleura, and if not evacuated, may perforate the lung. The danger of tuberculous infection of the lung in these cases is great, yet I have known the patients to recover. In some instances I have been able to demonstrate the continuousness of the pus track by injecting methylene-blue or pyoktanin into a sinus on the back and have it expectorated from the mouth.

In cancer of the liver, with extension to the diaphragm

and adhesion of lung, I have mistaken the condition for local encysted empyema, and have tapped unsuccessfully. I have had a similar experience in posthepatic abscess following appendicitis. Empyema from injuries of the liver and from abscess of the liver, or other infections following abdominal disease, has also occasionally deceived me. In malignant disease also of the spleen, or of the curve of the transverse colon, the surgeon may be misled unless a complete examination is made.

The fibrinous exudate, as drawn, sometimes presents a peculiar creamy appearance before it has been fully converted into pus, as illustrated in the following case of pleurisy of seven weeks' standing. The fluid was localized in front at the upper anterior portion of the chest, the heart being pushed downward two inches. I drained this accumulation in a child of 10, with speedy cure. The fluid had the appearance of an oil emulsion, and was about the consistency of pus, but on standing, did not separate in layers as pus does; even after 24 hours it was

Fig. 1.—Contracted left thorax following empyema, with tilting of body to right.

still of a creamy consistency and intimately mixed. Reaction acid. After making it alkaline, stains by the contrast method for 24 hours showed no tubercle bacilli. Plain stains showed a few diplococci, and a short, thick bacillus, but no streptococci nor staphylococci. A few polynuclear granular leukocytes were present, but no typical pus cells. There was much fibrin, which appeared in flakes, rather than in fibrils. This accounted for the consistency of the fluid.

Occasionally, spontaneous opening occurs in neglected cases; while the tendency seems to be anterior in spite of gravity, yet I have seen a number of cases of posterolateral openings. It is a very unfortunate complication when purulent accumulations are permitted to continue until they perforate the lung. To allow such an abscess to drain through the bronchi is to expose the lung to tuberculous infection, and to have the horrible, ill-smelling pus discharged from the mouth is exceedingly dangerous. These cases demand speedy interference and the

¹ Delivered, by invitation, before the Altoona Academy of Surgery, April, 1904.

freest drainage through a short route, *i. e.*, through the thoracic walls. A small serous effusion can be absorbed; it had better be withdrawn. Early recognition and early removal are therefore most important. I am not one who believes in the wisdom of compelling the absorbents to take up a pleural effusion, even though it be only serous. When aspiration is performed aseptically there is practically no risk, and the information to be gained thereby far more than counterbalances any slight detriment. It is the surest and safest preventive of empyema, and "prevention is always better than cure." The longer the lung is compressed, the more likely is the injury to become permanent. The error usually committed by practitioners, and one which I have seen several times during the past two months, is that this test is often made with an ordinary hypodermic syringe, the point of which is short and of small caliber. No liquid is obtained, and the physician decides that none is present, while the facts of the case are that he has not entered the pleural cavity at all. A false diagnosis is established, he is deterred from further attempts,

Fig. 2.—Contraction of left thorax following empyema, with tilting and rotation of vertebrae.

and the patient goes on to empyema under his very eyes. This test exploration should always be made with a long aspirating needle of good size, either the smaller or medium needle ordinarily connected with the aspirator set, and the vacuum bottle should be ready at hand for the complete withdrawal of fluid, if discovered.

Another very common error in the hands of a timid man consists in introducing the needle slowly; the thickened pleura is pushed forward in front of the instrument, and of course the fluid will not be reached. Again, if a small-calibered needle is used, flocculi of lymph or fringes from the membrane may block the orifice. A quick, short, vigorous thrust, the depth of the needle being properly guarded, is the best; if made just at the upper border of the rib, there is no danger of striking the intercostal vessels. Cocain infiltration or ethyl chlorid is sufficient, but a piece of ice dipped in salt and held against the part, is equally good. If a serous liquid is found, it should be thoroughly withdrawn with the

aspirator, and even if purulent or seropurulent, the withdrawal will be of advantage as a preliminary operation, since it gives an opportunity to the lung for expansion, and also relieves one of the serious conditions, namely, displacement of the heart.

Aspiration is an operation, however, only for temporary relief in pus cases. As before stated, it may allow the lung to expand and the heart to slide back to its position, and in some cases allow of slight recuperation on the part of the patient.

A few days' delay only is allowable for expansion. Thorough drainage should be the rule. How shall we drain? There are many methods. I have found none so helpful or safe and rapid in cure as the making of two large openings, with such an amount of resection of the ribs as may be indicated. The question of the resection of ribs will depend first, upon the condition of the pleura, second, upon the immobility of the lung. The resection may be an inch of a single rib, or it may be many inches from all the ribs. The surgeon cannot properly determine either of these conditions without a large opening, so that both palpation and inspection may be practised. When the pleura is dense and is degenerated, large multiple excisions are necessary, even complete thoracotomy. In doubtful cases it will be sufficient primarily to resect a portion of the ribs; thorough drainage will then put the patient in better condition for extensive resection of the walls. The site of the incisions will depend upon the position of the accumulation. The first opening may be made at any convenient point; let the pus flow slowly through a small opening; watch your patient's respirations; resect a portion of rib to admit the introduction of the finger, carry in a large-handled probe by means of which the most dependent portion of the cavity can be reached. An ordinary probe is useless for this work, but a long silver catheter or steel sound will sometimes answer as a substitute for the large probe, which should be a foot in length. The second opening should be at the very bottom of the cavity, with resection of a rib or ribs, to insure free drainage. If the lower opening is made too close to the diaphragm, the movements of this muscle may occasionally obstruct it. Again, the upper opening should not be made at a point that will be interfered with by the movements of the scapula. The amount of rib resection will vary greatly; in children, an inch at each of the openings is sufficient. It is very important that there shall be no pinching of the drainage-tube, and no obstruction to the exit of pus. In adults, the amount of bone removed will vary from two or three inches in the region of each opening, up to taking away nearly the whole chest wall. Ordinarily the difficulty is that the openings are made too small, not too large. In thoracic surgery of a lung that is not crippled by disease, the inlet of air will cause collapse and great dyspnea, but in empyema the lung is already compressed and fastened, so that there is but little effect upon the respiration, whether the opening be large or small, still the slow withdrawal of the fluid is better for the heart than rapid. The drainage-tube should be of very large size; for the first few days it should pass in at one opening and out at the other; later, it may be divided in the middle and shortened at each dressing, but extreme care must be used lest a section drop into the pleural cavity, as has not infrequently happened. Various devices of winged and infurled tubing have been invented to prevent this accident, which is certainly a most serious one, and many a secondary operation has been necessitated to remove the offending body. A tube with a collar may be employed, or a silk trailer may be attached, so as not to depend entirely upon the safety-pin, which may turn upon its long axis. Various forms of valves have been invented to exclude air and permit the passage of the pus, but they all seem to me unnecessary, since proper aseptic care and a free, rapid exit of the pus are infinitely more safe and curative.

Washings.—In my experience the washing of a chest cavity is nearly always disadvantageous. It is permissible in fetid accumulations, but even in these cases I believe that my patients have done better when it has been omitted, provided free drainage has been secured. After the first few days a fetid discharge indicates that the drainage is not complete but that pus is being retained; odor means that the openings should be extended so as to enable all purulent material to be immediately carried out upon the dressings.

The fact that irrigation is required shows that drainage is imperfect. The full and free exploration of the cavity at the time of operation, both by finger and by the long probe, is the best preventive of fetor. The use of irrigation at best should be only mechanical, and should consist of either salt or boric acid solutions. I have seen most violent irritation and inflammation aroused and great pain in consequence of the use of mercuric chlorid and other injections.

When the sinus persists after drainage, I have sometimes effected closure by laying open the entire tract, cutting away both soft and hard tissues, paring out the granulation tissue, and packing the wound, thus compelling it to granulate from the bottom.

Thoracotomy and Thoracoplasty.—In recent cases of moderate severity, free drainage is all that is necessary, but in the old neglected cases of pyothorax, in which the lung is collapsed and is thoroughly bound down, much more extensive operations are necessary. It is but natural that a cavity bounded exteriorly by rigid walls, supported by trusses like the ribs, and bounded internally by a rigid lung, should be unable to collapse and heal. Operative measures in such cases are of varying degree of severity and it is sometimes necessary to remove practically one-half the thorax of the individual. The radical operation in its extreme degree implies an excision of all the ribs, even to the first; the latter, however, is a dangerous operation, as it comes in such close contact with subclavian vessels. The "U" shaped incision for the extreme grade of operation starts from a point high up between the vertebrae and the scapula, runs down to the base of the chest, then upward and forward to the pectoral border near the anterior axillary line. The extent of the removal of the wall will vary in accordance with the condition of the pleura and lung. In some cases it is sufficient to excise a section only of the ribs in the path of the incision, raising a trap-door and then removing the ribs by incising each one upon the under surface, longitudinally to its axis, and shell-ing it out, or the resection may be made by dissecting up the skin and superficial tissues and excising the individual ribs from the outer face. In other cases the pleura and intercostal muscles are excised entirely in addition to the ribs, the skin flap being allowed to fall in and close the cavity. In such incisions I have always found it better to tie the intercostal arteries separately as cut, rather than to ligate any mass of tissue. Another plan which has for its object the expansion of the lung is to decorticate the lung (pneumoplasty as advised by Delorme, Fowler and others), dissecting away all the thickened pleura, releasing it from its adhesions, and then by deep breathing and other exercises endeavoring to cause the lung partially to obliterate the diseased space. All of these operations are exceedingly formidable, are followed by great deformity, and can all be avoided by early diagnosis and treatment. By any of these methods the ribs may be dissected from their costal cartilages nearly to the spine.

The use of the Röntgen ray will sometimes locate the pus, but ordinarily it is not satisfactory unless iodoform-glycerin is injected.

Even in the cases in which tuberculosis is present, it is often helpful to drain the abscess cavity, and in some cases even closure may be effected. In tuberculous cases extensive resections are apt to be serious; it is wiser not to be too radical. An extensive thoracoplasty is always

a serious operation; in fact, the deathrate even with an ordinary amount of excision of ribs is nearly one in four.

Postoperative Lung Gymnastics.—The use of deep breathing, dumb bells, muscular exercises, body flexions, playing of musical instruments, etc., is all important.

CONCLUSIONS.

1. Early diagnosis of pleurisy and early operation are the prime elements in the avoidance of empyema. The general practitioner is the one who needs to be on the alert.

2. A test for fluid should be made with the aspirating needle, not a hypodermic, as the latter is too small and short. Liquid, if present, should be immediately withdrawn; if purulent, further operation within a day or two is advisable as soon as the lung expands and the heart moves toward its normal position. Aspiration should be limited to diagnostic purposes, to the withdrawal of serum, and as a preliminary operation in empyema.

3. In all cases of pyothorax, free drainage, not aspiration, should be the rule. The larger the openings the quicker will cure be effected. Resection of ribs is imperative for exploration by the finger and for removal of fibrinous masses.

4. Washings are counterindicated, except in fetor, and even then more perfect drainage is indicated rather than irrigation.

5. In old chronic cases with contracted lung and degenerated pleura, more or less excision of the chest wall and pleura should be performed, even to the excision of the entire extent of all the ribs.

6. Even in tuberculous empyema, benefit is derived from thorough drainage.

EXPERIMENTAL PANCREATITIS CONSIDERED IN ITS RELATION TO THE ACUTE FORMS OF PANCREATITIS IN MAN.¹

BY

RICHARD M. PEARCE, M.D.,
of Albany, N. Y.

Director Bender Laboratory, Albany, N. Y.

The short space of time allotted me in this discussion will not allow a comprehensive statement of the many fruitful experimental researches having for their object the elucidation of the physiology and pathology of the pancreas. Various phases of the experimental investigations will, doubtless, be taken up by others who address you this evening; and I have therefore, with the approval of your president, decided to limit my remarks to a consideration of the acute lesions which may be produced experimentally. What we have gained by experiment in this field is practically a knowledge of etiology, and it is therefore more particularly the question of etiology that I will discuss. I will not hesitate, moreover, to compare the experimental lesions with the acute lesions seen in man, with the object as far as possible of correlating the knowledge gained by experiment and that gained by pathologic study.

In any consideration² of the acute forms of pancreatitis we are confronted at the outset with the question of classification. The division into hemorrhagic, suppurative, and gangrenous forms, as made by Fitz, would appear to satisfy all demands. Some writers, however, speak of a necrotic form. This is of doubtful value, for all forms show more or less necrosis; indeed, in the

¹ Presented before the Medical Society of the Greater City of New York, February 8, 1901, in a discussion of "Diseases of the Pancreas."

² In the preparation of this brief summary I have freely used the recently published work of Opie ("Disease of the Pancreas. Its Cause and Nature," J. B. Lippincott Company, 1903), and Flexner's description of the pathologic anatomy of the pancreas (Trans. Congress of American Physicians and Surgeons 1903, Vol. vi, 18); and I take this opportunity to acknowledge my indebtedness. I have not attached a bibliography. All references may be found in the bibliography of Opie's work.

hemorrhagic form, especially that produced experimentally, necrosis is a constant and essential part of the process, though not always evident microscopically. The possibility of pancreatic hemorrhage without inflammation—the so-called pancreatic apoplexy—is another debatable question which, in the present state of our knowledge, cannot be definitely settled. It seems probable from our present point of view, that thorough histologic examinations of such cases would furnish evidence of inflammatory changes and bring this lesion under the head of hemorrhagic pancreatitis. Seitz, the last writer (1892) to make a careful study of this lesion is, however, opposed to this view, and believes that some cases, at least, may be attributed to arteriosclerosis.

Hemorrhagic Pancreatitis.—The gross appearance of this form of pancreatitis—an enlarged organ with diffuse or mottled hemorrhagic areas of varying color and grayish-white spots or streaks of fat necrosis—is so well known that we may turn at once to the question of etiology. Our knowledge of the causes of pancreatitis is entirely the result of experiments having for their object the reproduction of the condition. Clinical observations have contributed nothing, and with the exception of Opie's observations upon the relation of cholelithiasis, the same may be said of general pathologic examinations. The simplest form of experimentation is the injection into the pancreatic duct of various irritating or supposedly injurious substances. A great variety of substances thus introduced has been found to produce typical hemorrhagic pancreatitis, usually with fat necrosis. These substances are deliquescent zinc chlorid (Thirollox), artificial gastric juice (Hlava, Flexner and Pearce), bile (Opie, Flexner, and Pearce), papain (Carnot), and bacteria and their toxins (Hlava, Carnot, Flexner). Flexner found various other substances, as formalin, nitric, and chromic acids, and solution of caustic alkalies, would produce the same results. The disease produced by these various means usually runs a rapidly fatal course, though some animals may live for weeks and present at death extensive suppurative or sclerotic changes. In some instances putrefactive microorganisms invade the injured organ and cause a gangrenous pancreatitis. If we study these various methods with the view of determining if any of them may operate to cause the hemorrhagic pancreatitis seen in man, we have four possibilities: Action of (a) ferments originating in the pancreas, (b) bacteria, (c) gastric juice, and (d) bile.

The possibility of the first is suggested by Carnot's experiments with papain, and some support is offered by Chiari's observations upon autodigestion of the pancreas. According to Chiari, this change occurs shortly before death, and may be accompanied by multiple small hemorrhages. The destruction of the parenchyma thus brought about affords an opportunity for the diffusion of the pancreatic ferments. There is some evidence that fat necroses may be caused by the fat-splitting ferment thus liberated, but as yet we have no definite proof that a true hemorrhagic pancreatitis may result from the action of this or other ferments liberated at the same time.

Various microorganisms as *Bacillus coli communis*, the pneumococcus, and the pyogenic cocci, have been found, not infrequently, associated with hemorrhagic pancreatitis. There has been no uniformity in these findings, and most of the writers reporting the results of bacteriologic examinations agree that the organisms represent a secondary invasion of injured tissue, and are in no way concerned in the etiology of the lesion.

That the gastric juice, as suggested by Hlava, may enter the pancreatic duct and produce an inflammation of the pancreas presupposes a powerful antiperistaltic, or other action, forcing the secretion into the duct. Of such action we have no definite evidence. Under normal conditions it is practically impossible to force fluids from the intestine into either bile or pancreatic ducts. I have recently made some experiments upon dogs in order to

determine this point. The intestine was ligated at varying distances above and below the orifice of the ducts and distended by injecting colored solutions and suspensions. After varying periods of time, the animals were killed, but no staining of the ducts could be demonstrated. In other experiments upon the dead animals, forcible manual pressure was exerted upon the similarly ligated intestine with negative results. On the other hand, it cannot be denied that under certain pathologic conditions of the duct orifice, intestinal fluids may possibly be forced into it. Concerning the action of the gastric juice upon pancreas parenchyma the following case would appear conclusive.

(Records of the Pathologic Department, University of Pennsylvania; Autopsy No. 01.48). The clinical history of this case is brief and incomplete. The patient, a negro, aged 41, was admitted to the insane department of the Philadelphia Hospital on July 19, 1900, with a diagnosis of delusional insanity. For the next six months his condition, apparently, was not noteworthy. "On January 28, 1901, the patient seemed rather dull and was put to bed." On February 11, regurgitation of blood mixed with milk curds was observed. This continued until his death on February 13. Physical examinations revealed a rather firm mass in the right hypochondriac region, which upon palpation caused the patient to complain of pain. At no other time did he complain of pain. Temperature was normal; pulse about 100, and of poor volume; no distention of abdomen; marked constipation. Albumin was found in the urine, and microscopically numerous hyaline and granular casts. The clinical diagnosis was cancer of the stomach and the liver, with chronic nephritis.

Autopsy. Pathologic Diagnosis.—Recent hemorrhage in and about pancreas and duodenum, chronic gastropancreatic fistula; chronic interstitial pancreatitis; chronic pulmonary tuberculosis; tuberculosis of the bronchial, gastrohepatic and retroperitoneal lymph-nodes; chronic mitral endocarditis; general chronic passive congestion; chronic diffuse nephritis (parenchymatous type).

Abdominal Cavity.—Stomach is greatly dilated, the lower margin extending below the umbilicus; pylorus touching the right costal margin. Beneath the pylorus and entirely surrounding the duodenum is a globular, firm, hemorrhagic mass, distinctly encapsulated and resting on the upper end of the right kidney. The subperitoneal tissues between the stomach and the transverse colon and in the neighborhood of the pylorus and adjacent abdominal wall are infiltrated with clotted blood. Stomach, pancreas, duodenum and transverse colon with hemorrhagic mass removed entire. Upon opening the stomach it is found normal except for the presence of a small orifice with smooth edges 4 cm. from the esophageal end. The outer wall of stomach about orifice is bound to the pancreas 9 cm. from its splenic end by dense fibrous adhesions. A probe passed through the orifice in the stomach enters a sinus leading to the pancreas. This sinus passed directly through the pancreatic tissue. Its walls are lined by dense fibrous tissue, and it contains bloodstained mucus-like fluid. The canal can be followed for a distance of 5 cm. It then approaches the surface of the pancreas, where it is continuous with the blood clot about the duodenum. No foreign body found in the sinus. The splenic end of the pancreas for a distance of 8 cm. appears normal; the middle portion for a distance of 4.5 cm. is paler and firmer than normal, and the lobulations are not so distinct; through the remaining 5 cm. constituting the duodenal end, the pancreas is extensively infiltrated with blood. Surrounding the duodenal end of the pancreas and completely encircling the duodenum is an encapsulated mass of black clotted blood 14 cm. in length and 7 cm. in diameter. The long diameter of this clot corresponds to the course of the duodenum. The source of the hemorrhage cannot be discovered. The pancreatic and common bile ducts are patulous. The mucous membrane of the duodenum is very thin, bloodstained, and at one point presents a small adherent blood clot 2 cm. in diameter. No fat necrosis.

Histologic Examination.—The wall of the sinus is composed of dense fibrous tissue. On its surface is a thin layer of granular material with a few pus cells. Sections stained by Gram-Weigert's method show a few cocci and bacilli. Scattered through superficial portion of sinus wall are many lymphoid and plasma cells and a few polymorphonuclear leukocytes. New bloodvessels are seen throughout and here and there are small areas of hemorrhage. In the deeper portions the hemorrhage is more diffuse, and here are seen small islands of atrophic pancreatic tissue infiltrated by lymphoid cells. From the sinus wall coarse bands of fibrous tissue run into the substance of the pancreas, and divide into finer lines which penetrate the pancreatic acini. Sections from various portions of the pancreas, at a distance from the sinus, show a moderate increase of perilobular connective tissue. The cells of the parenchyma are very granular and stain poorly. The islands of Langerhans are prominent and unaltered. Throughout the duodenal portion extensive hemorrhage is seen in the interstitial tissue, penetrating in places the parenchyma which is edematous. No necrosis or exudation is evident. The splenic portion is free from hemorrhage.

From this description it is evident that in the early development of the sinus the gastric juice must have been in intimate contact with the pancreas parenchyma but failed to produce a hemorrhagic pancreatitis. The hemorrhage into the duodenal portion, was unaccompanied by acute changes and was due apparently to extension from the large clot about the duodenum. The chronic pancreatitis was merely a localized process about the sinus. The case offers strong evidence against the possibility of gastric juice exciting a typical hemorrhagic pancreatitis.

The relation of bile to acute pancreatitis has received very substantial support from experimental observations and also from the not unusual occurrence of the lesion with cholelithiasis. The most important contributions to this phase of the subject have been made by Opie, who has worked out the pathogenesis of pancreatitis associated with gallstones, and by injecting bile into the pancreatic duct of the dog has produced a typical inflammation of the gland with associated fat necrosis. In one particularly fortunate autopsy he found at the apex of the diverticulum of Vater a small calculus completely blocking the duodenal orifice, but too small to obstruct the orifices of the common bile and the pancreatic duct. These ducts were thus transformed into a continuous closed channel from which it was impossible for their respective contents to escape. Upon dissecting the pancreatic duct it was found to be stained light green with bile, indicating that the slightly greater pressure in the bile duct, probably due to the contraction of the gallbladder, had forced bile into it. An acute hemorrhagic pancreatitis with disseminated abdominal fat necrosis existed.

The same writer has also analyzed the reported cases of acute pancreatitis and finds that cholelithiasis is very constantly associated with the hemorrhagic and gangrenous forms of the lesion. On the other hand, acute pancreatitis is a rare condition as compared with the relative frequency of cholelithiasis. In this connection it is important to point out, as Opie has done, that in only a small proportion of individuals (in about three out of ten) are the anatomic features such as to allow favorable conditions for bile to penetrate the pancreatic duct. The ducts, in a considerable number of individuals (10%) open separately and the diverticulum does not exist. Also, the size of the diverticulum bears an important relation to the production of the condition; its variation in length is from zero to 11 mm. the average diameter of the orifice being 2.5 mm. In only 30 of Opie's 100 examinations did the length reach 5 mm. Thus it is evident that a stone to produce obstruction of the duodenal orifice only, must be relatively smaller than the diverticulum, for otherwise the orifices of both ducts would also be obstructed and the secretions forced back upon their respective organs.

While cholelithiasis is thus definitely established as an important factor in the etiology of acute pancreatitis, it does not explain all cases. Many cases have been reported in which neither clinical history nor autopsy affords evidence of cholelithiasis, though it is noteworthy that since attention has been called to this association these cases are not so numerous. It should also be noted in this connection that the stone after obstructing the papilla orifice and causing a pancreatitis may pass into the intestine and escape observation, or perhaps pass from the intestine entirely. A dilation of the diverticulum may in such cases indicate the previous resting place of the stone. The following case would appear to be an example of this kind.

Patient of Dr. W. E. Fay, of Boston, Mass.

Clinical Abstract.—The patient was a robust woman of 36, with a history of occasional sharp attacks of gastroenteritis after excessive indulgence in wine. "The mortal attack began with a 'French' dinner on Thanksgiving Day. From claret she changed to whisky, drinking considerable between November 29 and December 8. When first seen, on the latter of these

dates, she was tremulous and sleepless, with a wild look in the eyes, intense burning in the epigastrium, and violent and continuous emesis. Neither water nor cracked ice could be retained. The vomitus was green, thin, and acid. After the hypodermic use of morphin, and careful administration of chloroform almost steadily for an hour, sleep was obtained lasting three hours. Restlessness then returned, with frequent hicough, and ceaseless cry for water, which was rejected in whatever quantity or temperature given. Washing the stomach and paraldehyd administered by enema afforded temporary relief. Abdomen was distended. Obstinate constipation was overcome by high enemas. Persistent flatulence was present in both stomach and bowel, and considerable pain centering in the epigastrium and extending throughout the abdomen. This condition continued, with temporary alleviations, for nine days after she was first seen. Then December 17, slight jaundice was noticed. The patient desired nothing but frequent drinks of milk and limewater. December 20 patient sat up and began to eat gruel, but had no energy. December 24 there was sudden enlargement of the right parotid and adjoining glands, with redness extending below angle of jaw; considerable emaciation had taken place. After sitting up parts of two or three days, which was agreeable to her, there was an increase of tenderness throughout the abdomen. Temperature rose to 101°. Distention was constant. Free fat appeared to float in the urine; sugar was present. The patient sank rapidly, and died on December 30."

Autopsy was performed six and a half hours after death.

Anatomic Diagnosis.—Hemorrhagic and gangrenous pancreatitis with fibrinous peritonitis and accumulation of grumous fluid in peritoneal cavity. Multiple fat necroses of omentum, mesentery, epiploic appendages and subperitoneal fat generally. Acute duodenitis with dilation of orifice of duodenal papilla. Localized dilation of common bile duct. Dilation of pancreatic duct. Fatty degeneration of heart, liver, and kidneys.

Abdomen.—Excessive amount of subcutaneous fat. Omentum, mesentery, epiploic appendages, and abdominal fat generally closely studded with round or grayish-white oval areas, 2 mm. to 5 mm. in diameter, and distinctly circumscribed. Many of the greatly enlarged epiploic appendages (3 cm. by 1.5 cm.) are entirely necrotic. In pelvis and both flanks is a thin, grayish-red greasy fluid, containing small black shreds of friable material. Omentum is glued to anterior abdominal wall by a bloodstained, fibrinous exudate. A similar exudate covers the coils of the small intestine. The position of the pancreas is occupied by a soft, friable, irregular reddish-black mass 4 cm. by 1.5 cm., freely movable. The cavity in which this mass lies is lined by reddish-black necrotic tissue, which adheres in places to colon and stomach. The mass on section shows at splenic end irregular areas of grayish pancreatic tissue separated by dark-red lines of hemorrhage and necrosis. Elsewhere it is uniformly necrotic.

Duodenum.—Contains material similar to that about pancreas and its mucosa is injected. The orifice of papilla is dilated, and 1 cm. from the orifice occurs a circular dilation with smooth walls, 1.5 cm. in circumference. No calculi are found in gallbladder, ducts, or intestine. The pancreatic duct is dilated and separated from the pancreas; a probe from duodenal end passing directly into cavity about the gangrenous pancreas. *Bacillus coli* was found in the necrotic material about the pancreas.

While this case is not conclusive, in as much as the stone was not found, the anatomic condition indicates that a calculus, at some time, was lodged in the common duct, and the possibility of later occlusion of the papilla with final discharge of the stone is evident.

The Sequence of Histologic Changes in Hemorrhagic Pancreatitis.—Much discussion has arisen concerning the precedence and succession of the three principal phenomena—hemorrhage, necrosis, and exudation. Katz and Winkler believe that the necrosis follows hemorrhage, and is the direct result of injury produced by the extravasated blood. Hlava found extensive occlusion of the bloodvessels after acid injection, and considered it to be the cause of both necrosis and hemorrhage. Opie found hemorrhage intimately associated with necrosis and followed only secondarily by inflammatory changes. From his earlier experiments Flexner drew the conclusion that hemorrhage and necrosis are the result of the simultaneous action of the injurious agent upon bloodvessels and tissue, and that they occur coincidentally. In a later series of experiments by Dr. Flexner and myself an attempt was made to settle definitely these mooted points. Dogs under chloroform narcosis received injections of 1% to 2% solutions of hydrochloric acid into the duct and directly into the parenchyma of the pancreas. Small portions of the organ were removed after periods varying from 35 minutes to eight hours,

and examined histologically. It was found that hemorrhage, hyaline necrosis, and exudation of fluid and leukocytes could be readily demonstrated in tissue removed one hour after injection. Sections taken at the end of eight hours represented the pathologic process at its height. That these lesions are correlated in the pancreas may therefore be considered demonstrated.

At the same time in order to determine the effect of red blood-corpuscles upon the pancreatic tissue, a condition analogous to hemorrhage was brought about by the injection of sterile defibrinated dog's blood through the duct and directly into the parenchyma. Such injections did not set up an acute pancreatitis, but were followed by chronic proliferative changes. Similar injections of dog's serum were negative.

Gangrenous Pancreatitis.—Experimental and post-mortem observations both indicate that in the majority of cases gangrenous pancreatitis is secondary to an acute hemorrhagic inflammation of the organ. The tissue primarily the seat of hemorrhage, necrosis and inflammation readily becomes gangrenous under the influence of putrefactive microorganisms invading it from the intestinal canal. The association of hemorrhage and gangrene frequently seen at autopsy was first emphasized by Fitz, who also recognized, however, the possibility of the lesion originating from perforating inflammation of the gastrointestinal canal or of the biliary passages.

In the series of experiments by Dr. Flexner and myself, two examples of gangrenous pancreatitis following acid and bile injections respectively, occurred. Death occurred in each instance in less than 24 hours, and the gangrenous portions of the pancreas were studded with emphysematous blebs. Films showed bacilli having the morphology of *B. aerogenes capsulatus*. Furthermore, gangrenous pancreatitis has the same relation to cholelithiasis as has the hemorrhagic form. In Opie's table of 37 cases of acute pancreatitis associated with cholelithiasis, 8 are described as hemorrhagic and gangrenous and 13 as gangrenous. Disseminated fat necrosis is a striking feature of this lesion.

Suppurative Pancreatitis.—Suppurative inflammation of the pancreas, unlike the hemorrhagic and gangrenous forms, does not differ essentially from that of other organs. It may be primary or secondary. The relation of the pancreas to the intestines allows the possibility of infection through the ducts, while lesions of adjacent hollow viscera may extend directly or as the result of perforation. In general infection of the blood, pyemic abscesses may develop in the pancreas as in other organs. Direct extension of an infectious pyelophlebitis may also occur. These lesions are seldom accompanied by extensive necrosis, hemorrhage, or disseminated fat necrosis. The accumulation of pus is not diffuse, but occurs usually as localized abscesses. Hemorrhage and necrosis, if present, are generally focal in character, suggesting the local action of an irritant. Rarely the pancreas may be entirely destroyed and appear as a sequestrum in a pus cavity. Experiments, especially those of Flexner, show that abscesses of the pancreas may follow the injection of various fluids, as weak solutions of hydrochloric, sulfuric and nitric acids, sodium hydrate and suspensions of *B. pyocyaneus*. In these experiments we have evidently a primary necrosis due to the irritant and a secondary invasion by microorganisms. Körte in a few instances produced abscesses by injecting pus containing a bacillus of the colon group. These experimental lesions are seldom accompanied by fat necrosis. A comparison of the lesion in man and of the experimental findings indicates that this suppurative form of pancreatitis is due to some local influence causing limited necrosis and suppuration. There is, however, some evidence that duct obstruction may rarely lead to the condition, probably in that it favors the entrance of bacteria. In Opie's table, previously quoted, "purulent pancreatitis" occurred in 4 of 41 cases complicated by

cholelithiasis. The common duct in only one of these, however, contained a stone. The following case illustrates suppuration of the pancreas, with fat necrosis, accompanying cancer of the diverticulum and cholelithiasis.

The individual, a male of 73, patient of Dr. A. W. Elting was admitted to the Albany Hospital on August 24, 1903, with a history of hepatic colic which began on August 15. Since May 1, he had suffered from gastric distress, nausea and dull pain in the region of the stomach, and had lost in strength and weight. Physical examination revealed a jaundiced, emaciated, feeble individual with evidence of arteriosclerosis, enlarged heart and emphysema of lungs. Upon palpation of abdomen a distinct irregular tumor mass was felt in the epigastrium; deep pressure elicited some tenderness. During the patient's sojourn in the hospital there was slight change in his condition; the jaundice continued and nausea after the taking of food persisted; the pain subsided, physical examination revealed nothing new. Emaciation and weakness progressed rapidly and death occurred on September 11.

Autopsy, by Dr. A. T. Laird, 12 hours after death.

Anatomic diagnosis.—Cancer of the diverticulum of Vater with ulceration of duodenum and metastases in liver; dilation of common duct and gallbladder; cholangitis, gallstones free in colon; jaundice; multiple abscess of head of pancreas; disseminated fat necrosis; hemorrhage into intestine; arteriosclerosis.

The individual is extremely emaciated and jaundiced. In duodenum, about 1.5 cm. above duodenal papilla is a circular ulcer 3 cm. in diameter with irregular edges and firm indurated bile-stained base. The base of the ulcer, 5 mm. in thickness, rests upon the head of the pancreas to which it is intimately adherent and upon indurated lymph-nodes. The tissues beneath the papilla are infiltrated by a dense grayish-white diffuse growth of new tissue. The duodenal papilla is prominent and rests on the indurated mass below it; bile readily flows from its orifice on forcible pressure of gallbladder. Common duct is slightly dilated. Gallbladder measures 10 cm. in length and is distended with thick fluid bile, no calculi present.

Liver is of a dark uniform greenish color and bile ducts are distended with thick bile. Scattered throughout the organ are numerous grayish-white firm areas .5 cm. to 2 cm. in diameter of fairly definite outline.

Pancreas measures 14 cm. in length. The duodenal end for a distance of 5 cm. is irregularly swollen. On section a yellowish purulent fluid escapes and the cut surface presents numerous abscesses of varying size with thin trabeculated walls. The middle portion of the organ is firmer than normal. Splenic end is unaltered. Duct patent, though its proximal portion is surrounded by the new growth. Peripancreatic fat presents numerous distinctly circumscribed yellowish opaque areas. The small intestine is bloodstained throughout its length and contains an accumulation of blood, fluid and clotted. A lesser amount of blood is found in the large intestine. The source of the hemorrhage is apparently the ulcer in the duodenum. In the lower portion of the descending colon are found two smooth faceted calculi composed of cholesterolin and inspissated bile.

Histologic examination shows a cancer about and involving the diverticulum and the common duct with extension to the duodenum and to the head of the pancreas and with metastases in the liver. The head of the pancreas is the seat of advanced perilobular pancreatitis, in the midst of which are numerous abscesses. These abscesses are chronic in character, and contain much necrotic material and zoogloea of large thick bacilli. The tail of the pancreas is the seat of a slight perilobular pancreatitis. Typical fat necroses are numerous. The ducts are dilated and contain an accumulation of mucous and desquamated epithelial cells.

Fat Necrosis.—This condition is so constantly a concomitant of acute pancreatitis and its elucidation so entirely the result of experimentation that a consideration of the experimental lesions of the pancreas would be incomplete without it. Hemorrhagic and gangrenous pancreatitis, as they occur in man or as the result of experiment, are generally accompanied by this peculiar lesion of the fat tissue. Rarely it occurs in connection with suppurative lesions, and occasionally, as will be pointed out later, with chronic interstitial pancreatitis. The characteristic appearance is that of small round or oval areas, white or grayish-white in color, and usually sharply circumscribed. Microscopic examination shows these areas to be composed of necrotic fat cells. In early necroses fatty acid crystals may be demonstrated. These areas are found most abundantly in the neighborhood of the pancreas, and are usually limited to the abdominal fat, but they may be widely disseminated and appear in the fat beneath the pericardium and the pleura, in the

subcutaneous fat, and in the marrow of long bones. Fitz first suggested that fat necrosis is the result of a lesion of the pancreas; but to Langerhans belongs the credit of first demonstrating the essential nature of the process. By chemic and histologic studies he showed that the changes within the fat cells are associated with the splitting of the fat molecule into its fatty acid and glycerin. The glycerin is absorbed and the acids are deposited in the cells as needle-like crystals. The cell loses its nucleus, and is apparently necrotic. Later, chronic proliferative changes occur about the areas. Leukocytes may enter the necrotic fat, but when numerous, indicate invasion by bacteria. Although bacteria have been frequently found in these necroses they are not concerned in the production of the lesion, and must be considered as secondary invaders. Instances in which the injection of bacteria into the pancreatic duct has resulted in the necrosis of fat are to be explained by the setting free of pancreatic ferments as the result of injury to or inflammation of the gland.

The first experimental proof of the relation of fat necrosis to pancreatic ferments was offered by Langerhans, who injected suspensions of the comminuted pancreas of the rabbit and dog into the perirenal fat of the rabbit. One of his 13 experiments was successful, and he concluded that these necroses are due to the action of the fat-splitting ferment of the pancreatic juice. Jung obtained similar results by introducing portions of the fresh pancreas of one animal into the abdominal cavity of another; Hildebrand and Dettmer, Williams, Whitney, Flexner, Milisch, Körte, and Opie have obtained similar results by various injuries allowing the escape of the pancreatic juice into the adjacent fat and the peritoneum. Their methods include ligation of ducts and vessels, ligation, laceration, and incision of the parenchyma; and excision of portions of the organ. The experiments of Hlava, Körte, Oser, Opie, Flexner, and Pearce, in which an acute pancreatitis, usually hemorrhagic, has followed the injection of various substances, as acids, alkalies, gastric juice, bile, bacteria, etc., have also caused the appearance of fat necrosis. In these experiments the fat necroses are not due to the substance injected, but to lesions of the pancreas which allow an escape of the pancreatic juice. The final link in this chain of experimental evidence was Flexner's demonstration, by chemic test, of the presence of fat-splitting ferment in the necrotic foci. Portions of the necrosed foci from both human and experimental cases when brought in contact with neutral butter fat caused a splitting of the fat with a freeing of fatty acids recognizable by their odor and reaction.

It has been claimed by some writers, especially by Oser, that the presence of a fat-splitting ferment will not explain the widely disseminated necroses, such as occur in the subpericardial, subpleural, and subcutaneous fat. Opie has, however, in a series of duct ligations demonstrated by Flexner's method the presence of the fat-splitting ferment in the distant necroses of the subcutaneous and subpericardial fat as well as in the peripancreatic foci. The diffusion of the ferment in these experiments he also found was hastened when the secretory activity of the pancreas was stimulated by injection of pilocarpin.

Wells¹ has found that commercial "pancreatin" will produce typical fat necrosis, but that this power is lost after heating for five minutes at some point between 65° C. and 71° C. Its power to produce fat necrosis decreases proportionally as the temperature is raised above 55° C. These observations indicate an enzyme action as the source of the lesion. He was unable however to determine which of the pancreatic enzymes causes fat necrosis, and could not produce fat necroses with the lipolytic extracts of hog's liver or cat's serum used either alone or in combination with trypsin.

He thinks it possible that the lipase causes fat-splitting after some other ingredient of the pancreatic juice has injured the cell; fat-splitting is subsequent to the necrosis and not its cause. The lipase normally in fat tissues exerts no fat-splitting effect upon necrotic fat if the latter be preserved from external influences. Foci of fat necrosis become visible to the naked eye three to five hours after application of "pancreatin" and were found outside the abdominal cavity as early as 12 hours after intraperitoneal injection.

In considering the application of the results of experimental fat necrosis to the lesion as seen in man it must be borne in mind that fat necrosis bears the same relation to obstruction of the pancreatic ducts as jaundice does to hepatic obstruction. Obstruction to the outflow of the pancreatic secretion causes its diffusion into the surrounding tissues (Opie). The escape of the ferment in the acute lesions of the pancreas is readily explained by obstruction or destruction of the finer ducts or by injury to the parenchyma. On the other hand either temporary or permanent obstruction of the duct of Wirsung by calculi or by cancer may be accompanied by fat necrosis. Usually other lesions exist as suppurative or chronic pancreatitis but in a few cases, as those reported by Fraenkel (stone in diverticulum) and by Flexner (stones in common duct) no lesion of the pancreas was found. There can be little doubt that in these cases the calculus causes compression of the pancreatic duct and an accumulation of secretion which finally becomes diffused into the adjacent tissues.

The following case would appear to belong in this group. A chronic atrophic cholecystitis with atrophy of the bile ducts and adhesions to head of pancreas apparently caused pressure upon the pancreatic duct.

Records of the Bender Laboratory, Autopsy No. 0.614.—Autopsy by Dr. A. T. Laird, 7½ hours after death; female, aged 42.

Anatomic Diagnosis.—Extensive syphilitic ulceration of nose and palate; edema of lungs, hydrothorax, chronic cholecystitis with almost complete obliteration of gallbladder and ducts, fat necrosis of pancreas. The gallbladder is greatly atrophied and lies in a mass of dense fibrous adhesions which bind it to the duodenum and the head of the pancreas and which also surround and penetrate the foramen of Winslow. The cavity of the gallbladder measures but 2 cm. in diameter. The pancreas measures 17 x 4 x 2 cm. At the head the capsule is much thickened by adhesions binding it to the gallbladder and to the duodenum. Over its entire surface, numerous grayish-yellow opaque areas, not extending into pancreatic tissue, are seen. The consistence of the pancreas is normal.

Histologic examination of the pancreas reveals numerous fat necroses, and dilated ducts filled with hyaline and granular material, desquamated cells and a few polymorphonuclear leukocytes. The latter also to a moderate degree infiltrate the walls of the larger ducts. No inflammation of the parenchyma proper is evident. The islands of Langerhans are unaltered.

The following accidental finding in a dog indicates that fat necrosis may follow a simple thickening of the orifice of the duct:

Dog 84; wt., 8,650 grams. Isolated February 6. Urine normal on February 7 and 8. Killed on February 12 for purposes of obtaining organs for injections in connection with cytolytic work. All organs were normal except pancreas, the capsule of which is studded with numerous small, grayish-yellow areas of definite outline and of firmer consistence than surrounding pancreatic tissue. No evidence of acute or chronic inflammation. No fat necroses of abdominal fat elsewhere. No obstruction of the duct is found. The papilla of duodenum, however, appears as a distinctly elevated, swollen, grayish-yellow ring; a sharp contrast to the normal appearance. A fine probe passes readily into the duct. The second pancreatic duct is not found. The orifice of bile duct, lying 1.5 cm. above pancreatic duct, can be located only by forcing bile from the gallbladder.

Histologic examination shows fat necroses chronic in character, pancreas otherwise normal.

Finally, as pointed out by Opie, we have fat necroses associated with cases of chronic interstitial pancreatitis, in which duct obstruction by calculi is not present. Here it is probable that the newly-formed fibrous tissue contracting about the smaller ducts constricts them, and allows an accumulation of secretion which finally diffuses

¹ Journal of Medical Research, 1903, ix, 70.

into the adjacent tissues. These necroses are most apt to be parapancreatic. I have found two examples of this condition in the autopsy reports of the Bender Laboratory; in one associated with localized chronic interstitial pancreatitis, in the other with atrophy and lipomatosis. Macroscopic evidence of duct obstruction did not exist. These reports are as follows:

0-223.—Autopsy 12 hours after death. Male, aged 49.

Anatomic Diagnosis.—Acute follicular duodenitis and ileitis; acute swelling of spleen and mesenteric lymph-nodes; fatty degeneration of liver; arteriosclerosis; atrophy of pancreas with lipomatosis, autodigestion, and foci of fat necrosis; general infection with the bacillus of Friedländer.

The pancreas appears to be of normal size, but much of the parenchyma is replaced by diffuse masses of fat tissue. On section small islands of pancreas are seen widely separated by fat tissue. This change is most marked at splenic end, where little pancreatic tissue remains. The parenchyma in some areas is whiter and softer than normal, and in other places presents a reddish-brown appearance, suggesting minute hemorrhages. On the surface and on section several minute opaque white points suggesting fat necrosis are seen. No calculi are found in the ducts; the vessels present a few small areas of atheroma.

Histologic examination shows small islands of pancreas widely separated by adipose tissue, slight self digestion of these areas, and typical foci of fat necrosis with minute hemorrhages. The interlobular connective tissue is increased in amount; the small ducts dilated and some acini appear as duct-like spaces with flattened epithelium and contain a finely granular material. In some islands these altered acini are very abundant, and apparently indicate atrophy from pressure within the lumen. The islands of Langerhans are unaltered.

0-332.—Autopsy 10 hours after death. Male, aged 63.

Anatomic Diagnosis.—Arteriosclerosis; hypertrophy and dilation of heart; general passive congestion; edema; double hydrothorax; thrombus of right auricular appendage; multiple infarcts of lungs; fat necrosis of pancreas.

Pancreas, 20 cm. long. Twelve centimeters from the tail, over an area 2.5 cm. in diameter, the capsule is greatly thickened; beneath the capsule the pancreas presents a congested area containing many small yellowish-white areas of soft cheese-like consistence. A few similar areas are found elsewhere in the pancreas.

Histologic examination reveals a slight localized interlobular pancreatitis with typical fat necrosis.

It is possible that the first of these cases belongs to the group described by Chiari, in which, in his opinion, self digestion of the pancreas occurs shortly before death as an agonal change, and allows the escape of the fat-splitting ferment and the development of fat necrosis with associated minute hemorrhages. That fat necrosis may develop very quickly is shown in one of the experiments of the series carried out by Dr. Flexner and myself, in which necroses were evident eight hours after injection of a 1% solution of hydrochloric acid into the pancreatic duct. Wells has observed them three to five hours after the application of "pancreatin." The theory that postmortem digestion of the pancreas may set free the pancreatic secretion and allow the development of fat necrosis has little evidence to support it. In connection with these agonal necroses, Opie believes that it is possible that shortly before death the character of the pancreatic juice may change, becoming thick and viscid, in consequence of which it flows slowly. Stagnation and slight diffusion of the secretion may result and cause the insignificant necroses occasionally seen.

Infant Mortality and Milk.—One of the things in which London is far behind New York and Chicago is the method and quality of its milk-supply, the importance of which Sir James Crichton-Browne dwelt upon at the annual meeting of the Sanitary Inspectors' Association in London. He laid particular stress on the importance of children being fed naturally. The nature of substitutes for mother's milk, he said, was responsible for the increasing infantile mortality. Of the 15,000 infants who are dying in England annually in the first year of their life, three-fourths have been fed artificially. In France the mortality among suckled children is 8%, while among hand-fed it is 61%. Patent foods, he declared, all should be condemned, as their exclusive use often leads to anemia, rickets and scurvy. He urged the further use of milk for adults. In certain sicknesses, such as typhoid, life may depend on milk, which may not only postpone the final issue in certain kinds of senile decay, but may contribute to the stability of vigor in maturity. He drew attention to the value of the goat as a milk producer.

ACUTE ANTERIOR POLIOMYELITIS IN ADULTS, WITH REPORT OF A CASE IN WHICH THERE WAS ALSO A PERIPHERAL FACIAL PALSY AND PARADOXIC PUPILS COMPLICATED WITH HIPPIUS.

BY

ALFRED GORDON, M.D.,
of Philadelphia.

Instructor in Nervous Diseases, Jefferson Medical College; Assistant Visiting Neurologist to the Philadelphia Hospital; Neurologist to Douglass Memorial Hospital.

Cases reported under the title of acute anterior poliomyelitis in adults should always be accepted as such with some hesitation. A careful reading of the old records will show now at a glance that a number of cases described as acute affections of the anterior cornua of the cord were in reality no more than examples of polyneuritis. Lately, however, the acute spinal diseases of adults, corresponding to the typical infantile palsies, have been reported more and more rarely, as our present knowledge of the subject enables us to make a better discrimination. It is true there are in the literature a few cases with undoubted microscopic findings (Gombault, Rissler, Williamson) and also some observations which clinically are types of true acute poliomyelitis, nevertheless, the histories of quite a large percentage of them are not at all convincing in regard to their poliomyelitic nature. The reason of the variety of the affection in adults as compared with children lies probably in the absence of a special predisposition to infectious diseases which characterizes childhood.

The case I am about to report presents clinically an affection which points to an invasion of the cells of a segment of the spinal cord and of those of a nucleus of the medulla, or perhaps to an involvement of two whole motor neurons; one in the cord and the other in the medulla. In my opinion, if it is not an example of a pure poliomyelitis, it nevertheless is undoubtedly not a case of polyneuritis.

M. D., aged 27, was admitted to the Philadelphia Hospital on November 9, 1903, with the following history: On May 8 while lying on the ground in the open air he fell asleep, and when he woke up he found himself in the Pennsylvania Hospital. The record of the latter institution, however, shows that the patient fell from a wagon and was brought to that hospital in a patrol wagon in a semiconscious state. On the third day a flaccid paralysis of the left upper limb was noticed. Three days later a left facial palsy of Bell's type was observed for the first time. When he left the Pennsylvania Hospital, on June 15, there was some improvement in the arm, but the facial palsy remained unaltered. The examination shows a very strongly built man, with perfectly normal viscera. The motor as well as the sensory conditions of both lower and right upper extremities are normal. The left upper limb is in a state of total flaccid paralysis, although there are some movements in the hand. All the reflexes (biceps, triceps, extensors of the wrist) of this limb, also Bechterew's reflex on the same side, are abolished. Sensations of the paralyzed limb present the following peculiarities: On the radial side of the hand in an area extending from the wrist to the tip of the thumb and to the ends of the first two phalanges of the index and medius there is a distinct delay to all forms of sensations. The rest of the entire limb is normal to touch. From the acromion down on the antero-external aspect of the arm, forearm, and hand, there is an area of an inch in width which is hypalgæsic and thermoanæsthetic. The same sensory disturbances are noticed on the auricle of the left ear (anterior and posterior aspects), also on the skin covering the mastoid process. The patient did not complain at any time of pain, but sometimes of numbness in the paralyzed limb. There is no tenderness on pressure of the nerve trunks. The deltoid, biceps, triceps, supraspinatus and infraspinatus muscles, first interosseous space, thenar and hypotenar muscles on the left side are distinctly atrophied. Fibillary contractions could be seen on biceps, triceps, and infraspinatus muscles. Electric reactions show diminution of contractility and reaction of degeneration in some muscles. The face shows distinct evidences of a previous palsy on the left side, although the orbicularis palpebrarum has recovered almost entirely. The muscles of the paralyzed side are retracted, so that the nasolabial fold is more elevated on the left than on the right, but when the patient is told to contract various muscles, it can be readily seen that the muscles of the left side are distinctly weaker than those of the right.

The pupils are unequal with predominance on the right.

The light reflex presents the following peculiarity. After the eyes have been closed for a minute, we notice on the opening that during the first second there is no reaction to light, but immediately afterward the pupils dilate and then hippus makes its appearance; contraction and dilation follow each other rapidly for a half minute. The ophthalmoscopic examination shows that both optic nerves are pale, especially the left; the arteries are rather narrow.

In making a diagnosis of this case three possibilities present themselves for consideration: Poliomyelitis, multiple neuritis, and hematomyelia.

As to the question of polyneuritis, our classic knowledge requires, among other symptoms, two essential points, viz., the presence of pain and a gradual onset. First of all, we know now that absence of pain is not a sufficient reason for rejecting the idea of this disease (see case of Guillain and Courtellemont).¹ In fact, it is difficult to conceive a pathogenic influence affecting exclusively the motor fibers of a certain nerve, since the mixed character of peripheral nerves is an established fact. The axis cylinders of the nervous elements as soon as they leave the spinal canal and enter into various plexuses (cervical, brachial, lumbar, and sacral) lose their unity and simplicity which they possessed at the level of their central origin. In the peripheral nerves the centripetal and centrifugal conductors are commingled so that there is no possibility of dissociating them. Primary or secondary affections of the peripheral nerves are therefore very complicated. Erb, however, expressed the view that a pathologic process affecting the cells of the anterior cornua primarily will involve secondarily the motor fibers, the nutrition of which depends upon those cells; and while the changes in the cells may be transitory, the changes in the motor fibers may persist and progress. Eisenlohr's case² proves almost conclusively this contention. When we take into consideration the various gradations of pathologic findings in poliomyelitis and polyneuritis from the mildest to the most marked forms and also the clinical evolution of both affections, one cannot but be convinced that an identical etiologic factor (infection) affects simultaneously, but to a varying degree, both the cord and the nerves, each of which is after all a segment of the same motor neuron; and if the suffering of the cells reacts upon the nerves, the opposite is also true.

According to the researches of Marinesco and others the localization, also the degree of the pathologic changes depends upon the nature of the infectious agent and upon the duration of its action. From the foregoing we can consequently conclude that the existence of a motor neuritis is admissible, but it is difficult sometimes to make a differential diagnosis between this form of neuritis and a poliomyelitis. A sudden onset on the other hand does not always speak against a polyneuritis, as cases of so-called apoplectic neuritis are known to us (Raymond, Dubois, Eichhorst) not in the sense of a hemorrhagic process, but from the point of view of a sudden appearance of the symptoms. The amyotrophy with reaction of degeneration are certainly symptoms which are usually found in polyneuritis. It is therefore evident that so far the paralytic symptoms in my case are not against the idea of multiple neuritis. From the foregoing it can be readily seen that it is difficult sometimes to draw a sharp line between an affection strictly limited to the anterior cornua of the cord or only to the motor fibers, as it is possible that in a great many cases the pathologic process affects the motor neuron *in toto*. The solution of the problem cannot be based upon the presence or absence of one or two symptoms. The entire course and the evolution of the disease should always be taken into consideration before we arrive at a conclusion. In a large majority of cases a symmetrically distributed bilateral affection with incomplete paralysis at the beginning, which increases gradually and insidiously and shows a tendency to become generalized and invades other portions of the body including those which are

innervated by the medulla, showing also almost complete integrity of objective sensations, finally a prompt amelioration of the symptoms—this is the usual picture of polyneuritis. If in addition to this we add the rarity of sudden onset and of absence of tenderness of the nerve trunks, we are led to reject the diagnosis of polyneuritis in our case.

Let us turn our attention to the two other possibilities, viz., poliomyelitis and hematomyelia. A sudden appearance of paralytic symptoms, with or without pain, should suggest first of all a hemorrhage. In my case, however, the monoplegia was detected only one to two days after he was brought to the hospital. Moreover, in hematomyelia, the reflexes are usually exaggerated and contractures make their appearance some time later. The suddenness is usually similar to that of apoplexy. In my case neither the onset, nor the character of the paralysis, nor the condition of the reflexes reminds one of hematomyelia. It presents, however, an objective sensory disturbance, which we find habitually in hem-

Pain (analgesic.)
Temperature (hypesthesia.)

Touch (delay.)

atomyelia, namely, the typical syringomyelic sensory dissociation (Fig.). On the other hand, the rapid onset of the monoplegia, the flaccid character of the paralysis, the loss of reflexes, the muscular atrophy with reaction of degeneration, and finally, the absence of pain—are all symptoms of acute poliomyelitis, although the usual history of an infectious onset (fever, vomiting, etc.) with an involvement at first of several extremities and confining itself later to one extremity is wanting.

Summing up all the points concerning the case, we may say that they admit the possibility of a spinal and peripheral lesion, and as we have symptoms in favor of and against each of these affections, the diagnosis is difficult. Nevertheless there are three symptoms which are almost decisive in favor of poliomyelitis, namely, the total flaccidity of the palsied limb, the loss of reflexes, and the absence of pain. If it is a poliomyelitis, its coincidence with a syringomyelic sensory dissociation of radicular type and with a facial palsy makes the case quite unusual. The latter is a possible occurrence in the

course of polyneuritis. That an infectious or a toxic element is apt to affect the peripheral nerves of the extremities, also those of the face, is a condition easily conceived and of a not infrequent occurrence. On the other hand, a nuclear involvement of the facial nerve with a cell involvement of the cord considered as one affection and caused by the same agent, is also a well-known pathologic condition. Taking into consideration the fact, that the facial palsy made its appearance only a few days after the onset of the flaccid paralysis of the arm, it is to suppose that we have here a degenerative process ascending in character and confined only to cellular elements of the cord and medulla. It is therefore a systemic affection, and because of its localization, it is a polioencephalomyelitis.

In discussing the differential diagnosis of the monoplegia in this case, I mention the possibility of a simultaneous involvement of the motor neuron *in toto* (cells and motor fibers). Owing to the peripheral character of the facial palsy we may, with equal right, admit now a possibility of an analogous involvement of the nucleus of the facial nerve with the motor fibers emanating from this nucleus. It is rational, therefore, to suppose that the same etiologic factor produced identical effects in the spinal cord and medulla; it is a bulbospinal affection.

Cases of anterior poliomyelitis complicated with facial paralysis have been reported, but they are not very frequent. In some of them the onset and course were those of typical poliomyelitis, in others the diagnosis could have been made as polyneuritis, still other cases show that there are intermediary forms. At all events infection or intoxications, which are considered as usual causes of poliomyelitis, may affect at various times various portions or systems of the entire cerebrospinal axis or various segments of the same neuron; their effect may be slight or grave, rapid, sudden or slow, transient or permanent. In the present state of our knowledge, the question as to the localization of the diseased process and to the effect of the latter on the nervous tissue, is elucidated almost in its entirety, but the question as to how the infection reaches the seat of the lesion is as yet surrounded with a mystery.

A point of interest in my case lies in the presence of syringomyelic sensory disturbances and in the radicular type of the latter. Syringomyelic sensory phenomena were observed in other pathologic conditions of the cord beside true gliosis, namely, in hematomyelia, compression of the cord, myelomalacia associated with syphilitic arteritis, Brown-Séquard's paralysis, tabes, also in leprosy, Morvan's disease, certain peripheral neuritis, finally in hysteria. In acute poliomyelitis, at least to my knowledge, the condition has not been described. The area occupied by the syringomyelic sensory dissociation in my case speaks in favor of its radicular distribution. The researches concerning the sensory distribution of spinal nerves, conducted by various authors do not all coincide in their results, and we can say that the extent of bands of skin supplied by each of the roots cannot be exactly determined, as the boundaries are usually ill-defined. According to the most recent investigations, the disturbed sensory area in my case will correspond to the fifth and seventh cervical roots.

As a last interesting feature I wish to call special attention to the curious condition of the pupils. Under the name "paradoxical pupil" we understand a condition which is characterized by a reversal of the normal pupillary reflexes: Dilation instead of contraction and vice versa. My patient presents beside the typical paradoxical pupils, also a typical hippus. Such an association of pupillary phenomena was observed by Raggi as far back as 1885 in a case of paresis. A paradoxical response of the pupils to light has been observed in various diseases. In 1887 Kahler³ described it in a case of basilar meningitis, Marina⁴, Mouney⁵ and Muchin⁶ in tabes, Obersteiner⁷ in diffuse syphilitic meningitis, Frenkel⁸ in syphilis with pseudotabes, Lépine⁹ in hysteria, A.

Leitz¹⁰ in tuberculous meningitis, Hirschl¹¹ in paresis, Silex¹² in a case of injury to the occiput with loss of consciousness. J. Piltz¹³ made an exhaustive and critical study of the subject. A careful analysis of all the varieties of paradoxical pupils described, leads to the following conclusions: The paradoxical reactions of pupils may show themselves in the act of accommodation as well as in light reflex. In both cases instead of a dilation of the pupils, a contraction is obtained and vice versa. Up to the present time three varieties of the paradoxical light reflex have been described: Morselli, Leitz and Silex observed a dilation of pupils under the influence of light without a preliminary contraction; V. Bechterew described a similar case with this difference that the dilation was preceded immediately by a momentary contraction; finally Piltz observed a variety of paradoxical pupil manifesting itself in a contraction of the pupils in the dark without a preliminary dilation. In addition to these three varieties I may add a fourth, as shown in my case: When a light was thrown into the pupils of my patient, on the first instant there was no reaction at all, but one second or a half second later the dilation took place and only then the display of the hippus followed. Paradoxical pupils is a rare condition, as its literature is very meager, and because of this rarity the pathogenesis is not at all elucidated. The occurrence of it in anterior poliomyelitis has never been observed before, at least to my knowledge.

NEURITIS AS A COMPLICATION OF SOME PORTION OF THE CHILD-BEARING PROCESS.

BY

WILLIAM R. NICHOLSON, PH.D., M.D.,
of Philadelphia.Obstetrician to the Maternity Hospital of Philadelphia. Assistant
Obstetrician to the Philadelphia Hospital.

The following cases are of interest as examples of a rather rare complication of the puerperal period.

CASE I.—Mrs. J. was seen by me six weeks after the birth of her last child. She could give no reliable history further than that she had noticed nothing abnormal during her pregnancy until a short time before labor when she had an attack of "typhoid fever." From the details furnished by the family I do not consider this illness to have been typhoid fever, as the duration of the attack was too short, and as I was further unable to obtain any symptoms at all suggestive of that condition. However, the fact remains that she had been quite sick for two weeks before labor began. Labor was easy and rapid and no instruments were used; she complained of no unusual severity of the pains and noticed nothing abnormal until several days had passed when she found that she could not move her legs. On the tenth day her attending physician told her to get up and repeated this injunction at intervals until the case was taken out of his hands. He told her husband that she was simply lazy.

Her condition when first seen by me was as follows: She was unable to stand without support and could not take a step even when supported. There was an apparent incontinence of feces and from the history I judged that there had also been a previous urinary incontinence. The physical examination was negative as regards the heart, lungs, and kidneys and a pelvic examination showed nothing abnormal save a relaxed pelvic floor, a moderately lacerated cervix and a subinvolved but freely movable and anterior uterus. There was no sign of exudate in the pelvis. Her temperature was normal. As an additional sign that her labor had been easy it may be noted that the lacerations referred to were old, being due to her first and only previous delivery some 18 years ago. The pelvic measurements were approximately normal.

Dr. Hirst kindly gave me permission to admit the patient to his wards at the University Hospital. We both felt after

examination that it was a case of true myelitis, but later study disproved this. A more careful consideration of the case decided us that there had been no true incontinence of feces or urine at any time.

Dr. C. W. Burr kindly examined the patient with me in the ward of the hospital and his examination is in brief as follows:

Flexion and extension of the toes of both feet very imperfect. Dorsal flexion of the ankle impossible, *i. e.*, decided foot-drop present. Knee-jerks, absent. Irritation of either sole causes a slight movement of the leg, but none of the toes. Achilles-jerk absent. Flabbiness of the muscles of the calf and the thigh, but no atrophy present. Nerves of calves very sensitive to pressure, as are also the nerves back of the knees. Sciatic nerves not sensitive to pressure. Tactile anesthesia present in both legs below the knees and in a lesser degree above them. A pin prick is felt as pain. The patient at this time stated that she remembered suffering a considerable amount of pain in her limbs in the latter part of pregnancy and soon after the birth of her child. She could bend her knees when her foot was supported on the bed. She could also lift either leg off the bed.

Dr. C. B. Potts kindly examined the patient to determine the condition present in the palsied muscles with regard to their electric excitability, with the following result:

Left leg: The calf muscles (gastrocnemius and solens) respond to very strong faradic currents, as does also the adductor magnus; none of the other muscles responds at all. The anodal contraction is stronger than the cathodal in the tibialis anticus and peroneal muscles, while in the calf muscles the cathodal is greater than the anodal closure, about eight milliamperes being required to cause contraction, and even then the response is very slow.

The thigh muscles gave no contraction to any current that the patient would stand (8 milliamperes used).

Right leg: Marked fibrillary contraction in the muscles of the right thigh when irritated or struck; all muscles respond to very strong faradic currents except those of the posterior part of the thigh; at times there is quite marked twitching of the muscles when patient is at rest. The peroneal and calf muscles, the tibialis anticus and extensors of the toes give a greater cathodal than anodal contraction. The anodal closure is greater relatively than normal, contractions are slow; the muscles of the anterior part of the thigh give a greater cathodal than anodal closure; the contraction is not as slow as below the knee but slower than normal; muscles of the posterior part of the thigh do not contract to any current which the patient can stand.

The patient remained in the hospital for several weeks and left without any marked improvement. Unfortunately she has since that time been lost sight of, but we are safe in believing that improvement to say the best will be slow.

CASE II.—The patient was seen some two months after her delivery. She came to the Gynecean Hospital because of a complete tear which had not been repaired. Labor had been difficult and forceps had been used, she had had decided pain in her right leg after delivery and was unable to walk for some time afterward because of pain and weakness of the limb. When I saw her first she still had a slight limp and some weakness of the muscles; there was nothing in the pelvis which could explain her condition and I believe that prolonged pressure by the fetal head on the lumbosacral plexus was the cause of the loss of power.

I operated to repair the lacerations and when the patient left the hospital her loss of power was greatly improved; this was undoubtedly due to the rest in bed subsequent to the operation.

For a long period of time it has been known that women during pregnancy and the puerperium are more or less often the subjects of various paralyses, and a considerable literature has developed on this subject which, however, has received but scant mention in the greater number of textbooks, the authors evidently believing that the subject could be better handled by neurologic writers. Many years ago Churchill published a paper in which were collected a considerable number of cases of nerve lesions associated with some period of the child-bearing process. As the majority of these appear to have been cases of uremia, and as no definite facts as to presentation or pelvic measurements are included, their value is nil, except for the fact that the author states his disbelief in the influence of difficult labors or forceps extraction as causative factors, and rather in advance of his time attributes them to autoinfection.

On the other hand, Basedow, in 1838, asserted his belief in the efficacy of head pressure upon the pelvic nerves, as a cause, in certain cases which he had seen. His paper leaves but little to be desired so far as his description of his cases is concerned. Coming to our own period we find that observers are not agreed as to the cause of the condition, and this can be explained

by the fact that various types of cases have been seen by different men. Thus one will attempt to explain all cases on the ground of autoinfection when perchance he has only seen cases of general or diffuse neuritis, while another's experience will have been limited to local lesions in the arm or the leg, and he will claim for pregnancy some such influence as is shown by lead or the toxins of diphtheria in the production of local paralyses. Still another with a large experience in the use of forceps in difficult cases of labor will attribute the laming of the limbs to nerve-pressure. While all these reports are founded on good and sufficient grounds, as a careful study of the reported cases will show, no one of them alone will explain, as has been attempted, all or nearly all of the cases encountered.

In considering the etiology we find that the classification which various authors have made use of is of considerable interest; thus Ross and Bury divide all cases into two general classes: (1) Those due to injury or disease of the pelvic nerves either as a result of trauma or inflammation; (2) those due to multiple neuritis. Tuillant divides all cases into two classes: (1) Those general in type due to an autoinfection; (2) those showing local lesions which he supposed to be due to a poison from without.

It is of interest to note that in the cases of general involvement reported by this author there was a very frequent association of marked vomiting in pregnancy together with muscle weakness, and he considered that both were the results of the same cause.

Möbius confines his paper to arm injuries alone but mentions that all the cases that he has encountered in which the legs were involved were due to inflammatory pelvic changes.

He also expressed the belief that the enlarged uterus or the forceps might cause direct injury to the ischiadic nerve.

Hünemann assembles all cases under one of the following heads: (1) The influence of pregnancy upon an unstable nervous organization; (2) pelvic exudates; (3) severe puerperal infections which may play the same part in the production of paralysis as do scarlet fever and diphtheria; (4) those cases due to the pressure of the fetal head or the traumatism of the forceps. Regarding his fourth division he says that the head of the child is much more often operative than are the forceps, particularly if the presenting part be well flexed and attempting to enter a pelvis contracted in all its diameters. He also emphasizes that the duration of the labor, the degree of disproportion and the strength of the pains are factors determining the gravity of the nerve injury.

Mills who approaches the subject from the standpoint of the neurologist classifies under the heads: 1. Traumatic paralysis of the peroneal type usually associated with severe neuritis. 2. Sacral neuritis aggravated by disease or displacement of the pelvic organs or tissues. 3. Septic or other infections which may cause either local or multiple forms. 4. A special class, peculiar to this author, due to phlebitis of the pelvic veins and therefore to be classed as septic. 5. Myelitis due to some infection.

Windscheit, quoted by Thomas arranges these cases under the following heads: 1. Neuritis gravidarum (etiology not known, probably toxic). 2. Infections. (General pyemia may cause neuritis of all nerves of the body.) 3. Mechanical injury. 4. Puerperal (localized or general).

Eulenberg considers but two groups, basing the distinction between them simply on the extent and severity of the lesions presented, and so divides them into first, the less severe and localized forms, while in his second class he groups the severe diffuse forms, which may simulate at times Landry's paralysis, or may even be found involving the cerebral nerve areas. It may here be mentioned, that Sottas, Lutz, and Eulenberg

have all reported cases simulating the paralysis of Landry. My preference in so far as the etiologic classification is concerned, would be as follows: 1. Those cases supposedly due to some toxemia. 2. Those cases arising from a septic process. 3. Those cases resulting from some mechanical agent operative during labor or in the early puerperium.

These three classes include all cases which can in any way depend on pregnancy as the causative factor. It should be remembered that myelitis or other disease of the nervous system may show the first signs during pregnancy, and that in such cases the influence of pregnancy is not to be considered as causative except as any other marked strain. With regard to the first division, namely, the toxic group, we know but little. Quite a number of cases have been reported which it is difficult to explain under any other supposition. Of course, these are most usual in pregnancy, though rarely they are also encountered in the puerperium. As regards their true causation we know practically nothing; they may either be general or limited to special nerves. I consider that my first case falls under this division as to causation, but I cannot be sure whether it was really a case of puerperal neuritis or whether its inception occurred during the latter part of the pregnancy. Until we become more familiar with the true nature of autointoxication we will, I think, be unable to explain these cases. The second division (the septic) is decidedly easier to explain. It is perfectly justifiable in the light of our knowledge of septic processes to consider that either by continuity or contiguity there may be involvement of the trunks of the pelvic nerves, as in the case of exudate, or abscess, or that by transference through the blood or lymph channels any group of nerves may be involved. Furthermore, we know that the gravity of these cases depends upon the individual susceptibility and the virulence of the poison, these factors either determining a simple transitory neuritis, an ascending myelitis, or any of the lesions intermediate between them.

Of course, from the nature of things, sepsis is more often operative during the puerperium than in pregnancy, and so we are less liable to meet these cases during pregnancy. We now come to the consideration of the last division, according to the above classification; this is probably by far the most frequent variety.

The second case reported is a mild form of this type; a considerable number of authors have considered that instrumental interference is the most prolific cause of this group, but investigation shows that such is not the case, but rather that the delay in the advancement of the presenting part, which occasions the employment of instruments is of itself the reason for the palsy. In order to understand the true etiology of this class, the mechanical, we have only to turn to the anatomy of the sacral plexus. The nerve-supply to the lower leg is derived from the terminal branches of the great sciatic nerve, and the latter is derived from the lumbosacral plexus and the first, second, and third sacral nerves. The external popliteal or peroneal nerve takes its origin from a certain special group of filaments which are derived chiefly from the dorsal portion of the lumbosacral plexus, while the filaments which form the internal popliteal arise from the ventral portion of the same nerve. From the arrangement of the nerve fibers with reference to the bones and muscles of the pelvis, it will be seen, on reference to fresh dissection, that the lumbosacral plexus is the only portion of the plexus which is exposed to direct violence between any passing body, the remainder of the plexus being guarded by muscular fenders. While the lumbosacral plexus traverses the pelvic brim near the base of the promontory, *i. e.*, in the sacroiliac notch, it may nevertheless be easily exposed to pressure under certain conditions. Finally, the filaments to the peroneal nerve take their origin from the dorsal segment of the cord, and they are therefore in a position which will subject them to increased chances

of pressure, lying, as they do, directly on the bony ridge known as the iliopectineal line.

These anatomic facts will explain the most usual form of neuritis associated with pregnancy, namely, that involving the peroneal nerve on one side and resulting in a motor and to a less degree sensory paresis of the muscles of the anterior portion of the lower leg and dorsum of the foot. Now as to the factor which occasions the pressure in the majority of instances: A glance at any pelvis will show that the forceps cannot be held as the responsible agent, since the situation of the lumbosacral plexus cannot be injured by their blades in any proper application; we question, indeed, whether injury could occur to this nerve by any, even an improper, instrumental operation, as its position guards it so well from assault in any direction except one, namely, by a force operating directly upon its anterior surface. Moreover, symptoms of nerve injury occur after labors that are easy and rapid, and in which no forceps have been used. This is difficult to explain, but it certainly shuts out the necessity of instrumental causation; on the other hand, it is unquestioned that such injuries are more likely to occur in labors that are difficult, especially if such difficulty be due to a small pelvis, of the generally equally contracted variety. The simple flat and the rachitic flat pelvis do not show the same tendency to produce this condition, since in these types of deformity the projecting promontory serves as a protection to the lumbosacral plexus. In addition, it should be remembered that it is not the extreme grades of contraction which give rise to this lesion, since for the head to impinge upon the lumbosacral plexus it is necessary for it to be able at least partially to engage. Those generally contracted pelvises with a true conjugate of from 8.5 cm. to 10 cm. are the forms of deformity which give rise to the greater number of cases of palsy of one or both limbs. It is possible that in severe cases there may be an ascending inflammation which will be transferred through the cauda equina or the cord itself to the nerves of the opposite leg, and there give rise to a more or less complete paraplegia. It is even claimed by some that there may be a true degeneration of the cord secondarily to peripheral neuritis. This then is the principal cause which explains a neuritis in the puerperium with consequent palsy of one leg, namely, a combination of a medium grade of contracted pelvis, usually of the generally contracted variety, together with a presenting part which either with difficulty passes or is unable to be delivered without instrumental aid. As an additional factor may be mentioned the strength of the expulsive pains, since the greater the *vis a tergo* the more pressure will be developed by the presenting part upon the nerves. It may be mentioned that the after-coming head has been known to produce the same injury as has just been ascribed to head-first presentations.

Aside from the influence of direct fetal pressure upon the nerves there are other causes which have been considered operative in certain cases; these are a decidedly enlarged uterus (this we doubt), a perimetritis, a previous severe laceration of the supravaginal tissues, with resulting scar formation, any pelvic inflammatory collection, and, finally, a phlebitis of the pelvic veins.

An instance of the latter causation occurred two years ago in my service at the Maternity Hospital. The patient was delivered with forceps, and symptoms which occurred afterward led us for some days to believe that the woman was suffering from an incidental typhoid fever. Her temperature range was typical, there was a slight splenic enlargement and a little abdominal distention; in addition, a very few atypical spots were found. The repeated use of the "Widal" test, however, failed at any time to substantiate this diagnosis, and in a few days the true etiology was disclosed by the development of phlegmasia alba dolens. After a tedious period of convalescence the patient recovered, with,

however, a decidedly noticeable dragging of the left leg in walking. The patient was seen once, three months after delivery, and was heard from one year later, and the dragging spoken of was still present.

I do not desire to consider the treatment of these cases of neuritis as such, as this is within the special province of the neurologist, but I feel that a study of the prophylaxis of the condition points out some very important facts which practical obstetricians may well take cognizance of. I refer to the treatment in cases of delayed labor, whether due to contraction of the pelvis or not, for it will be remembered that while cases of neuritis may occur from toxic causes which we cannot govern and after easy labors, by far the greatest number are the result of delayed labor from some of its many causes. The necessity is therefore enforced that pelvic examinations be made before labor in order to determine whether or not there be any factor, such as contraction, which will tend to produce delay and that when labor has once begun that an accurate diagnosis of position be made and forceps applied when indicated. The use of chloroform to diminish spasm of the pelvic muscles and thus decrease their bulk would seem to be also an important agent. As regards the application of forceps, it is well to remember that while their use is advised in proper cases it is presupposed that they are intelligently applied and used, for while we do not feel that the lumbosacral plexus is at all likely to be injured by even a faulty use this does not hold good as regards the lower sacral nerves. It is hardly needful to emphasize the importance of asepsis as the production of a neuritis from pelvic foci of infection is but one of the many evils resulting from its neglect.

As regards the prognosis, it may be said that in all probability in a considerable number of mild cases of peripheral neuritis the patients recover without any diagnosis of the condition having been made, as the period usually spent in bed after delivery would be amply sufficient for this in such cases. In the more severe forms, the prognosis is doubtful or good, according to whether the reactions of degeneration are present or not. In any event, considerable time frequently elapses, even under careful treatment, before a cure results.

The symptomatology of these cases varies, of course, according to the severity of the lesion, and careful inquiry will sometimes be rewarded by the history of the inception of the trouble having occurred in pregnancy. This may be true of the forms of pressure neuritis, as well as of the toxic and septic. In the former the mere friction of the presenting part in the latter part of pregnancy upon the nerves at the pelvic brim is at times sufficient to produce at least their transient irritation. The time of onset may then be in the latter part of pregnancy, during labor, or at any time subsequent for a period of several weeks; the cases due to intrapelvic fetal pressure occur promptly after labor as a rule, and also generally show a considerable amount of pain during the labor, while those due to sepsis occur later according to the special development of the case. As regards the actual symptoms, it will be found that they vary from a transient pain often ascribed to rheumatism, etc., and without any localizing nerve signs to a symptom-complex resembling "Landry's paralysis" or myelitis. The usual type of case is one intermediate between these extremes, presenting some pain, loss of power, perhaps some sensory disturbances as paresthesia and atrophic changes. The nerves involved are in less severe cases the median or ulnar, or if the leg be affected, the sciatic, the gluteal, and especially the external popliteal, the peculiar symptom of the latter being the presence of the so-called foot-drop. In the grave cases threatening life there is a general involvement of all the nerves of the body. The symptomatology of the secondary involvement of the cord and brain, which rarely occurs, does not need to be considered here.

CLINICAL REPORT OF A CASE OF LITHOGENOUS ICTERUS.

BY

BYRON ROBINSON, B.S., M.D.,

of Chicago.

A diagnosis of hepatic calculus rests chiefly on the historic clinical symptoms. The operative procedure may be of the most simple nature or so difficult as to test the best skill of one who has devoted a lifetime to abdominal surgery. The prognosis is favorable in the majority of cases, yet the experienced are well aware that with lithogenous icterus a mortality as high as 30% may occur. The following case, referred to me by Dr. Wm. Reese, of Dodgeville, Wis., presents many facts of interest:

The patient, a woman of 44, had been afflicted with attacks of hepatic colic for more than 10 years. She had seven living children. In the first years icterus and the attacks were both light; the attacks occurred at intervals of two to five months. During the later years the hepatic colic seizures were more frequent and severe, as well as the icterus. For the past two months the attacks have been quite frequent and the icterus intense and continuous. For seven weeks she has been very ill in bed with a very irregular temperature, 99° to 105°; respirations, 20 to 24; pulse, 95 to 120. The peculiarity about the clinical course was that one or more times during the 24 hours the temperature would suddenly rise from 100° to 105° and rapidly sink to 100° again. Vomiting had been severe and some of the vomitus was bile, according to the report by Dr. Reese and the family. The pain for 10 years was occasionally strong, but for the past eight weeks it has been severe most of the time. The pain radiated toward the right scapula. Constipation with clay-colored stools existed. Appetite was defective. The patient was so ill for six weeks that she did not wish to be turned in bed.

Condition presented four days previous to the operation: The patient was fairly well nourished. The face showed rather grave suffering. There was marked icterus of the scleras and general body, which had been continuous for seven weeks. Examination of the abdomen was negative, except in the right proximal quadrant a distinct local resistance could be felt. Liver was not enlarged. The distal border could not be palpated. There was pain on pressure in the region of the cholecyst. Abdomen was flat, soft, no ascites. Bimanual vaginal examination was negative, except for a slight pelvic peritoneal exudate from the left side. Urine showed albumin, pus, hyaline and granular casts; daily quantity 40 ounces. Bowel evacuations were clay-colored. Temperature 102°, pulse 95, respirations 24. Blood: Hemoglobin 80%. The diagnosis indicated calculus in the common bile duct. The pain accompanied with icterus favored this view. The long course of the disease (10 years) was against carcinoma, as well as the fairly good color and panniculus adiposus. The right-sided pain and tenderness on pressure, and the constipation, indicated adhesions of the duodenum, colon and omentum, due to infectious invasion through the tunica mucosa and tunica muscularis into the peritoneum. I was doubtful as to whether any bile had passed. She was prepared for operation by the careful drainage of every visceral tract for five days.

Operation.—An incision was made from the costal arch along the external border of the rectus abdominis for 5 in. Muscle was slack and friable. After peritonectomy the liver came in view. It was dark, elastic, and atrophic. By reflecting its sharp edge proximally, a solid mass of adhesions could be observed, consisting of the omentum, duodenum, and the transverse colon. The contracting adhesions had drawn the left half of the stomach in contact with the liver. No cleavage was possible. Separation of the viscera was performed by the knife or tearing. After careful separation and incision of adhesions, I finally came to a solid rod-like cord, 1½ in. in diameter, extending from liver to pancreas, consisting of hepatic artery, portal vein, cholecyst, and bile ducts. In the midst of this solid mass a still more solid mass existed, 2 in. by 1 in. in dimension. This was the calculus in the bile

duct. No trace of the cholecyst could be found; it was obliterated. With the aid of a finger and a blunt instrument the solid mass was exposed, but the portal vein, hepatic artery, or choledochus could not be recognized. Anatomy teaches that the bile ducts are located on the right, the portal vein lies in the middle, and the hepatic artery is located to the left, but anatomy had ceased to exist in this case; it was replaced by pathologic anatomy. The membrane covering the calculus was incised for an inch, and the calculus extracted from its securely

the subject of hepatic calculus is early diagnosis from symptoms and early removal of the calculus. Surgery does not indicate removal of hepatic calculus before symptoms arise, for in 600 postmortem abdominal inspections, I found hepatic calculus present some 70 times but no symptoms having arisen, neither patient nor physician was aware of the calculus, the pa-

Fig. 1.—A röntgen ray of the ductus pancreaticus (I to V), ductus choledochus (I to II), ductus cysticus (II to III), and ductus hepaticus (I to III). Ductus pancreaticus was injected with cellulidin and red mercury sulfate. The biliary channels were injected with red lead and starch, after which the specimen was röntgen rayed and sketched as a model. Dorsal view.

imbedded channel. It measured 2 in. long by $\frac{3}{4}$ in. in diameter, and was uniformly rod-shaped. A considerable quantity of dark, bloody bile followed. The calculus extended in the choledochus, well through the head of the pancreas and dorsal to the duodenum. The choledochus was amply large in diameter for exploration of the finger. The choledochus was drained by thin strips of gauze introduced into its dilated lumen. Also large strips of gauze were introduced on each side of the ductus choledochus to meet in Winslow's foramen. The abdominal wound was closed by silk-wormgut sutures. The operation lasted 50 minutes. Pulse was strong, 130, face somewhat pale. The patient continued in good condition until some 12 hours subsequent to the operation when she was seized with great pain; the pulse rapidly increased in frequency until it could not be counted, and soon after could not be felt in the wrist. The temperature rapidly rose to 105°; respirations, 30; she died some 15 hours after the operation. No autopsy was held, however; I think she died from the distribution of septic emboli. That septic foci existed was proved by the frequent rise and fall of temperature for 7 weeks and the continuous rapid pulse. The operation, though severe, was not of such traumatism as to invite any form of collapse. She was not shocked, as she conversed with me in comfortable condition, pulse 100, two hours after the operation.

Courvoisier's law that in 80% of the cases of obstruction in the common bile duct due to calculus there is contraction of the cholecyst, while in 90% of cases of distention of the cholecyst the obstruction is due to causes other than calculus, was confirmed in this case. No trace of the cholecyst could be recognized. It is doubtful whether any considerable quantity of bile could pass the choledochus obstructed by a calculus 2 in. by $\frac{3}{4}$ in. and the atrophy of the liver added further proof. I am aware that experience teaches that in acute cases with icterus and calculus in the choledochus, operation should not be performed, but our patient was in the best condition of a 7 weeks' attack. Beside I believe that in all benignant cases the patient should have the right of complete operation when possible though it may border on the line of danger, trauma and shock. With the anatomy of the bile and pancreatic ducts before us demonstrating their direct continuity and consequently that the bile and the pancreatic fluid must mix it is evident that the infection of the liver is carried into the pancreas by it direct and vice versa. Continuous hepatic infection sooner or later ends in pancreatic infection. However, I found no fat necrosis present. The greatest advantage to

tients dying from intercurrent diseases. The accidents accompanying operations, chiefly from emboli, furnish the surgeon's life with ample agony. However, useful surgery is built on its faults. Without operation my patient would have died a lingering, septic and painful death. After a painstaking diagnosis and thorough preparation of the patient with conscientious execution of the operation we had hoped vainly for success.

POSTERIOR GASTROENTEROSTOMY, WITH ENTERO-ENTEROSTOMY: A STUDY OF CONDITIONS FOUND AT AUTOPSY.

BY

W. L. WALLACE, M.D.,
of Syracuse, N. Y.

In *American Medicine*, February 20, 1904, p. 312, I described the steps of an operation used in a case of pyloric stenosis.

The relations of parts at the close of this operation are indicated in Fig. 1. The jejunum, about eight or ten inches from the duodenojejunal angle, had been passed through the transverse mesocolon and united by silk stitches with the posterior wall of the stomach and the two arms of the jejunum had been joined together by a Murphy button about three and one-half inches from their communication with the stomach.

The operation was performed December 10, 1903. The man made a good recovery, the Murphy button appearing on the twelfth day. Three days later he left the hospital. From this time he had no gastric distress or vomiting, and was able to eat and digest large quantities of food. In the middle of January, after morning and afternoon temperature had been normal for weeks, he had an attack of pneumonia, involving the base of his left lung—a typical case—with chill and prune-juice expectoration. In the early part of February, he was greatly weakened by pulmonary hemorrhages, and he died February 17, ten weeks after his operation, from anemia following a hemorrhage.

An autopsy was performed February 18 by Dr. H. S. Steensland, director of the pathologic laboratory of Syracuse University Medical College. The left lung contained a cavity at the base posteriorly; otherwise the lungs were large and sound. Heart, liver, spleen, pancreas, and kidneys were normal. The stomach contained a tumor, which involved the pyloric portion; a hard, white mass, one inch in thickness, surrounding and closing, to the size of a probe, the pyloric orifice. No softening

or ulceration and no enlarged glands or metastatic growths could be discovered.

A study of the specimen removed at autopsy shows interesting anatomic conditions following the operation. These are illustrated by Fig. 2.

The opening from the stomach into the intestine, while large and ample, stood closed, as if by muscular action, the stomach containing at this time about 1½ pints of liquid food in good condition. The fine silk ligatures were still in place, the anastomosis was smooth and perfect, and no inflammation was apparent around the stitches. The proximal and distal arms of the intestine had fallen together and become adherent, forming a double-barreled tube (3' 4'). The food which originally passed 1, 2, 3, 3', 4' to 4, now passed from the stomach by 3' and 4' to 4. The partition between the proximal and distal arms of the intestine had been cut by the Murphy button at 5, short-circuiting 3 and 4, and allowing the bile to pass directly on into the intestine, thus avoiding the danger of its passing up into the stomach and being vomited.

Two fingers easily passed through the opening from the stomach into the intestine, then both could be passed through either arm 3' 4' to the point 5 where the Murphy button had been used, or one finger could be passed through the proximal arm 3' and the other through the distal 4', meeting at 5.

I could find no difference in the caliber of the two tubes 3' 4' leading from the stomach; the bowel 3 from the duodenojejunal angle to the enteroenterostomy 5 was somewhat smaller in diameter than the arm 4 continuing into the ileum, which seemed somewhat enlarged.

The passage 3, 5, 4 was distended with gas like the rest of the intestines, but the tubes 3', 4' were collapsed, so that although when straightened they were about 3½ inches long by 2 inches in diameter, at the time of the autopsy they were wrinkled together, closed and very short.

The direction of the tubes 3' 4' from the stomach was down and somewhat to the right in the direction of the flow of the food and bile, and this inclination, with the collapsed condition of the tubes would seem to exclude any possibility of regurgitation of bile from the intestine into the stomach. I have seen it proposed to obliterate the proximal arm 3' in order to be sure that the bile could not pass out into the stomach, but the findings in this case would seem to prove that there was no such liability when an enteroenterostomy was used, and, moreover, if the danger did exist, it would be equally great in both arms of the intestine.

The opening made by the Murphy button was so satisfactory that the bowel 3 passed to 4 by way of 5 as if this passage had always existed, no scar or indentation being visible on the outside or diaphragm on the inside. However, the anastomosis made with the silk was very much stronger than that made with the Murphy button. Both had stood the test of 10 weeks, and undoubtedly would have been permanently successful, but as the button was recovered on the twelfth day, it probably gave no support after the eighth or tenth day, and yet the repair even at the end of 10 weeks could be pulled apart by very slight traction. On the other hand, the anastomosis made with the silk was still supported by the stitches and by an exudate around the stitches, and must have been very secure from the beginning, and 10 weeks after the operation seemed as strong as any other part of the alimentary canal. The double tube of bowel 3' 4' passed from the lower portion of the posterior wall at about the middle of the inferior border of the stomach, through the transverse mesocolon. The mesocolon was adherent to this tube all around, but did not constrict its caliber. The transverse colon ran across in front of the anastomosis, in its usual position.

The pathologic report of Dr. Steensland, shows that the tumor at the pylorus was a simple stenosis, a hypertrophy of the submucosa and muscular coats. Before the operation the nature of this tumor was doubtful; while it was apparently a cancer, several conditions were against this diagnosis; the patient did not have cachexia, and the family history was good, the examination of the stomach contents showed free HCl present and lactic acid absent; and the blood contained 4,700,000 reds, 8,000 whites, and 70% hemoglobin. In favor of cancer we had this large tumor closing the pyloric opening, which had developed within a few months, in a man of 40, with no history of ulcer, with vomiting three to four hours after every feeding, and with loss of 50 pounds in weight. At the time of the operation, it looked and felt like cancer, and was so large and fixed that its removal was out of the question. At the autopsy, it had all the macroscopic appearance of cancer. While the pathologic report ought not to have occasioned much surprise, it teaches that unless a case is undoubtedly cancer, an operation offers hope. The tumor was smaller at the time of the autopsy than at the operation, and as it was only a hypertrophy it would probably have continued to diminish in size.

In making a gastrointestinal anastomosis a point on the intestine should be used at a great enough distance from the duodenojejunal angle so that 5 can sag toward 4 in the direction of the flow. If 3 were short, 5 would be dragged to the left of the stomach opening, and the flow of food from the stomach would meet the flow

of the bile, and the bile coming through 3 might be inclined to pass through 3' 4' into the stomach. Bearing this point in mind, it might be well not to fasten the jejunum to a point in the stomach exactly opposite the opening in the transverse mesocolon, but to select a point on the stomach wall well to the left of the opening in the transverse mesocolon.

When a Murphy button is used, it would seem safe to reinforce with a few stitches, and when the gastroenterostomy is also made with a Murphy button a large enough size should be used at 5 to allow the upper button to pass without straining the repair, if the button should happen to come down the proximal arm 3'; or the suggestion should be followed of ligating the proximal arm.

The safe and rapid operation would seem to be a posterior gastroenterostomy with silk, after some such method as was described in my previous article, together with a Hartley enteroenterostomy, reinforcing the Murphy button repair by a few silk stitches.

The autopsy report, by Dr. H. S. Steensland, is as follows:

Autopsy number, S.U., 04.12. J. C., aged 41. White. Autopsy 12 hours postmortem in a private house. Body embalmed. Body of a slender, rather poorly-nourished man. In umbilical region, immediately to the right of the umbilicus, is the scar of an operative incision 11 cm. long.

Peritoneal Cavity.—Omentum is adherent to the scar of the incision. Gallbladder and various regions of peritoneum are

Fig. 1.

Fig. 2.

1, tumor at pylorus; 2, opening of common bile duct; 3, 3', proximal arm of jejunum; 4, 4', distal end of jejunum; 5, opening between 3 and 4, made by Murphy button; 6, transverse duodenum behind stomach.

markedly emphysematous. Stomach is united to the liver by a few fibrous adhesions.

Pleural cavities are almost entirely obliterated by fibrous adhesions.

Lungs.—At base of left lung is a large cavity about 9 cm. in diameter, with brownish necrotic walls. (This cavity was regarded as tuberculous, but the subsequent examination of a smear from the wall of the cavity made at the time of the autopsy showed no tubercle bacilli.) Bronchial lymph-nodes large and necrotic.

Stomach.—Wall at pyloric orifice from 1.8 cm. to 2 cm. thick. Mucosa and submucosa from 1 cm. to 1.5 cm. thick. Muscularis from 0.4 cm. to 0.6 cm. thick. Serosa from 0.1 cm. to 0.3 cm. Mucosa emphysematous, but no evident ulceration. Pyloric orifice patent.

Microscopic Examination.—Frozen sections of wall of pylorus stained with Löffler's methylene-blue show numerous mast cells and numerous bacilli of the morphology of *Bacilli aerogenes capsulatus*. Sections through three different parts of the pylorus are examined. The mucosa has undergone marked postmortem change. The submucosa, greatly thickened, consisting of a dense only very slightly cellular and vascular connective tissue. The cells are largely spindle-shaped, and there are a few lymphoid cells. The muscle fibers of the muscularis are divided into large groups by wide bands of stroma. The muscle fibers seem large. The serosa consists of a fairly dense connective tissue. No evidence of necrosis is seen.

ANATOMIC DIAGNOSIS.

Scar of surgical incision. Adhesion of omentum to scar. Hypertrophic stenosis of pylorus; gastroenterostomy; enteroenterostomy; emphysema of gallbladder and various regions of peritoneum; chronic adhesive pleuritis; tuberculosis with cavity formation in the left lung (?); tuberculosis of bronchial lymph-nodes (?).

OBSERVATIONS ON THE DUTY OF THE PHYSICIAN TO HIS PATIENT THROUGH THE SURGEON.¹

BY

HENRY SEWALL, PH.D., M.D.,

of Denver, Colo.

One of the distinctive intellectual marks of the present age is the close relation which exists between the medical profession and the community at large. Human ailments that were formerly permitted to run their natural course unaided are now placed under the ministration of the medical adviser. This is the age of hospitals; through no single means has the efficiency of the medical armamentarium been more enhanced. More and more they are regarded by the public as homes for the relief of the suffering, and by the medical profession as institutions offering every means for the exact observation, diagnosis, and treatment of disease. These betterments in the facilities for good work correspondingly magnify the responsibilities of the medical practitioner in his chosen field.

The increased confidence of the public in the ability of the physician and of the surgeon is the resultant of the general evolution of biologic science. The bacteriologic laboratory was the cradle of antiseptic surgery and has been the main source of the surgeon's success. Scientific medicine, trusts less and less to drugs in therapeutics but seeks rather to prevent disease through the application of the principles of hygiene; while looking forward with confidence to a future when the great class of infectious disorders may be subdued through specific principles like diphtheria antitoxin.

Therapeutics, the physician's ancient ally in the conflict against disease, lags painfully behind in the march of science, and the physician, and much more the surgeon, must constantly readjust himself to the changing conditions of his practice.

In a recent essay on the progress of medicine Dr. Osler said: "The battle against polypharmacy, or the use of a large number of drugs (of the action of which we know little, yet we put them into bodies of the action of which we know less), has not been fought to a finish. There have been two contributing factors on the side of progress—the remarkable growth of the sceptical spirit fostered by Paris, Vienna, and Boston physicians, and, above all, the valuable lesson of homeopathy, the infinitesimals of which certainly could not do harm, and quite as certainly could not do good; yet nobody has ever claimed that the mortality among homeopathic practitioners was greater than among those of the regular school. A new school of practitioners has arisen which cares nothing for homeopathy and less for so-called allopathy. It seeks to study, rationally and scientifically, the action of drugs, old and new. It is more concerned that a physician shall know how to apply the few great medicines which all have to use, such as quinin, iron, mercury, iodid of potassium, opium, and digitalis, rather than a multiplicity of remedies the action of which is extremely doubtful." Dr. Clifford Allbutt says: "It has been one of my aims as a teacher to keep before the mind of the student that a disease is a figment of the mind; that there is no such thing; the things are men in particular states, no two of them being exactly alike. So it is with therapeutics, which is a collection of abstract rules; the thing is the physician. Clinical doctrines are a sort of *memoria technica* which in the particular case remind us what to look for, but do not pretend to contain all its peculiarities; so therapeutic doctrines remind us of the tools we may use, but by no means tell us all we can do with them in the individual instance. Many and many a time I have seen patients cured or relieved by unwearied solicitude and timely manipulation of this common remedy or that, in the hands of country physicians of no great pretensions to learning or conversation with the broader and more ingenious principles of the consultants whose diagnosis was abstract, and whose treatment was abstract; abstraction embracing abstraction to infinite sterility."

However much we may differ in detail from the positions taken by these masters in medicine, it must be granted that medical treatment of disease, pure and simple, is hardly worthy of the life energies of a man with scientific impulses. But when that treatment is based upon a comprehensive grasp of physiology, pathology, and etiology, and I may add psychology, when it is applied as the final test of a differential diagnosis, then therapeutics becomes a worthy branch of the greatest of natural sciences.

Though medical treatment, which for the most part seeks to modify cellular activity directly, lacks nearly everything in exactness and certainty, there is a form of treatment of disease which deals not with cellular vitality directly, but chiefly with mechanical hindrances to the proper functioning of that vitality, and this kind of treatment approaches mathematic precision in its calculations. It is the field of the surgical operator. And as medical therapeutics is vain without diagnosis founded upon pathology and etiology, so the operative manipulation is disastrous without the thought that runs before.

It has seemed to me that a useful purpose might be served by attempting to define anew the relations of the physician to the surgeon in handling the patients whom both seek to serve. And there is a certain appropriateness, in that one who is fitted neither by attainments nor inclination for surgical practice, should venture to discuss these relations from the standpoint of the internist.

Every votary of our art probably views with bias, based on his individuality and educational environment the cases committed to his care. His very enthusiasm, that indispensable spur to thorough work, is often the practitioner's chief impediment to a judicial attitude in weighing the propriety of radical measures of relief. He must constantly bear in mind that, on the one hand, precipitate surgical interference furnishes the surest and most humiliating rebuke of a mistaken diagnosis; while on the other, a misinterpretation of true conservatism leads to those fatal delays wherein, *e. g.*, a relatively harmless inflammation may become a general septic conflagration. It is a trite saying that, in affections in which the only relief can be found through the surgeon's knife, the physician should at the earliest possible moment call in consultation, the surgeon. I consider it a self-evident absurdity to proclaim that from a medical standpoint the proper treatment of a patient is by certain measures but that from a surgical point of view opposite procedures are best. There can be but one best method of treatment, and so far as the patient is concerned the medical and surgical viewpoints are identical.

It seems to me that the time has come when the physician who ponders upon any case of disease whatever should consider whether surgical interference is demanded in its treatment. When the operator and anesthetist are sufficiently skilled the normal human body almost always reacts from the narcosis and the mutilations of the knife. Most surgical lesions in their incipency are local, and when abolished leave normal tissues to react. But the longer operation is delayed the more reduced is cellular vitality, the more intense is general intoxication and the less able is the organism to respond to the strain the operation throws upon its powers of resistance. It is self-evident, then, that if surgical interference is demanded for the relief of symptoms, it is the physician's duty to call for it at the earliest possible moment.

One of the chief functions of the thoughtful physician today is to determine what classes of symptoms demand surgical interference for their relief. For nothing is clearer in the light of recent surgery than that medical practitioners are now often vainly attempting to relieve by medical means organic conditions which, in their very nature, can yield only to the knife. While the conscientious physician recognizes that a large and increasing proportion of the cases under his care properly belong to the domain of the surgeon, he must in turn demand of the surgeon the possession of a soundness of judgment and operative skill, which at once puts out of action a certain fraction of the operating fraternity. Efficient dexterity in this or that operation requires constant practice, and the physician is loath to devote his patients as material for training. Though the physician occupies the position of a mere onlooker by the operating table, he is nevertheless bound to exercise an independent

¹ Read before the Denver County Medical Society, April 19, 1904.

critical judgment as to the expediency of this or that surgical measure. He knows that it is the nature of all progress, and preeminently of surgical progress, that its pathway shall be strewn with obsolete fads, the cast-off misfits of the torch-bearers of science.

The past generation of women suffered from the fad of ovariectomy, and now that the physiology of the internal secretions has been established, we regard much that was done in the high tide of gynecologic section work as abominable mutilation. We hear but little now of the treatment of reflex disturbances through operative fixation of the movable kidney. It is painfully borne in upon us that decapsulation of the kidney for the relief of nephritis has not the wide range of usefulness that at first was hoped for it.

The demand for diagnostic skill on the part of the physician has greatly increased since the surgeon has learned to cure what were once considered as "medical diseases." The opinion is becoming more and more general that appendicitis is a purely surgical disease, and that operation should be performed when practicable.

But the physician who contemplates referring his case must also bear in mind, what Gerster has recently pointed out, that operation on even the quiescent appendix may set free an infective thrombus and lead to fatal liver abscess, or put in action divers other causes of fatality.

Few would now deny that the presence of gallstones is an indication for surgical interference, but, practically, the medical man often misses the meaning of his patient's symptoms until they have complied with the demands of textbooks written in comparative ignorance; when the diagnostic symptoms have reached this stage the surgical condition is often incapable of amelioration.

There is a class of liver disorders presenting few local symptoms, probably due to nonsuppurative infection of the gall ducts within and without the liver, which medical drainage by means of cholagogues is not able to relieve. Such cases are not treated of, so far as I know, in the textbooks as yet. They are apparently cured by temporary drainage of the gallbladder. It is to be suspected that this class of patients is a very large one; certainly the surgeon, through whose help alone they can hope for recovery, rarely sees them.

The time is scarcely past when gastric disorders invited the attention of the surgeon only for relief of the distress caused by cancer, or when there was danger of fatal bleeding from ulceration. But very lately the relation of surgical treatment to the manifold symptoms of dyspepsia incident to gastric or duodenal ulceration and to dilations of the stomach, especially with obstruction, has become, perhaps, the most prominent medico-surgical question of the day.

All physicians know the tedious and unsatisfactory course under medical treatment of many cases of dyspepsia due now to suspected ulceration, now to stagnation of food within the dilated stomach.

The patient may, indeed, be relieved, but the relief is often conditional upon the patient's pursuing the straight and narrow path of a strict dietary and the avoidance of innocent pleasures which help make life worth the living. Now comes the surgeon and claims to cure once and for all many such sufferers and to replace them among the ranks of healthy people. Mr. Moynihan, in a recent address before the American Surgical Association, speaking of gastroenterostomy in the treatment of ulcer of the stomach, says: "Inveterate dyspepsia is in itself an ample warrant for surgical treatment." A distinguished surgeon recently said to me, in effect, that he considered any chronic condition of the stomach marked by undue retention of food with pathologic results, to be an indication for gastroenterostomy. Dilation of the stomach is a condition so commonly found that a reference of all such cases to the surgeon would lead to a veritable operative orgy. It is the business chiefly of the physician to discriminate between those cases in which relief can only be hoped for through surgical interference and those in which operation offers not only little hope for cure but the possibility of harm. With the comparatively small experience at present available in this field of treatment, it would seem to be a conservative rule to recommend for operation practically all those cases of dilation accompanied by obstruc-

tion at the pylorus and possibly also cases which (the patients possessing sound nervous systems) are characterized by simple atony of the stomach and in which cathartic medical treatment has, after a prolonged trial, failed to relieve the dyspepsia. But it would seem unwise to refer to the surgeon any case of atonic dilation of the stomach until it is apparent that medical treatment is unable to bring the patient to a normal plane of life. The mistakes in the near future are likely to arise from surgical intervention in the gastrectasis so commonly accompanying neurasthenia; cases in which it is so often difficult to estimate whether the state of the stomach is primary or secondary to the general nervous instability. In a letter recently received from Dr. W. J. Mayo, he says: "We have not intentionally operated upon any patients with neurotic dilation. We fight pretty shy of that class in a surgical way." Another very large order of cases to which the surgeon's attention may be conservatively called is that in which persistent or recurring epigastric pain refuses to yield permanently to medical treatment. The symptoms are usually due to gastric or duodenal ulcer and find a happy relief in operation.

SUMMARY.

It would seem to behoove us who assume to practise internal medicine to look upon abdominal pain and accompanying symptoms with a new and enlightened interest. The female pelvis, the appendix, the gallbladder, the kidneys, the duodenum and the stomach present an array of disorders meeting us on every hand. It is possible in many cases, through a careful review of the history and a study of the symptoms of the disease, to make a correct differential diagnosis.

The affections under consideration admit of but incomplete palliation under medical treatment and such temporizing may jeopardize the life of the patient. Expert surgery is capable of curing these diseases, and when operation is undertaken while the organism at large is still normal, the danger of fatality is very small. Every abdominal symptom should suggest to the physician the expediency of operation. If careful consideration points to a "surgical condition" the diagnosis of the definite seat of the lesion is a minor matter and, as has been said elsewhere, may well be left to the exploratory section.

To wait for the development of certain classic symptoms, such as jaundice with gallstones, or hematemesis in gastric ulcer, will, in the majority of cases, disturb the aim of the physician—the relief of his patient.

Discriminating diagnoses and early operation when indicated must greatly increase the percentage of cures. The confidence of the public will thereby be welded to us and patients will trust themselves to our advice while their vital forces are still capable of responding to every therapeutic endeavor.

It is far beside the mark of my observations to palliate in any way the crime of indiscriminate surgical operation.

True conservatism may demand now action, now delay. No one understands better than the true surgeon that surgery often demands that he watch and wait. The spirit of what I have meant to say is that all rays of light come from the one focus—Diagnosis.

"Paupers" Have Means of Support.—Thus far in the investigation ordered a month ago by Judge Barrett, it has been ascertained that 450 patients maintained by the city in the Norristown State Insane Hospital as paupers have relatives of sufficient means to support them. The city now pays \$1.75 a week for each of them, while the State pays an equal amount. The investigation concerning this matter arose upon the application for his discharge of a patient who had been supported as a pauper when investigation proved that he had money in the bank and owned several pieces of real estate. Liberty was refused this patient on the ground that he recently made accusations against his wife and daughters, which, taken together with the circumstances, proved him clearly insane. Judge Barrett, in rendering his decision concerning this patient, concludes his opinion as follows: "The duty which devolves upon the court of remanding to an asylum for the insane a man who seems to have all his mental faculties upon matters that have no relation to the subject under discussion, and who undoubtedly appreciates liberty, and must be sensitive as to his position, is an exceedingly sad and difficult one; but in the interests of the relator as well as of those who might suffer serious bodily harm by a mistake in this matter the duty is a plain one."

THE SANTA CRUZ MOUNTAINS OF JAMAICA, WEST INDIES, FOR THE TUBERCULOUS.

BY

MR. LOGAN RUSSELL,
of Kingston, Jamaica.

AND

Climatology of the Mountain Heights of Malvern Range.

BY

LESLIE ALEXANDER, ESQ.,
of Malvern.

Among the diseases affecting the human system none demands such close observation and practical study as that of pulmonary tuberculosis.

There is no malady so insidious at its commencement and so fatal in its termination. It has been recognized from time immemorial as the "wasting disease," and too surely and steadily does it waste its victim, even to the very death.

It is not the malady peculiar to the occupant of aristocratic circles or the pauper. It knows no distinction in rank or station. The monarch on his throne, surrounded with every luxury that art or science can furnish, fed on the choicest products of the soil, clothed in the most costly raiment, protected from every fitful gust that blows, is by this disease treated with the same reckless and unrelenting hand as the pauper, far removed from such protection, poor, unknown, uncared for, and whose constant thought is for the sustenance of the day and some friendly shelter for the night.

The plague, with its awe-spreading and frightful ravages, can bear no just comparison to this, for though it decimates the ranks with an alarming and certain precision, its time is, at the most, limited, and its departure sudden and permanent, or at least, so permanent that after the expiration of many years it is forgotten and may never return. Pulmonary tuberculosis *lives*¹ among us. It has its hot-bed in our midst, where it is nourished and expanded to its utmost limits, doing its work from day to day with a certainty unrivalled by any malady. It rests not as a simple malady departing with the death of its selected victim, but passes its seed of contagion to the offspring who, unless placed under favorable hygienic influence may, and probably will, at an early age in life develop the characteristic symptoms.

It becomes our duty to examine into, collect, and diffuse such knowledge as we have obtained, trusting the same may tend to check or mitigate the sufferings of those who are affected with this disease.

With this in view, we trust these observations may prove of beneficial assistance to the numerous readers of *American Medicine*, many of whom being in doubt as to a suitable locality for the recommendation to those under their care.

Many and varied are the drugs that have from time to time been tried and lauded as beneficial, and in not a few cases marked, "specific," for pulmonary tuberculosis, and while these have in many instances proved of great advantage, we find on extended experience that the great prophylactic is that dispensed by Mother Nature, free of any charge and obtainable at all hours and at all places, fresh air. Fresh air naturally differs, and while that of a locality may prove of beneficial service to a special class of diseases, resulting in convalescence and early, absolute recovery; to another class convalescence may be tardy, so much so that removal to a higher or lower altitude is ordered, when speedy and satisfactory results follow.

¹ The word *lives* among us, is intended as general to such climates that are subject to sudden transitional changes. Locally, we may say, we have no pulmonary tuberculosis other than those cases generated by ignorance and persistent refusal to regard the general and simple hygienic law of acquiring as much fresh air as possible. Some persons have so decided a fear of the "night air" entering their rooms that every window is shut, and each crevice carefully guarded; as a result in a short time the pure air becomes exhausted and nothing is left but the prebreathed carbonaceous waste; life maintained on that will certainly produce pulmonary tuberculosis.

Many who have arrived afflicted with pulmonary tuberculosis have gone to the higher ranges of the Island, and by carefully avoiding alcoholic drinks and leading proper lives, have recovered and lived to ripe years.

I do not write to imply that every patient with pulmonary tuberculosis who arrives, will certainly be cured, but simply wish to direct the attention of the profession to the great advantages to be derived in incipient cases, and in well-selected cases. But such patients must not remain in or about this city (Kingston) for here the heat is tropical. The dust in circulation from constant and heavy road traffic is excessive at times, and decidedly aggravating to impaired pulmonary and bronchial tissues. The best spot in the Island is Malvern, located in the Santa Cruz Mountains at a height of 2,350 feet above sea-level.

The climate of Malvern is such that the open-air treatment of pulmonary tuberculosis can be uninterruptedly carried on throughout the entire year. The Island is gradually being recognized as a health resort, and increased steamship facilities that have been established within the last few years have done much toward bringing the Island before the notice of the traveling public.

For a distance of over 16 miles the Santa Cruz range runs parallel to the sea, ending abruptly in the Southfield district with a cliff 1,550 feet high and less than half a mile from the seashore. At no spot does the range diverge landward further than 8 miles from the sea, a feature which contributes largely to the dryness of the atmosphere. The most central portion of the range is "Malvern heights," where an ideal climate is found, one in which there is a mixture of mountain and ozone-laden air, very dry, and with a most equable temperature. A careful record during a period extending over 10 years shows the average maximum temperature to be only 72½°. The average minimum 63½°, and an average range of 9½°. The following figures represent the average temperature for 1 year:

	Minimum.	Maximum.
January.....	59°	66°
February.....	57°	64½°
March.....	59½°	66°
April.....	61°	71°
May.....	62°	72°
June.....	62½°	74½°
July.....	66°	76°
August.....	68°	80½°
September.....	68°	79°
October.....	64½°	78°
November.....	64°	74°
December.....	61°	73°

The average rainfall as shown by the records of the government gauges during the past 4 years has been only 55 inches. Malvern may therefore boast of a unique and exceptional climatic reputation, ranking, as a recent expert opinion puts it as a "wonder of the world."

During the past 10 years only once did the rain fall for 3½ whole consecutive days, and that was in 1899, a year in which floods occurred in every one of the 13 parishes of the Island. The rainy months are May and October. In May, two whole consecutive days may be looked for, the fall never exceeding ½ in. in any 1 day, and not more than 8 in. for the month. In October, afternoon rains of a couple hours' duration may be looked for, and generally during the latter part of the month. In this month the mornings are bright, sunshiny, and bracing. Owing to the limestone formation of the range, and consequently perfect drainage, one can enjoy walks along the well-kept mountain roads within an hour of the heaviest rain.

There is literally no forest land in and around Malvern. The entire range of mountains is a pimento region, a product which grows in open common pasture where there is absence of shade and humidity. So with the temperature at 52° or 54° in the morning in the months of January and February, no mist is to be seen, and out-door exercise is very enjoyable. Scores of patients have obtained a new lease of life by a residence here. In all throat and lung troubles, laryngitis, bronchitis, pulmonary tuberculosis, asthma, catarrh, the climate produces marvels.

Dr. Charles Reinhardt has been here recently, at the instigation of Sir Alfred Jones, with the view of establishing a sana-

torium for lung diseases. Dr. Reinhardt was the first physician to advocate the open-air treatment in England. He gave the following opinion:

The climate of England is no bar to the success of the open-air treatment for pulmonary tuberculosis. At the same time its discomforts are unavoidable. The great changes which occur in temperature make it inevitably a little uncomfortable, though much less so than the patients fear. Persons suddenly stricken down with pulmonary tuberculosis dread the English climate more than they would if they had experience. Those fears must be reckoned with, and the only climate in the world in which the open-air treatment can be carried on summer and winter without discomforts is that of the Santa Cruz Mountains.

I am familiar with the climates of many health resorts, especially with Swiss and Austrian Alpine regions, which are recommended for the tuberculous.

The treatment at these places must necessarily be intermittent, because when you get the winter season the patient has to move off, and this frequently does considerable harm. There is a class of patients who should live continuously in a rarefied atmosphere, who could not live anywhere else, and who break down as soon as they move to another climate. For this type the climate of Santa Cruz, being identical with an English summer in its best mood, would be free from the disadvantages. Before coming to Jamaica, I had interviewed several patients who had been previously sent to the Santa Cruz Mountains and had returned to England. I have also interviewed several patients now there, and in every case the results have been good beyond all expectation. * * *

On the Santa Cruz Mountains you have the wonder of the world, and in all my experience there is no such place that I have ever heard of where there is so exceedingly equable and so pleasant a climate. * * * I think the day cannot be far distant when the English-speaking world will recognize Malvern as a place in which to seek and find renewed health.

Such is the opinion of one of the leading specialists of the world, who has studied the climate.

The history of a resident at Malvern interviewed by Dr. Reinhardt may be summed up as follows:

Ten years since while at work on the plains I was stricken with lung trouble. Seven local physicians advised change to Malvern, which I did during the summer months for 3 consecutive years, and the climate worked wonders. I resigned my appointment in the government service. I have been here since October 4, 1897, and have entirely recovered except for a slight huskiness of voice. I had lost 24 pounds, but now maintain a standard weight of 147 pounds and have had no illness for 4 years. I live on the humblest fare. I was a flautist, but had given it up. I can now play for 3 or 4 consecutive hours without the slightest discomfort. I can walk from 6 to 8 miles any morning. I keep an apiary of 100 odd colonies, one which I attend without any assistance. The people here cure themselves of tuberculosis while continuing their avocations.

There are in and around Malvern and within a radius of 2 miles of the post and telegraph offices, 4 reputable boarding-houses and a hotel.

All American and English groceries and foodstuffs are to be had at Malvern.

In conclusion we would say there are hundreds of charming sites in the Santa Cruz Mountains suitable for the erection of sanatoriums by government or private enterprise, local or foreign.

Elks Endow Beds.—The Society of Elks, in New York City, has endowed two beds for the Postgraduate Hospital. Champe S. Andrews, exalted ruler of the New York lodge, in his presentation of the two beds, said that since 1868 the mother Lodge of Elks had dispensed in volunteer charity nearly \$250,000.

Pulmonary Tuberculosis in Relation to Life Insurance.

—T. D. Lister states that the normal danger to the office arising from pulmonary tuberculosis is made up of three factors: Inherited vulnerability, largely diminished after middle life—i. e., decreasing with age. Acquired vulnerability increasing with age. Infection, equally likely at all ages. The sum of these three factors causes the normal danger from pulmonary tuberculosis to be the same at all ages, but as age advances the percentage of deaths from pulmonary tuberculosis out of the total number of deaths diminishes with growing rapidity, owing to the large number of other causes of death which occur in the later years. All additions for any extra risk from pulmonary tuberculosis must, therefore, be larger in early life, but especially so with the danger decreasing with age. An excessive danger from pulmonary tuberculosis may be inferred in an individual when he has inherited vulnerability, acquired vulnerability, or a risk of infection (or two of these) in a degree greater than average healthy members of his own class. Personal condition is an important factor in determining this degree.—[*Indian Medical Record.*]

6. Complications and Degenerations of Uterine Fibromyomas: A Pathologic and Statistical Study of 280 Cases. ELLICE M'DONALD.
7. The Treatment of Fibroid Tumors of the Uterus. CHARLES P. NOBLE.

1.—Intestinal Perforation in Typhoid.—B. B. Davis calculates a total of 8,333 persons whose lives might be saved annually in the United States by timely operation. Operation requires only 20 or 30 minutes, and deaths from shock are very few. A large proportion of the operations that have been done have been for general peritonitis instead of mere perforation. It is for this reason mortality has been so high. Keen opposes operation in the first 12 hours, but analysis of cases will probably show that the greater mortality at this period was due to the greater severity of the disease in the cases he operated on, stupor having masked the perforation until peritonitis occurred. Those operated on in the second 12 hours are those probably who were not so very ill from the disease—with minute perforations, little leakage, and insusceptible to peritoneal irritation. If shock is prolonged beyond the time necessary to prepare for operation spreading infection is more dangerous than operation and the latter should not be delayed. The most marked symptoms of perforation are sudden abdominal pain, localized tenderness, thoracic breathing, and muscular rigidity. Leukocytosis is unreliable. There is a sudden rise in blood-pressure. Operation should be done at the house. The best incision is along the right semilunar or through the outer border of the rectus. A mattress or running suture of fine silk, parallel with the bowel should be used, no paring of the edges, but simple infolding being all that is necessary. Resection is too formidable. If several perforations are crowded together an artificial anus may be established or gauze may be packed about the loop to sequester it. The extravasated matter if still localized should be wiped away, irrigation often spreading infection. Anesthesia may be discontinued as soon as the perforation is found, the closure and peritoneal toilet giving very little pain. [H.M.]

2.—Operative Treatment of Eclampsia.—C. S. Bacon states that as labor is frequently the exciting cause of convulsions, any operation having the effect of a severe and prolonged labor should be avoided. Abdominal cesarean section is done in contracted pelvis. All operations should be under complete ether anesthesia. Ether is not more dangerous to the kidneys and is safer for the impaired heart. Morphin is much better than ether to control convulsions. When the cervix is effaced, we have three methods of dilation, incision, digital, and bag dilation. For incision, the posterior lip is first caught on each side of the median line and cut to the vaginal junction, and then the anterior lip in the same way. When the cervix is not effaced, these incisions are not sufficient and vaginal cesarean section will probably secure the best results. A longitudinal incision should be made from behind the meatus urinarius to the external os through the vaginal mucous membrane, the bladder being separated by gauze sponges. Then cut the cervix through to the median line with scissors, making traction with vulsellum forceps to bring more of the anterior uterine wall in reach. Then push up the vesicouterine fold of peritoneum. If the child is at term it may be well to split the posterior cervical wall in the same manner as the anterior. Unless the head is in the pelvis, delivery is best accomplished by version and extraction. If there is no hemorrhage, the incision in the uterus should be closed before delivery of the placenta, expressing the latter before suturing the cervix and vagina. [H.M.]

3.—Hypnotics.—W. B. Stewart emphasizes the importance of ferreting out the causes of insomnia before treating, and advocates the use of other than drug treatment, whenever possible, such as hypnotic suggestion, head massage, hot drinks on retiring, warm baths, and avoidance of exciting work in the

evening. Sleep from alcohol is not restful. Sulfonal and trional among drugs have the least harmful after-effects. We should never fall into the rut of prolonged administration of any drug. [H.M.]

4.—Serotherapy.—H. T. Ricketts reviews the discoveries which led to our present knowledge, lists the prophylactic and curative injections, describes Ehrlich's side-chain theory, and summarizes the practical results of serotherapeutic measures. Success depends on administration as soon as possible after infection. The writer has recently studied reactions, leading him to the belief that cytotoxicity may be accomplished by a reduction process which may lead to important results as to the chemistry of immunity. [H.M.]

5.—The Apostoli Treatment.—G. B. Massey states that a prolonged observation of cases of fibroid tumors of the uterus under this treatment teaches that three-fourths of the cases will be practically cured, as attested by inquiries made from three to 16 years after the cessation of treatment. The cases that respond poorly are not harmed by it when properly applied, and heroic measures may then be used. Hemorrhagic and interstitial fibroids are best adapted to the treatment, while subperitoneal or degenerative fibroids and those complicated with pyosalpinx are least so. But one of the seven deaths among 110 patients has been due to progress of the growth itself, proving the nonmortal character of this affection. Of the remaining six, one died of a totally unconnected affection, one of septicemia under electric treatment, and four under operation with the knife. [H.M.]

6.—Complications and Degenerations of Uterine Fibromyomas.—E. M'Donald believes all fibroids producing symptoms and all except those designated as small (especially when subserous or intramural) should be removed, because risk from operation is less than that of the tumors themselves from sarcomatous changes, carcinomatous associations, and complications. Thorough pathologic examination should be made for evidence of malignancy. Particular study should be devoted to those tumors which are necrotic, cystic or both, as among these are found the largest proportion of malignant changes. [H.M.]

7.—Treatment of Fibroid Tumors.—C. P. Noble has estimated that because of degenerations, 16%, and because of complications, 18% of patients would die without operation. Others would die of intercurrent disease contracted because of the resulting reduced state of health. If there is any class of fibroids which does not require removal it is the subserous and intramural group. It is more than doubtful whether it is conservative to advise against the removal of a fibroid in any instance, unless owing to disease in other organs an operation would be hazardous. An analysis of reported cases shows the following facts: Sarcoma developed in 1.5%, adenosarcoma of the corpus uteri in 2.5%, carcinoma of the cervix in 1%, necrosis in 6.1%, cystic degeneration in 3.4%. One third of women having fibroid tumors die unless the tumors are removed. The risk of radical operation in uncomplicated cases is not more than 1% or 2%; in the average of cases it is about 5%, rising to 10%, 20%, or 30% in the gravely complicated cases. [H.M.]

Boston Medical and Surgical Journal.

2. Tuberculous Meningitis in Adults. HENRY JACKSON.
3. Claudius' Iodized Catgut. HORACE BINNEY.
4. Concerning Danger of Infection to Attendants of Tuberculous Patients. LOUIS FAUGERES BISHOP.

1.—Hysteroneuroses.—D. H. Craig quotes Engelmann's definition of these as "Those phenomena which simulate a morbid condition in an organ which is in an anatomically healthy state and which are due not to structural changes in the organ in which they appear, but to morbid or physiologic changes in the uterus or ovaries." In studying his own recent private records he finds that in 14% these cases had been misinterpreted by other physicians on account of lack of thorough physical examination. No symptoms should be accepted as a hysteroneurosis until every other cause has been rationally excluded. A thorough search for extrapelvic causes of symp-

toms often makes an intrapelvic examination unnecessary and in doubtful cases in single women the therapeutic test may often seem justifiable. With a supersensitive patient nothing so greatly facilitates pelvic explorations as nitrous oxid. [H.M.]

2.—Tuberculous Meningitis in Adults.—H. Jackson mentions trauma, syphilis, cerebrospinal meningitis, meningitis secondary to pneumonia and sepsis, and tuberculous meningitis as having many symptoms in common. The fever, headache, malaise, and often leukocytosis are usual in other diseases. A high white count may occur but is uncommon in tuberculous meningitis and when present will eliminate typhoid. We may base our diagnosis on the pulse-rate and paralyzes of various muscles especially of the eye and face. If the pulse is irregular or intermittent as well as slow it furnishes greater cause for alarm. A pulse in harmony with the general symptoms is presumptive proof the case is not cerebral. There is rarely paralysis of any of the larger muscles; deviations of the eye muscles may be so slight as to suggest merely a permanent cast. Lack of evidence of preexistent tuberculous trouble is no strong evidence against the probability of tuberculous meningitis. It is common, however, to find at postmortem healed processes insusceptible of clinical diagnosis. In many cases the writer has found the onset abrupt. The prodromal symptoms in all were indefinite. In only one case was headache a prominent symptom. In adults the disease is not usually marked by the same headache, photophobia, cerebral cries, and extreme restlessness that make the picture in childhood. In eight cases of lumbar puncture the fluid spurted, showing pressure, but in only one was the bacillus found. Retraction of the head, Kernig's phenomenon, and opisthotonus are less frequent than in cerebrospinal meningitis. [H.M.]

3.—Claudius' Iodized Catgut.—Horace Binney states that the ordinary so-called sterilized catgut is often not sterile. Gut prepared by the cumol method is sterile, but the method is very expensive. The method suggested by Claudius has been tried by Binney in nine different instances with satisfactory results; in eight of these, the catgut was used in the fascia in closing the laparotomy wounds. From experiments with rabbits and a few clinical tests it has been found that the iodized gut corresponds closely in duration with plain catgut in the time required for absorption. Schon has used the iodized catgut in 17 resections of the breast with perfect healing resulting in every instance. His conclusions are: Catgut prepared by Claudius' method is superior to other catgut in that: 1. It is invariably sterile. 2. It is readily absorbed in the tissues. 3. The ease and simplicity of its preparation enables the surgeon to prepare his own sutures with a minimum of trouble. 4. It is comparatively cheap. For details of Claudius' method see *American Medicine*, Vol. VII, No. 21, p. 831. [A.B.C.]

May 19, 1904. [Vol. CL, No. 20.]

1. Enterostomy in Peritonitis. ROBERT B. GREENOUGH.
2. A Comparative Study of the Deaths for the State of Massachusetts for the Years 1850, 1875 and 1900. WILLIAM F. WHITNEY.

1.—Enterostomy in Peritonitis.—Robert B. Greenough considers this question at length, giving abstracts of 41 cases, and concludes as follows: (1) The obstruction of the intestine in diffuse peritonitis is the result of a combination of causes; (2) the most important cause is suspension or paralysis of peristalsis; (3) paralysis of peristalsis is due to inhibition, to toxic paralysis and to the paralysis of distention; (4) mechanical causes such as infiltration of the bowel wall and light adhesions in certain cases contribute to this paralysis; (5) pure mechanical obstruction due to adhesions is the result of chronic or local peritonitis of at least some days' duration; (6) enterostomy is indicated in addition to other operative measures in the graver forms of diffuse peritonitis; (7) its greatest advantage is the drainage of the gases and decomposing contents of the bowel and the relief of paralysis of peristalsis; (8) by enterostomy the surgeon obtains direct control over the intestine for lavage and for the introduction of stimulants, nourishment, fluids and cathartics; (9) for the relief of paralysis of peristalsis primary enterostomy is to be preferred to the secondary operation; (10) enterostomy is best performed by the use of the Mixter tube; (11) the cecum is the most satisfactory part of the bowel for a primary enterostomy, and the jejunum

is to be avoided; (12) spontaneous closure of the fistula may be expected when the cecum is opened, if the opening is kept below the level of the parietal peritoneum; (13) by the systematic use of enterostomy in the graver forms of diffuse peritonitis the number of patients dying on the second, third and fourth days after operation is reduced; (14) the symptoms of visible peristalsis and spasmodic pain in intestinal obstruction indicate a mechanical cause for the obstruction; (15) the persistence of these symptoms, unrelieved by enemas and cathartics, is an indication for operation; (16) under these circumstances the cause of the obstruction should be removed if possible by operation; (17) in advanced cases of obstruction of this form enterostomy of the coil of intestine nearest above the obstruction should be done. [A.B.C.]

2.—Old and New Deathrates in Massachusetts.—In conclusion, a comprehensive view of the picture shows the expectancy of life in 1850 was better for children than it is now. They stood a better chance of reaching the end of their first year, while from that time on the infectious diseases claimed many victims. But those who reached 50 could look forward more confidently to an old age. In 1875 the new era of medicine had only just begun, and with the passing away of the quieter and simpler modes of living, with the crowding out of fresh air and sunshine, the natural checks upon infection were broken down, and the result was what would be expected. But, fortunately, today preventive medicine and hygiene have been able to minimize infection, and thus to more than offset the evil effects of our concentrated, high-pressure civilization up to 50; after that period modern science appears to be powerless against the diseases of old age, to which the survivors of this strenuous existence seem more readily to succumb. [A.B.C.]

1. The Treatment of Pneumonia. JOSÉ M. FERRER.
2. Renal Redecapsulation. GEORGE M. EDEBOHLS.
3. Operative Surgery Applied to the Seminal Vesicles: A Demonstration of Some New Principles. EUGENE FULLER.
4. Who is Treated? HEINRICH STERN.
5. Tetanus Treated by Intraneural Injection of Antitoxin. JOHN ROGERS, JR.
6. Multiple Gonorrheal Periarthritis in a Child, Probably Due to Inoculation Through a Wound. HENRY HEIMAN.

1.—Treatment of Pneumonia.—J. M. Ferrer reviews the treatment of a quarter of a century ago. Later years have witnessed the complete triumph of the expectant plan. Hygienic measures, good nursing, active interference if necessary, avoidance of fussing, discretion in diet and supporting measures, attention to the bowels, and relief of pain, fever, and restlessness constitute about all we know of treatment. Salicylates and iodids have proved ineffectual. Creasote compounds he uses only in catarrhal cases. Quinin seems to have a decided effect on temperature. A sunny room, responsible nursing, quiet, a temperature at 75° to 80°, and disinfection are matters that he insists upon. For the initial chill he uses hot bottles; for nausea and vomiting, reduced diet, mustard plaster, cerium oxalate, or calomel; for pain, ice-bags, or preferably heat. In intense pain nothing will take the place of morphin. Mortality is increased by bleeding. Tympanites may be relieved by calomel, irrigation, change of diet, or turpentine. Sponging is grateful with a temperature over 103°. Oxygen seems to allay irritation. Heart stimulants should be postponed until indicated. Hypodermoclysis is sometimes efficacious. In diet, the patient's inclinations should carry great weight, even solid food being allowed when there is no intestinal indigestion. [H.M.]

2.—Renal Redecapsulation.—George M. Edebohls states that one invariable effect of renal decapsulation is the formation of a new capsule proper, which is always more succulent and more vascular than the original. He reports an instance in which he did a redencapsulation upon a patient, who, two years previously, underwent an operation for double renal decapsulation at his hands, the trouble being chronic Bright's disease. Following the primary decapsulation for chronic Bright's disease on a male patient of 26, there was primarily no improvement in the condition of the urine. The patient then went abroad, to a number of health resorts and for a time there was some improvement, but the whole period was a rather stormy

one. Finally, about two years after the primary operation, the renal condition becoming worse, the patient returned to Edebohls, who did a double renal redencapsulation with the hope of affording relief. He states that both kidneys were of the same size at the second operation as when he operated primarily and were distinctly less dense and friable than at the original operation. The patient, who was in a uremic condition at the time of operation, failed to rally and died five hours afterward. The stripping off of the capsule in the last instance was not difficult. [A.B.C.]

3.—Operative Surgery Applied to the Seminal Vesicles.—Eugene Fuller states that he formerly operated with the patient lying on his abdomen with the buttocks over the raised end of a Trendelenburg table. This position he has abandoned for one in which the patient is placed on a flat table with the knees flexed sharply under him, and the shoulders so depressed that the side of the face rests on the table. His later experience encourages the belief which he formerly entertained in operative procedures applied to surgical conditions of the seminal vesicles. Up to the present time he has operated on 21 patients without a death. The surgical method which he claims to have originated for seminal vesiculitis consists in seminal vesiculotomy with exposure of the cavity of the vesicle by means of a free longitudinal incision. The surgical treatments which he claims to have introduced are drainage of the cavity, curetment, and the removal of the intravesical neoplasms, and also the freeing of the organ through peripheral dissection from surrounding inflammatory adhesions. His 21 cases he divides pathologically into 5 groups: Group 1 consists of extremely chronic cases of seminal vesiculitis; group 2, consists of instances of seminal vesiculitis less marked than the preceding; group 3, cases of acute diffuse periseminal vesical abscess; group 4, adenoma and involving the wall of the vesicle; group 5, tuberculous involvements of the seminal vesicles. He claims that his method is superior to that of (1) perineal section with median incision through the trigonum; (2) incision through the rectal wall; and (3) perineal incision through the prostate. [A.B.C.]

5.—Tetanus Treated by Intraneural Injection of Antitoxin.—John R. Rogers, Jr., states, that after the development of the symptoms of tetanus, subcutaneous, intravenous, or intracerebral, injections of antitoxin are manifestly useless. Experiments show that the most minute abrasion of nervous tissue is sufficient for the entrance of the toxin, therefore the usual lumbar puncture offers a reasonably safe and sure method of obtaining the desired result. He reports the case of a boy of 12, who suffered a wound of the left palm from a toy pistol; four days later the family physician removed some portions of wadding; 14 days later initial symptoms of tetanus appeared, and two days later were very distinct, there being trismus, lockjaw, opisthotonus, and tonic muscular contractions. Under either the brachial plexus was exposed, and the inner and outer halves of the median nerve, the trunks of the ulna, musculospiral, musculocutaneous, and circumflex nerves were punctured by an aspirating syringe and 5 m. to 10 m. of antitoxin injected into it. At the same operation, the needle was introduced between the third and fourth lumbar vertebrae and 1 dr. of the antitoxin injected subdurally. The palmar wound was thoroughly curetted and cleansed. There was a distinct change for the better in the patient's condition. A second lumbar injection was given on the day following; the patient completely recovered. The author holds that this was not necessarily a chronic case, but one conforming to the type termed "delayed acute," which is quite as fatal as the ordinary acute form. [A.B.C.]

6.—Multiple Gonorrheal Periarthritis in a Child.—Henry Heiman calls attention to a recent article on the "Gonorrhea of Infants," by Kimball, in which he notes the prevalence of gonorrhea in infants and children occurring in epidemic form in institutions, describing six such cases, and suggests that infection occurs by way of the upper air passages or mouth. Heiman refers to a previous paper by himself, in which he reported some cases in infants in which one or both of the parents were simultaneously suffering with the disease, and mentioned cases of vulvovaginitis and arthritis in which the mode of entrance of the gonococcus to the body was unknown. In the present paper he reports the case of a male

child of 4 years, which had been a healthy and well-developed child; he suffered a slight injury to the sole of the right foot; five days previous to this time the father had been treated for gonorrheal urethritis, prostatitis and epididymitis; somewhat earlier the mother was treated for vulvovaginitis. The child's illness began with pains in the foot; he was unable to stand; there was a temperature of 101°; both great toes and the left wrist were red, swollen and excruciatingly painful. On the inner side of the sole of the right foot was a puncture 1 cm. in diameter discharging seropus. Scurvy, osteomyelitis, acute rheumatic fever, etc., were thought of and excluded. Three weeks after the onset there was suppuration about the metatarsal phalangeal joints; the suppurating parts were treated surgically. Cover-glass specimens were prepared and cultures taken; the gonococcus was unmistakably found. [A.B.C.]

New York Medical Journal.

1. The Vasomotor Center in Inhibition of the Heart. CHARLES E. DE M. SAJOUS.
2. Intussusception. JOHN F. ERDMANN.
3. Prostatic Crisis. SAMUEL H. FRIEND.
4. Mucous Colitis with Special Reference to Treatment. F. J. RUNYON.
5. Experimental Researches on Resuscitation after Death from Chloroform. ROBERT COLEMAN KEMP and A. W. GARDNER. (Concluded.)

2.—Intussusception.—J. F. Erdmann maintains that this disease, barring a few accidental cases, is one that demands prompt surgical interference. We should not temporize with air inflation or water injections. He believes that the symptomatology, as given in former textbooks on diseases of children, etc., should be rewritten with a view of placing all stress upon blood or bloody mucous stools, and not upon the presence of a sausage-shaped tumor. In over 60% of a series of 26 cases seen by him, in 23 of which he operated, no tumor of any kind was palpable per rectum or through the abdominal wall. He has not found a single instance in which blood, bloody stool, bloody mucus, or bloody serum was not found, either upon the diaper, in the commode, or expelled from the anus after digital examination. Sudden pain is almost invariably the first symptom the child manifests, then a degree of shock varying in intensity and efforts at defecation take place; these are followed by manifestations of spasmodic pains; a peculiar whining cry or fits of crying. In the first hour or two the abdomen is lax and no marked evidences of pain are produced upon palpation; tumor is not felt unless the intussusception is of considerable extent and is taking place rapidly. After a few hours, depending entirely upon the degree of obstruction, abdominal distention and evidences of complete obstruction occur. When a tumor is felt it is not usually the proverbial sausage-shaped tumor, but is more apt to be round or nodulated and moderately movable. Rectal enemas in the first few hours are not productive of harm, but may, though rarely, be followed by reduction. Admitted that one secures occasionally reduction by use of enemas, still an important fact must be remembered, *i. e.*, that the whole mass may be reduced but the ileocecal junction and one or more inches of the ileum, then all the symptoms clear up for a time. They again return and necessitate operative interference at a time when the conditions of this region are not nearly so favorable. Two cases are reported, one of spontaneous reduction several hours after enema, and one of a subacute variety of over six days' duration with recovery after operation. [C.A.O.]

3.—Prostatic Crisis.—The object of the paper by S. H. Friend is to show that one of the early symptoms of tabes, the perineal pain, is located in the prostate gland. He believes that this pain should be named "prostatic crisis." [C.A.O.]

4.—Mucous Colitis.—F. J. Runyon believes that this condition is the result of mechanical irritation, irritation resulting from chemic processes in the intestinal canal, or from fermentative processes, the result of germs in the intestinal tract. It is most important in this affection to obtain the confidence and cooperation of the patient, for in many cases suggestion is of great value, and should be constantly employed. If the case is at all severe, if there is present much abdominal pain and soreness, if much mucus is discharged, and especially if this is blood-tinged and diarrhea is present, the patient should be put

to bed and kept there until acute symptoms at least have subsided. When these have well subsided the patient should be forced to be up and out. If constipation is present, the diet should preferably be liquid. Milk should not be given. Runyon prefers beef juice and broths, and these made more nutritious by the addition of bread or some of the cereals, and subsequently strained; or powdered beef peptonoids can be added to this. Many of the prepared foods here serve a useful purpose. When there is diarrhea, he prefers usually rather a dry diet, as beaten biscuit, toasted soda biscuit, or toasted light bread and crackers, rice, etc.; boiled meats in moderation. If the condition is due to irritation, epsom salts are indicated. At night, an hour before retiring, he directs the patient to take, in the recumbent position, an injection of just enough normal salt solution to cleanse the bowel. Then an hour later an injection of an ounce of sweet almond oil containing about 5 gr. of iodoform and 10 gr. of bismuth subnitrate in an ounce of hot water is used. Fluid hydrastis may be used, in either event the last injection should be retained all night. [C.A.O.]

5. Cancer of the Intestine. J. G. SHERRILL.
6. Fracture of the Base of the Skull as a Cause of Epilepsy: Report of Case. CHARLES J. ALDRICH.

1.—Lesions Peculiar to the Pancreas.—Eugene L. Opie, in an interesting paper on this subject, states that diseases of the pancreas may be conveniently separated into those affecting the secreting apparatus of the gland, and those which have their seat in the islands of Langerhans and interfere with the influences which these structures exert on carbohydrate metabolism. Pawlow and his pupils have shown that the pancreatic juice contains three ferments, which have a preeminent part in the digestion of the three most important constituents of the food. Fatty necrosis for the surgeon may often serve as an index to pancreatic disease, and, recognized during the course of an exploratory laparotomy, frequently explains an otherwise obscure case. The various forms of pancreatitis are dealt with at some length. A considerable number of cases of hemorrhagic pancreatitis are associated with gallstones. Opie has collected 41 reported cases, in which gallstones have been found in association with acute pancreatitis; in seven of these instances a calculus was lodged at the duodenal orifice of the common bile duct, dragging the bile into the pancreatic duct. Gangrenous pancreatitis is usually associated with suppuration, limited to the lesser peritoneal cavity. Chronic pancreatitis is discussed. Fitz has collected from literature 29 cases of pancreatic disease in which fatty stools were noted during life; in 14 of these cancer was present; in 7 calculi; in 2 the pancreatic duct was obstructed; the small number indicates the infrequency of fatty stools in diseases of the pancreas. Clinical observations begun by Thomas Cawley, as early as 1788, have shown that diabetes mellitus is frequently associated with grave diseases of the pancreas, but the relationship of the pancreas to carbohydrate metabolism has not been clearly recognized until von Mering and Minkowski succeeded in completely extirpating the organ in dogs. Of the pancreatic lesions, which have been often associated with diabetes, the most common is chronic interstitial inflammation of that organ. Opie suggests that the pancreas may bear some such relation to diabetes mellitus as the thyroid gland bears to myxedema. Pancreatic extract administered in cases of diabetes mellitus, however, has not yielded the brilliant results that thyroid extract has in myxedema. [A.B.C.]

2.—Diseases of the Pancreas.—G. R. Butler points out that prevention of these lies in an appreciation of their causes, including syphilis, tuberculosis, arteriosclerosis, alcoholism, cardiac, pulmonary, and renal disease, acute and chronic infections, obesity, diabetes (not of pancreatic origin), proximal neoplasms, catarrhal and bacterial diseases of the intestine, and

affections of the liver and gallbladder. Disease is rarely recognized *intra vitam*. Various remedies have been used with reported good results, but the correctness of the diagnosis is in each case open to doubt. Iron, nitromuriatic acid, chlorin, calomel, and corrosive sublimate have been lauded. Pancreas therapy has been disappointing, in that disease of the organ has not been modified, though some pancreatic preparations have measurably improved the digestion of fats and proteids. Treatment is confined to a relief of symptoms. In the presence of pancreatic calculi, injection of pilocarpin increases pancreatic secretions. [H.M.]

3.—Classification and Symptomatology of Diseases of the Pancreas.—Charles G. Stockton states that tumors of the pancreas occur as carcinomas of various forms, adenomas, tuberculosis, syphilis, and cysts, the last being divided into at least three varieties: Retention cysts, proliferation cysts, and hemorrhagic cysts. The inflammatory diseases of the pancreas are chronic pancreatitis, which is usually described as indurated, although fatty degeneration and ingrowth of adipose tissue often form a considerable part of the mass. When induration involves the head of the pancreas it may, from pressure, obstruct the common bile duct and give rise to phenomena that suggest malignant growth or cholelithiasis. If the common duct escapes there may still ensue symptoms of more or less importance depending upon interruption of the pancreatic function. If the disease invades the islands of Langerhans, diabetes may arise, but if these regions are spared, nothing more than a persistent glycosuria could be expected. The symptoms are those of intestinal indigestion, occasionally fatty stools, lipuria, sialorrhea, emaciation, and in some instances severe anemia. Robson classifies inflammatory disease of the pancreas as acute, subacute, and chronic; Fitz describes pancreatic hemorrhage, acute hemorrhagic pancreatitis, gangrenous pancreatitis and suppurative pancreatitis as well as the chronic forms. The symptomatology of acute pancreatitis is dwelt upon at some length. [A.B.C.]

4.—Renal Decapsulation from the Pathologist's Point of View.—Joshua M. Van Cott and Archibald Murray carried out a series of experiments for the purpose of determining the effect of renal decapsulation upon normal kidneys, and also the relation of the renal collateral circulation to atrophic conditions of the kidney. Sixteen operations were performed upon eight cats; in some instances the kidney was delivered through an incision in the back, close to the vertebral column, the capsule stripped, ablated, the kidney returned, and the wound sutured; in others the kidney was delivered in the same manner, decapsulated and returned between the muscles and the superficial integuments, for the purpose of gaining a larger capsular blood-supply. In both of these operations the artery alone, the vein alone, and both vessels together, were ligated in secondary operations, time being allowed for the healing of the primary wounds. The uniform result was a positive injury to the normal kidney. Their conclusions are that (1) on teleologic grounds the renal circulation can not be restored by decapsulation; (2) no amount of renal circulation would restore the integument of the cortex; (3) chronic nephritis being a local expression of a general disease will yield only to such treatment as is calculated to cure the general disease. [A.B.C.]

5.—Cancer of the Intestine.—J. G. Sherrill states that primary cancer of the intestine occurs more frequently than is usually believed. Hemmeter has collected 69,083 reported autopsies with 5,796 carcinomas (8.4% of the whole number); of these 1,296 were of the intestine. DeBovis gives carcinomas of the small gut, 6.3%; sigmoid, 11.9%; colon, 20.4%; rectum, 49.2%; which leaves 12.2% for cecum and appendix. Nothnagel's 12 cases of sarcoma show one involving the duodenum, 3 the jejunum, 4 the ileum, 3 the cecum, and 1 the rectum. The most common symptoms of the disease are tumor, which appears in every case, lasting for any length of time, and cachexia, together with the symptoms of chronic obstruction. The author reports in detail two cases. In the first the patient was a woman of 26, a laparotomy upon whom revealed a carcinoma of the cecum and ascending colon, and the other was a man of 54 with a carcinoma of the cecum and ascending colon. The first patient died; the second was suffering a recurrence at last report. [A.B.C.]

6.—Fracture of the Base of the Skull with Resulting Epilepsy.—C. J. Aldrich reports that at the age of 18, a young man fell into the hold of a vessel, a distance of 12 feet, striking squarely on his feet; he was unconscious and blood flowed from the mouth, nose and left ear; it was found that he sustained a fracture of the base of the skull; there were no marked contusions on the body. Four weeks following the injury he was completely unconscious and at times delirious. Consciousness returning his mind was a complete blank. He had forgotten everything and had practically to relearn what he had forgotten. Eight months after the injury he returned to a sailing vessel but did not appear to fully regain his faculties for over a year. One year after the injury he was seen to have a "spell," which was undoubtedly an epileptic convulsion; 11 years later (1899) he had another epileptic convulsion and since then he has suffered repeated attacks. The attack is not preceded by an aura; the patient is a perfectly healthy man, weighing 190 pounds, without the least sign of degeneration, has no history of alcoholism or syphilis. Aldrich has been able to find reported but one other instance in which epilepsy has resulted from fracture of the base. This was the case of Golebiewski. [A.B.C.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

The Clinical Importance of the Appearance of the Tongue.—The importance of the symptomatology of the lingual mucous membrane has been recognized by physicians from the earliest recorded date of the practice of clinical medicine. Whatever other attentions may be expected by the average patient on the approach of a physical examination, he always anticipates that his doctor will feel his pulse and look at his tongue. One of those items of research revealed the state of the circulatory, the other of his digestive organs. The physicians of olden times also looked at the urine; but, it need hardly be added, the further chemic and physical examination was absolutely defective. Having regard to the state of the physical sciences down to within less than a century ago, it was a very natural consequence that the physician of former times attached an undue importance to the value of these three series of phenomena; on which his diagnosis and prognosis—and, of course, his treatment—were inevitably based. For him the tongue was the mirror of the stomach. Its mucous membrane being an essential, and a specially sympathetic, portion of the lining of the digestive tube, its condition unfailingly indicated that of the latter—more particularly of the stomach, to which was attached the leading role in the process of digestion. If the tongue was heavily furred, the gastric surface was also loaded with detritus, and an active emetic was required to free it of its objectionable coating. This often gave considerable relief, but when it failed to do so, as frequently happened, the process was repeated again and again, sometimes with gruesome consequences. In a recent communication,¹ Drs. Mathieu and Roux have critically examined the value of lingual diagnosis, and clearly pointed out the reasons of its frequent failure. They point out, following Lasg  , that the tongue is really a muscular mass, covered by mucous membrane. And they further proceed to indicate the important fact that the investment of this organ is really a false mucous membrane, derived from an invaginated process of the external layer of the blastoderm, and not, like that of the gastrointestinal surface, from the inner layer of that structure. Accordingly, in pathologic processes, it comports itself more like a portion of skin than of mucous membrane. On this account, the physician must be guarded against attaching too much importance to the information yielded by the time honored examination of the tongue. The general conclusions at which

¹ Gazette des H  pitaux, September, 1903.

Drs. Mathien and Roux have arrived are: (1) The lingual mucous membrane is really a process of the cutaneous investment of modified structure; (2) its furred condition is the result of an "excessive abundance" of filiform papillas, which form a dense thicket over its surface; (3) its (raw or) desquamated condition is usually the result of a form of superficial dermatitis.

REVIEW OF LITERATURE

Immunity in Variola and Vaccinia.—C. A. Hodgetts¹ reports several cases that throw light on the question of immunity caused by variola or by vaccination. The first is the personal experience of an English physician, who was vaccinated in April, 1893, had an attack of discrete variola the following December, was successfully vaccinated in 1897, and had an attack of variola in 1903. Three personal cases are as follows: An unvaccinated woman had smallpox in 1901, transmitting the disease to six other persons; in 1902 she was vaccinated in two places with vaccine from two sources; both were effective. The two other cases were instances of a second attack of smallpox within six weeks in one, and 11 weeks in the other, after the first attack. Hodgetts believes that the mild form of the disease that has prevailed in his province during the past few years confers but slight degrees of immunity when the person is brought in contact with variola in its more virulent form. It is perhaps inferior to that of a successful vaccination, and he thinks it extremely dangerous to allow such persons to remain unvaccinated after such an attack. [A.G.E.]

Therapeutics of Sea Voyages.—Martyn Westcott² says, on a sea voyage there is plenty of open sunshine and light, the air is uncontaminated by organic particles, passive motion takes the place of exercise for the feeble, tissue change is hurried, and theoretically we have a condition well suited to the convalescent, but for many patients the voyage proves anything but restorative. As a tonic and restorative and sedative for worn out or brain-fagged people a sea voyage is well suited, but for tuberculous patients, subject to pleurisy, a sea voyage is unsuited, especially in the tropics. The fast going steamers are not so well suited to convalescent patients as are sailing vessels, except that the latter are generally not provided with the conveniences required by patients, and even in the former these are of sufficiently meager character for surgical patients. On shipboard there is an entire absence of all the facilities for dressing and care needed. Dyspeptics who require a specialized diet, the aged or nearly bed-ridden people, and those with chronic rheumatoid arthritis should not be recommended to travel at sea. [A.B.C.]

Cause of Chronic Habitual Constipation.—H. Lorisch³ finds that the cause of habitual constipation probably lies in the too complete absorption of the food in the intestinal canal. In cases of constipation the solid matters of the feces are much less in amount than under normal conditions. This is due to an extraordinarily complete absorption of the nutrient substances taken in. The feces are thus rendered poor as a nutrient medium for the intestinal bacteria. The digestive and decomposition products are thus greatly reduced, and an important stimulus to intestinal peristalsis is therefore lost. This accounts for the sluggishness in intestinal movements which is probably the cause of the constipation. [B.K.]

Acute Leukemia.—A. Gilbert and P. E. Weil⁴ report two cases of this affection, one in a woman of 25, the other in a child of 9, both having previously been in good health. They insist particularly on the form pharyngeal of the disease; their former buccopharyngeal type they now divide into two—the anginous and the pseudoscorbutic; the latter is rare. The other types of the disease are the hemorrhagic, anemic, and the typical; in the last the lymphoid enlargement is sufficiently marked to make the diagnosis plain. The typical form is most rare and has an evolution that is subacute. The blood picture of acute leukemia, while apparently lymphocytic, is in reality myelocytic in origin. The writers consider that no cause is at present known for either acute or chronic leukemia. [A.G.E.]

GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

EDITORIAL COMMENT

The Prognosis of Radical Operations for Hernia.

—A glance through some important recent articles on the radical cure of hernia will reward the surgeon with a number of valuable suggestions, and afford most convincing proof of the rapid increase in popularity of operative treatment. Whereas ten years ago the use of trusses was almost universal, even with surgeons, and reports of a series of 200 operations from a single clinic were extremely uncommon, there are now many clinics where over 200 operations for the radical cure of hernia are performed in a single year. The almost perfect safety of operation in the hands of competent men gives confidence to the surgeon and the patient which now leads so many to undergo operation. Most striking proof of the safety of operation is given in the statistics of Pott,¹ who, continuing a statistical study which was awarded a prize at the University of Berlin in 1901, gives the results of a study of over 200 monographs published in recent years dealing with this subject. In 3,532 operations which he has tabulated from the reports of prominent surgeons since 1895, he finds a deathrate of a half of 1%. He quotes Borelius, who collected 650 operations by representative Scandinavian surgeons in 1895, without a death; and Champonniere, of Paris, who in 868 operations performed between 1881 and 1901 had only five deaths. Hilgenreiner² reports no deaths during the first six years in a series of 828 operations performed in Wölfler's clinic in Prague and one death from postoperative pneumonia in the last year during which 421 patients were operated upon. The question of greatest interest, next to the safety of operation, is the probability of permanent cure, and in this respect modern results are most encouraging. Halsted³ reports no recurrence in a large series of operations done by him personally since June, 1892. He attributes his success to improvements in methods of operating, such as the utilization of the cremaster muscle in closing certain cases; excision of the veins of the cord when much enlarged; and transplantation of the lower part of the rectus muscle in cases in which the conjoined tendon is obliterated or very weak. Transplantation of the rectus muscle was first introduced in Wölfler's clinic, and Hilgenreiner⁴ reports almost 2% improvement in the small percentage of recurrences (now 6.7%) since this method was introduced. Another important factor in preventing recurrence in recent years has been the freedom from infections. Both Halsted and Hilgenreiner specially mention the great things which the introduction of operating gloves has done in bringing about this improvement, and they find it possible to limit the number of infections to less than 1% since gloves have been used. We believe Ochsner⁵ deserves much credit for emphasizing several indispensable conditions for obtaining good results, among them the importance of one of the great principles of surgery, that there should be no tension in suturing in connection with the operation for the radical cure of hernia. The rapid increase in the use of local anesthesia by many surgeons is another noteworthy point. Goldner⁶ states that in Hochenegg's clinic in Vienna most operations for the radical cure of inguinal hernia are now done under local anesthesia, the number of cases in 1899-1900 being 130. Local anesthesia not only relieves the patient of the disagreeable necessity of losing consciousness, but greatly lessens the

danger of postoperative pneumonia; by eliminating vomiting after anesthesia it prevents strain on the wound and the tearing out of stitches. The most important factor of all is the care and experience of the operator. While recent reports from a number of clinics show almost entire freedom from recurrence, Coley, whose personal results have been strikingly good, reports 361 recurrences which came under his observation at the New York Hospital for Ruptured and Crippled. Almost all of these failures could probably have been avoided had the patient first consulted a man thoroughly acquainted with the best methods. Considering the extent to which patients are hampered by wearing a truss, its discomfort and the ever present danger of strangulation if it is removed even only for a bath, and on the other hand, the freedom from danger and a practical certainty of permanent cure by the radical operation, it would not seem that there should be any question in the minds of intelligent practitioners as to the course of treatment which it is desirable to advise for patients who are suffering from hernia.

REVIEW OF LITERATURE

Deep Ulnar Nerve Paralysis.—Tennyson Patmore¹ reports that a carpenter of 27 was struck by a hammer over the left lower radial region while the ulnar edge of the hand sustained the counter blow. Two weeks after the accident he noticed the ulnar fingers were commencing to become bent, later he found it impossible to pick up small objects with the left hand; four months after the accident the hand was markedly smaller than its fellow and the intermetacarpal space distinctly hollow, there was waste of the thumb and small finger muscles and the two fingers were markedly clawed. He had complete sensation in the ulnar portions of the hands and fingers. The peculiarity was with complete deep ulnar paralysis we have still remaining a good rough hand-grasp; we have the thumb opposing powers and flexion powers derived from the median and we have the lost adductors supplanted to a useful degree by extensor and flexor muscles. It is important to differentiate complete destruction from incomplete destruction, though both are serious. Operation was recently done on the patient in question, but the results had not become apparent. [A.B.C.]

The Newer Methods for Diagnosing Unilateral Kidney Lesions.—M. Krotoszyner and W. P. Willard² detail the results of studying eleven cases. They find that none of the methods for determining the functional capacity of the kidneys are accurate enough to determine that a kidney should be removed; their value is in comparing the two organs. A necessary condition for the application of these methods is ureteral catheterization, preferably of both ureters. If both urines thus obtained are subjected to cryoscopy, phloridzin test, urea examination, and microscopic study a fair idea of the functional value of either kidney may be secured and safe conclusions as to operative procedures adduced. The writers believe that urinary segregators should be restricted to the very few cases in which cystoscopy is impossible. In one case of contracted, sensitive bladder where a small quantity of fluid rapidly became cloudy, spinal anesthesia allowed satisfactory filling and examination. Infection from ureteral catheterization must be a very remote danger. The phloridzin test was found fully as valuable as was cryoscopy; its true value lies in comparing the results on the two sides. [A.G.E.]

Fractures of the Skull.—Louis B. Rawling³ concludes his second lecture concerning fractures at the base of the skull. With reference to prognosis and treatment, he says, the discharge of cerebrospinal fluid does not materially influence prognosis; large quantities of the fluid may be lost without producing any striking effect and the danger of infection does not appear to be materially increased, since the outflow tends to wash away any microorganisms present in the external meatus. Battle records 36 cases of fracture at the base with a

mortality of 25%, and another writer 11 cases with a mortality of 27%. The general mortality in all cases of fracture at the base is estimated at 32%. It is most inadvisable to syringe out the ear, as a stream of fluid is driven into the middle ear and often further, if the tegmen be extensively comminuted and the danger of infection is proportionately increased. The meatus should be merely swabbed out with some strong antiseptic, a little iodoform powder lightly blown in, and absorbent protective dressing applied, the whole being maintained by a firm bandage. Frequent change of dressing may be necessary, the patient must be watched carefully to prevent attempts to interfere with the bandages. When the fluid escapes from the nose or into the nasopharynx little can be done to lessen the risk of infection, and as a result meningitis is most commonly secondary to fracture of the anterior fossa. [A.B.C.]

Open Treatment of Wounds by Exposure to Sunlight and Dry Air.—As long ago as 1886, O. Bernhard¹ noticed the excellent influence of the mountain air and sunshine upon wounds of all kinds. Tuberculous patients, by simply changing their abode from the valleys to the mountains, often improve so much as not to require operation for glands, joints or other processes. He always exposes such individuals first to light, air and sunshine for a definite time, to note their action on them before proceeding to operate. Of wounds, the most suitable for open-air treatment are the granulating wounds, also the invisible diseases lying near the surface. Deep pockets also diminish quickly in size. The patient's wounds are exposed daily, even in cloudy weather, for some hours to light and air and in the meantime are protected only by a gauze dressing. The secretions of the wound rapidly dry under the influence of the dry air and the wound becomes covered by a parchment-like skin, which protects it very well. This must be lifted up at times to permit the wound to be treated directly. A series of photographs well illustrate the effectiveness of the method. [E.L.]

Case of Double Gangrene following Mild Attack of Enteric Fever.—A. Dodds² reports that a man of 22 suffered from enteric fever, going through a typical mild attack, the temperature never rising above 101°. Two weeks after admission he complained of pain in the right calf, which later became hard, but was not inflamed, though there was an area of anesthesia on the outer surface; two days later the dorsum of the right foot showed some discoloration, which later extended up to the ankle, and there was great pain in the calf. At the same time the patient complained of similar pain in the left leg and anesthesia on the outer side of the left calf, and the following day discoloration likewise appeared in this leg, while the discoloration of the right had extended almost to the knee. Treatment aiming to combat the gangrene was of no avail; from the very beginning no pulsation could be felt below the popliteal space in either leg. There being no line of demarcation, and the patient being in poor condition, amputation was advised but refused until three weeks after the onset of symptoms of gangrene. Then double amputation was done, though with small hope of saving the patient's life. Accordingly the right leg was amputated in the middle third of the thigh, and five days later the left; two days after the last amputation the patient died. A necropsy showed that the stumps were doing reasonably well, but evidently the systemic poison had reduced the patient's vitality to such a degree that a fatal termination ensued. [A.B.C.]

Renal Skiagraphy.—L. H. Harris³ has examined 328 patients suspected of having renal or ureteral calculi; from them 50 correct positive results, proved by subsequent operation, were obtained, and 7 mistakes were made. Two of the mistakes were made on thin patients. The best results are secured with soft tubes and long exposures. The negative contains all the reliable information. Of the 50 calculi found, only 2 were ureteral. Harris believes that Leonard's figures of 50% for ureteral calculi are entirely too high, and that his findings of 4% is much nearer the true frequency of ureteral as compared with renal calculus. E. LINDAUER

REVIEW OF LITERATURE

The Chlorid Reduction Treatment of Chronic Parenchymatous Nephritis.—F. Widal and A. Javal¹ give in detail the results of 72 days' treatment of a case of parenchymatous nephritis during which the amount of chlorids in the diet was suddenly changed nine times; in this way they produced alternately five times a discharge of chlorids and four times their retention. The hydration or dehydration of the system was obtained at will and according as the hydration was pushed they produced either simple increase in weight or edema. The degree of albuminuria followed the oscillations of the chlorid retention curve. Widal and Javal assert that salt is the dangerous foodstuff in certain cases of chronic parenchymatous nephritis and a chlorid reduction cure must at times be insisted upon. The favorable effect of milk in nephritis is largely due to its relative poverty in chlorids; foodstuffs hitherto considered harmful may with advantage partially or wholly replace milk if sodium chlorid be not added to them. Among these are meat, bread, sugar, potatoes and butter. Rice and pastry, if made without salt, will give similar results. The nature of a food is less important than the question of its salt content. It is not the albumin in a meat diet that is harmful but the salt that is added to it. In the experiment cited it was only the addition of sodium chlorid to the meat and potato diet that gave rise to the retention of chlorids, hydration and albuminuria. [A.G.E.]

Massage in the Treatment of Constipation.—Among contributing causes of chronic constipation, says J. K. Mitchell,² are: Weakness of the abdominal walls; inefficient peristaltic action; deficiency of intestinal, pancreatic, or biliary secretions; irregular habits of defecation; and accumulation of feces in the intestine, causing dilation and consequent enfeeblement of the intestinal muscular walls. Inability of the rectum to contract with power enough to expel feces is another occasional cause of fecal retention. In the treatment of these several states the masseur must discriminate. When the abdominal walls are very relaxed and weak, as, for example, after frequent pregnancies at short intervals, their muscles will need manipulation, and active exercises to strengthen them should also be prescribed. To general abdominal massage the operator should add, in persons of constipated habit, several manipulations of the abdomen—fist-kneading, cart-wheel movement (knuckle-kneading), and deep digital-kneading along the colon in the direction of movement of the intestinal contents. The hand-grasp of the abdominal walls should be as deep as possible and pick up as much of the walls as can be retained, while the thumbs are used to perform friction along the large intestine. General pétrissage of the abdomen with one or both hands, sharp tapotement (slapping or clapping), and, finally, vibration of the whole abdomen complete the sitting. The effect is to stimulate the muscles of the abdominal wall, and in time to strengthen them. The peristaltic movements of the intestine are stimulated and increased both directly and reflexly, and so are the secretions of the intestinal glands. The circulation, venous and lymphatic, is hastened, thus adding to the amount of intestinal liquid, and, lastly, the accumulations of feces are broken up and their passage along the intestine mechanically hurried. When the conditions point to a lack of biliary secretion, special manipulations, chiefly vibration and tapotement, in the neighborhood of the liver and gall-duct, should be performed. For atony of the rectum or impaired action of the ileocecal valve vibration movements must be applied; for the former condition the fingers held pyramidally together are pressed deeply down in the left iliac fossa, so as to approach as near the head of the rectum as is possible, and strong rapid vibratory movements are then imparted to the hand by contracting the forearm muscles. To stimulate the relaxation of the ileocecal valve and allow the propulsion of intestinal contents from the small into the large

intestine, a similar movement should be administered at the point of junction of these two portions of the intestine. Vibration applied directly to the anal orifice is said to have a stimulating effect on rectal contraction. Vibration given at the ileocecal junction and also about the head of the rectum, if well done, will frequently produce an evacuation of the bowel within a few minutes.

Antimalarial Work.—Frederick F. Mossell¹ reports results of two seasons' work against malaria at Fort Washington, Md. The fort is an isolated community of 400 people, mainly soldiers, on the left bank of the Potomac, 13 miles below Washington. The reservation comprises 365 acres, and there are a number of ravines and wide marshes which have been favorite breeding places for mosquitos. In July 1901, war was waged against the mosquito by the use of mineral oil and illuminating oil in the destruction of the larvas. Little seemed to be accomplished the first season. Before the attempt to exterminate the mosquitos, the malarial cases for 1898, 1899, and 1900 ranged from 16% to 19%. The second year the warfare was extended, and the pools and breeding places were treated with petroleum from the first of April, twice a month, to the end of the season. The most effective treatment was by the drainage of the swamps and marshy localities. The improvement is well shown by the monthly average of cases which within two years has dropped from 19% to 4%. [A.R.C.]

"Migranin" (Antipyrin) Poisoning.—H. Henneberg² reports the case of a girl of 20, who on account of severe headache, had taken a "migranin" powder. "Migranin" is a powder composed of 85% of antipyrin, 9% of caffein, and 6% of citric acid. She took the usual dose, 1.07 gm. (16½ gr.), on an empty stomach. She vomited immediately, and shortly after lapsed into unconsciousness. When Henneberg first saw her, her lips were blue, face pale, pupils dilated, her limbs cold, and her pulse could be felt with difficulty. She was still unconscious. While her stomach was being washed out she came to, and by the next day she was perfectly well. He cites similar cases from literature; in some of them symptoms of poisoning were noticed after even smaller doses. As the ability to take this compound varies so much in different individuals, Henneberg advises: (1) To begin with smaller doses; (2) never to take it on an empty stomach; (3) to prohibit its sale except on prescription. He has seen violent vomiting and dizziness after taking small doses of pyramidon. [E.L.] [The coaltar products are all and always dangerous. Their use as palliatives for headache is worse than foolish; their use as antipyretics in the light of present knowledge criminal. Migranin is one of the worst of the proprietary combinations with fancy names. S.S.C.]

Treatment of Hemoptysis.—J. Penn Milton³ states that the cases of pulmonary tuberculosis with hemoptysis should be divided into four classes: 1. That in which the hemoptysis occurs early and is the first initial sign of tuberculosis before consolidation can be demonstrated. In these cases exercise is a valuable remedy when counterindications do not exist. The rationale is that the bloodvessels in all parts of the body become dilated and take a certain quantity of blood away from the lungs: this compensates for the extra amount of blood, which, induced by exercise, passes through the lungs. The treatment must be applied individually and not generally. The counterindications are fever, loss of blood sufficient to weaken the patient and nervousness. 2. That in which the disease has existed for some time and physical signs reveal decided consolidation. Here the treatment should be directed toward strengthening vitality and improving nutrition by sanatorium treatment and forced dieting. 3. That comprising advanced cases of the disease in which cavitation is present. Hemoptysis is here serious, and apt to be copious, and terminate in death from ulceration into a large bloodvessel. Treatment consists in rest, lessening the heart-beats and lowering blood-pressure. 4. That comprising plethoric subjects. The treatment indicated here is to lower blood-pressure. A full amount of exercise, provided there are no counterindications, and a modified diet are indicated. [A.B.C.] [Exercise during bleeding cannot be commended. S.S.C.]

VOL. VII, No. 23.

JUNE 4, 1904.

\$5.00 YEARLY.

The Patent Medicine Frauds and the Postoffice.

—*American Medicine*, as our readers know, has been very persistent in pointing out the fraudulent character of many of the so-called "patent medicines," the nauseating literature of which fills the cheap newspapers and the United States mails. Some of our subscribers have even thought we were unwise in being at least among the first, and surely the most insistent, in advocating the restriction of the evil by means of the law and some government control. The Women's Christian Temperance Union, and especially that tireless Superintendent of the Department of Nonalcoholic Medication, Mrs. Allen, deserves the congratulations and gratitude for the noble work done. A method, simple and practicable, has been found whereby, if courage does not fail the United States Government officials, the shameless scoundrelism may be vastly lessened, if not extinguished. Every physician, every one of the more than 100,000 physicians of the land, should write his word of hearty encouragement, and in all ways support the postal authorities in their purposed crusade against the fraudulent nostrum vendors. With the assistance of government scientists, the department seeks to bar from the use of the mails the host of patent medicine concerns and exploiters of proprietary medicines and nostrums which chemic analyses show are harmful or are incapable of performing the wonderful cures claimed for them.

Government Analyses of "Nonalcoholic" Nostrums.—We have often published accounts of the absurd claims of the patent medicine vendors, and the analyses of many of these preparations which have been made by the Massachusetts State Board of Health, etc. The U. S. Governmental chemists, at the request of the post-office authorities, have recently published reports of their own analyses of some of these concoctions. Joining the two lists, we have the following results:

	Percent alcohol.
Lydia Pinkham's Vegetable Compound . . .	20.61
Warner's Safe Tonic Bitters	35.7
Hostetter's Bitters	44.3
Colden's Liquid Beef Tonic	26.5
Kilmer's Swamp Root	7.23
Parker's Tonic	41.6
Drake's Plantation Bitters	33.2
A Famous Catarrh Remedy	27.3
Howe's Arabian Tonic	13.2
Schenck's Sea-weed Tonic	19.5

	Percent alcohol.
Hooiland German Bitters	25.6
Whiskol	28.2
Kaufman's Sulfur Bitters	20.5
Goldcura No. 1	41.11
Goldcura No. 2	28.22
Peruna	28.59
Vinol	16.77

These cheats, it must be remembered, are often if not always recommended as "cures for alcoholism," "cures for inebriates," "not a rum drink," "entirely harmless," "free from alcoholic stimulant," "nonintoxicant," "whiskey without its sting," "for the alcohol habit," "for the liquor habit," etc. Thus are they not only manifestly fraudulent, not only increase inebriety, but they fix the habit under the plea of curing disease in those who have not been addicted to it. Could meanness and outrage go further? It is time that the people and their government should crush the hideous crime.

Some Nonalcoholic Frauds.—Sins of omission, lies, and deceptions of many kinds may be almost as harmful as the positive alcoholic trickeries. The proprietors of the White Ribbon Remedy were more cunning than those of the "Bitters" and alcoholism cures. There was no alcohol, indeed no active substance whatever in the stuff, and water could not have been more inert than the milk sugar and ammonium chlorid it contained. Among the remedies which have been analyzed by the Bureau of Chemistry of the Department of Agriculture the following are noteworthy: "Mormon Bishop pills" were found to contain "red pepper, starch, and a bitter principle." "Tuberculozyne," two preparations, was found to consist of water, alcohol, sodium phosphate, tartaric acid, and glycerin; also water, alcohol, copper oxid, and glycerin. The chemists say of them: "Not one of the ingredients, or a combination of the same, contained in the two packages examined is of any recognized service in the cure of tuberculosis." "Sir John Hampton's Vital Restorative" consisted of pills composed, one of saw palmetto and licorice, the other of methylene, which latter produces an effect calculated to frighten the patient. "Tissue Food" consisted of an emulsion flavored with lavender. The Department says of it: "There is no such virtue in this article as claimed for it in the advertisement." "Dr. Ferris's Medicine" and "Four Special Prescriptions," also from Dr. Ferris,

contained chiefly starch. The Department says of them: "It is perfectly evident that starch paste is of little value as medicine."

Newspaper Debauchery.—Thousands of newspapers, surely 99 out of 100 of those of the whole country, will probably rise in open warfare against the attempt of the United States postal officials to exclude from the mails even the vilest and most patently fraudulent of patent medicine literature. It should not be forgotten that the fraud order will apply logically and necessarily to the newspapers whose chief and most certain income is derived from the wretched advertisements. One must doubt if there is so much virtue in any body of politicians as the actual carrying out of the order would require. It would seem as if no political party could live, or continue its officials in power with thousands of newspapers furious at financial loss and at the politicians who would allow it. There is no sort of question as to the righteousness and justice of the movement, and some time and in some way it must be actualized. The great body of the religious press, profoundly irreligious in such matters, will also join in the hue and cry, and every devotee of eddyism and of a thousand similar types of humbuggery will not be silent, each in his and her way. All faith cures whether by means of nostrums, "thought," occultisms, vibrations, healings, metaphysical or intensely physical, are at heart united in the common bond of hating science and loving non-science and nonsense. The professional duty is not a whit the less clear. However hopeless it may at first seem, reform may come in strange and unexpected ways. Far more important than any political question which now motives party action is the patent medicine disgrace, and it is more harmful to the people than any abuse "denounced" in the platforms of national conventions. If they "mean business" let a thoroughly united profession hold up the hands of the Postmasters General and of the administration which supports them.

Medical Advertising Again.—At last the sense of the community seems to be waking up to the unfortunate evils that inevitably underly medical advertising. Certain newspapers throughout the country that are under the control of one very wealthy man, the policy of whose editorial utterances is always keyed at a high note of sympathy for the poor, have been especially flagrant in this matter. These newspaper enterprises have unfortunately become, because of the success which they have achieved, the models for many other newspapers throughout the country. It is especially interesting then to find that attention is being called to the fact that in the midst of all this pretense of care for the poor there is what is practically a combination for money-making purposes with certain forces of evil that make for the cheating of the poor out of their hard earned wages.

One of these papers published in New York city is known for the editorials in many kinds of type with abundant use of capitals, which are supposed to educate the poor man to a knowledge of his rights. A New York contemporary, *Collier's Weekly*, for May 21, 1904,

suggests a special editorial in medical advertising as something that would be likely to tell at least one great truth to hosts of sympathetic readers much more honestly than is usually the custom on the editorial page. The suggestion has all the features of display type and punctuation peculiarities that characterize these newspaper efforts along the same general lines, and as presidential campaigns make men sensitive to a degree not always noted at other times perhaps it will have a good effect. As it expresses some very telling truths in very straightforward manner we give it:

LISTEN.

To the billion readers in our Hearst family ONE WORD.

Let them EXAMINE this paper.

They will find over a page of advertisements by quack doctors, of a kind which reputable papers will not print.

They will find masses of advertisements of patent medicines. One contains 44 percent of alcohol. One, advertised as "safe," contains over 35. We KNOW they are poison.

We aid and abet clairvoyants, palmists, astrologers, and card-readers. Why do we carry all these schemes to CHEAT THE POOR?

Did you ever study proportion?

Neither has the poor savage of Australia, but we have, and our morality is determined by the ratio of cost to what we get out of it.

As it is in these petty swindles, so is it in the larger bunco games of politics.

We defend the poor when it PAYS.

We cheat the poor when it PAYS.

THINK IT OVER.

Physicians will be interested in this brief but pointed exposition of the policy of newspapers that pretend to be doing good to the poor. It might be well for members of the profession generally to carry a copy of this scathing rebuke so as to spread the light of truth with regard to the difference between editorial pretense and the stern realities of editorial policy as manifested by the advertising department of newspapers. The present lamentable abuses in this matter will never cease until an enlightened public opinion has condemned them. In this as in many other things physicians must be leaders and moulders of public opinion, and then we can look for the amelioration of present conditions which ought to be expected from our twentieth century civilization. Then perhaps too there will be less half-hearted action on the part of those who recognize the evil yet compound with their consciences as regards the milder manifestations of it. For *Collier's* itself is not above carrying medical advertisements the character of which is of more than dubious honesty even as medical "ads" go.

State Supervision of Water-supplies.—Dr. Benjamin Lee says that if Butler has slain her hundreds, Philadelphia in like manner has slain her thousands, and has gone on with her massacre with a cold-blooded, diabolic unconcern almost incredible for more than a generation, in spite of tears, petitions, remonstrances

and importunities. The Butler Water Company must bear the heaviest burden of responsibility for the typhoid epidemic in that city. The lessons to be learned from the Butler epidemic, Dr. Lee concludes, are as follows:

1. The necessity for the enactment by the next Legislature of a law establishing a health authority in every county and in every township, amenable to the central health authority, but possessing ample power to enforce its own regulations.
2. The adoption of legislation compelling the reporting of deaths and communicable diseases in all cities, boroughs and townships, and the registration of the same at the Central Bureau of Vital Statistics.
3. The passage of laws for supervising the construction and inspection of all dams and of all waterworks.
4. The moral obligation resting upon physicians, entirely apart from legislative enactment or compulsion, to report to the health authorities with the utmost promptness every case of communicable disease occurring in their practice.
5. The danger of using any surface water without filtration.

The chief criticism of the present Township Health Board act, and that which nullifies its effect for good, is that it is only permissive, not mandatory. Until there is compulsory supervision by the large central authority there will be no reform of the present deplorable conditions which entail so much unnecessary illness and so many needless deaths.

"The Man Who Made Consumption Pay."—A professional consumptive, or mendicant, a church and hospital "rounder," is up for trial in New York. It seems that this fellow of many aliases has made a good living for at least 12 years by appeals to the selfish charity givers. He has "operated" upon at least 20 church organizations and societies. To his virtues and vices he has, of course, added larceny. From a woman who had just given him \$20 he had the poor judgment to steal \$5 more, and now his victims are combining against him. His scheme was to join a church, attend its meetings, and make acquaintances personally and through the "year book," which generally gives the names and addresses of contributing members. Soon he had a stock in trade of reminiscences of meetings and personal words to pass around from one person to another, telling that he was sent by such and such a personal friend. The trouble always was that he had consumption and must go to a warmer climate. When one church began to wake up to his plan he flitted to another. Only by the methods of investigation of the charity organization societies, or better, through these societies themselves, can society be ridded of these pests, who are more numerous than is supposed.

The work of the Philadelphia Pediatric Milk Commission, for the years 1902 and 1903, gives evidence of a peculiarly valuable combination of science and benevolence. The profession and citizens of Philadelphia should take pride in and give encouragement to the unselfish labors of the members of the commission, and other cities may well study the methods and results attained here. The commission now certifies to seven milks and four creams, the products of six dairies. This shows an increase of the demand for certified milks. A

standard of 25,000 bacteria to the cubic centimeter of cream has been settled upon although the vast majority examined have a less bacterial content than 15,000. A high bacterial content is now almost always traced to some specific cause. In the standard of 20% cream a variation between 18% and 22% is allowed. The standard of milk proteid is 3.5%, with a variation between 3% and 4%. The variation for the fat content has not been changed, but the commission now certifies to 5% fat milks. These results emphasize several facts. It is possible to produce milk and cream having a fairly constant fat content; the proteid content of a large number of standard milks, determined by the Kjeldahl method and examined at irregular intervals, at all seasons of the year, over a long period of time, is very close to the present accepted average of 3.5%; the variation of the fat content is much greater than that of the proteid, and both vary sufficiently to produce decided daily variations in the percentages of our milk modifications. The committee regrets that there has not been a proper demand for clean milk. "If any of the ordinary uncooked foods were prepared under as unhygienic conditions and contained the filthy products that the ordinary market milk contains, we would not tolerate them."

The Therapeutics of Morbid Emotion.—The chief component of mind is feeling, says a great modern philosopher, and suiting the action to the word, in a double sense, the superintendent of a modern psychopathic hospital finds one of the best methods of treating his patients to be through the medium of the emotions themselves. The effect of peace, quiet, woods, and country life upon the diseased mind is undoubtedly great and the huddling of thousands within the crowded walls of city hospitals should show a higher rate of incurability and mortality than when the institution is located "far from the madding crowd." Another illustration is suggested by the question if much of the good derived from medical calisthenics does not come from the rhythmic movements of the drill. "No less potent on the emotions is the influence of the recurrent attitude of the head, limbs, and body which express cheerfulness, hope, courage and other expansive feelings. Especially is this true if the exercises are given in a pleasant gymnasium before an enthusiastic instructor who injects into the figures the spirit of play with plenty of mirth and laughter. This physical attitude begets corresponding emotions, which react happily on the organic sensations, completing in this manner the circuit of reaction which in its recurring round of excitation lifts the mental invalid to the level of restored health."

The medical pension examiner, according to report has made himself too much of a politician. Is the criticism just? There are said to be about 4,500 such examiners scattered throughout the whole country, each, so it is said, appointed by the locally dominant political party, leader, boss, or authority. They are called "politician-doctors," charged with securing their appointment through partisanship, and using their

influence to uphold their appointers. It is even said that the trouble caused by the pension examiners, the expense and worry in getting one suspended and another appointed who will be a better vote-getter, etc., is responsible for much of the demand for a straight-out service-pension.

A congressman, so the report goes, expects the commissioner to dismiss a doctor who does not give him or his party a cordial support, and substitute somebody who will. If the commissioner balks, the congressman makes his life a burden. I have known one of these gentry to carry his protest and appeal first to the Secretary of the Interior, and then all the way up to the President himself, where a commissioner has refused to make a change he demanded. This sort of thing keeps us in a hurly-burly all the while; and as for a commissioner's temper—you never saw one that could stand it through a whole administration, no matter how good natured he was when he entered office. I shouldn't wonder at Commissioner Ware's welcoming any system that would give the doctors least to do, and us least to do with the doctors!

All of which, of course, if true, becomes a professional matter, as the whole body is judged by these representatives and the public estimation is lowered by such practices. But, again, are the criticisms and charges deserved?

EDITORIAL ECHOES

Health and Morality in Porto Rico.—The population of Porto Rico during March was 953,243, and the number of deaths was 1,852, or 23.4% per 1,000. This is 3% higher than the deathrate of New York city, according to the last United States census, and 5.6% lower than that of New Orleans. Sanitary conditions are better here every year. Fever is not feared as in former years, and, all around, there is a decided sanitary improvement. The mortality from anemia was 313 for the month. This is the scourge of the island, the poor half-starved native falling an easy victim to it, and, in fact, inheriting it from father and mother. The Insular Government is doing all that it can to stamp out the disease, but economic conditions will have to change before radical cures can be expected. Of the deaths on the island, 50% are entered under the head of "All other diseases." It is an open secret that most of these were natives—children mainly, who died like dogs with little or no attendance, except what a "voodoo" doctor may have been called upon to give for a few pennies. The little value placed on human life—where death comes from no political excitement or trouble that may excite the passions—is evidenced in the method of burial. Hundreds of Porto Ricans are buried every week with neither coffin nor decent burial clothes. The coffin—when one is used—is hired for the occasion, and at the grave the body is dumped out into the earth without the slightest covering. The coffin serves on many another occasion. Of the 9,170 births on the island during March, 38% were illegitimate. These figures among the natives—both of high and low degree—neither astonish nor beget a desire to improve the deplorable conditions. That nearly 4,000 children should have no right to a father's name is considered not even a piece of bad luck. The mother is neither held very much disgraced nor degraded from any circle in which she may be accustomed to move. Her mother and grandmother before her probably passed through the same experience, and were not ostracized. A shrug of the shoulders is all the return obtainable when a protest against the immorality is advanced.—[Special Correspondence *Evening Post*.]

AMERICAN NEWS AND NOTES

GENERAL.

Great Crusade against Baby Farms.—It is reported that the American Medical Association will take action upon this practice which is apparently prevalent all over the country. Aroused by the exposure made in Philadelphia, the American Medical Association, when it meets in Atlantic City, June 6, will make an attempt to rid the country of baby farms, mal-practitioners and unlicensed physicians. Since the crusade was started against these law-breakers by the police and the Philadelphia County Medical Society many cities have taken similar action.

Prizes Offered to Women.—The Naples Table Association, which has for its object the promotion of scientific research by women, has announced at Boston the offer of a prize of \$1,000, to be awarded in April, 1907, for the best thesis, submitted by a woman, on a scientific subject involving laboratory research. This is the third prize to be offered by the Association. The first prize was awarded in April, 1903, to Dr. Florence Sabine, of Johns Hopkins Medical School, for a research on the origin of the lymphatic glands. Mrs. Ellen H. Richardson, of the Massachusetts Institute of Technology, is chairman of the Prize Committee.

Candidates for Annapolis Must be Perfect Physically.—This announcement has been made by the Navy Department. Owing to the vital importance of obtaining young men who are practically perfect physically, the physical examination of candidates for admission to the Naval Academy has been committed to a medical board specially appointed for that purpose, and their decision will be held in every case final. No appeal will be entertained by the secretary. This rule was determined upon by the President at a Cabinet meeting recently. This places the physical qualifications, which in the naval service are of the utmost importance, upon the exact basis of the mental qualifications, which by statute must be finally determined by the academic board of the Academy.

The Discovery of Anesthesia by Ether.—Mrs. Elizabeth Morton, the widow of W. G. T. Morton, of Boston, to whom is attributed the discovery of anesthesia by ether, died on April 21, from pneumonia, at the Hotel Martha Washington. Mrs. Morton, whose maiden name was Whitman, was born in 1826, in Farmington, Conn., and was married to Dr. Morton in 1844. Soon after marriage her husband began that series of experiments which ended in the famous public demonstration that by the inhalation of ether vapor surgical operations could be rendered painless. It is a sad illustration of the proverbial ingratitude of republics that the American Government never admitted that Mrs. Morton had any claim on it, although the reports of six Congressional committees during her husband's lifetime had recommended that an appropriation of several hundred thousand dollars should be made in recognition of the value of ether anesthesia during the Civil war.

Disease Lurks in Canal.—Dr. Richard P. Strong, director of the biologic laboratory at Manila, P. I., has a paper in the fourth annual report of the Philippine commission showing how the Panama canal may become a factor in introducing yellow fever into our eastern possessions and the entire Orient. He shows that the Hawaiian Islands, Guam, and the Philippines will be exposed to the importation of cases of yellow fever or of infected *Stegomyia fasciata*, unless the disease can be banished from Panama. The disease often follows the lines of commercial maritime travel, and many instances are on record of its introduction by vessels into hitherto uninfected regions. It does not seem improbable, therefore, says Dr. Strong, that unless extreme precautions are taken against vessels passing from these regions and bound for ports in the far East, infected ships, and even cases of yellow fever will be conveyed from the above mentioned cities to Honolulu, or even directly to Guam, Hongkong, and the Philippine Islands.

Fighting Tuberculosis.—The spur given to research work for the extermination of the plague of tuberculosis has constant demonstration in the published discoveries of reputed remedies. The latest announcements emanate from New York, where a reputable physician has found that massage has a notable curative influence by removing obstructions to normal breathing and by increasing the patient's respiration; and from St. Louis, where two enterprising doctors declare they have found the secret of overcoming the "white scourge," to inhale in the plan of injecting a very powerful proteid found in healthy blood, thus increasing its carrying power in the patient and throwing off the disease. Another recently promulgated idea is that of the Italian physician, Dr. Maragliano, head of the University of Genoa, who is the foremost exponent of the plan to vaccinate consumptives with the tuberculosis serum, and who, it is stated, has inoculated fully 2,500 patients, with good effect. There is the essential element of hope for the sufferer in the cheerful activity of the medical men in their determined search for the antidote to the tuberculosis poison.—[*Boston Transcript*.]

Miscellaneous.—Philadelphia: The annual commencement of the Jefferson Medical College was held in the Academy of Music, Philadelphia, May 28; 165 men received degrees. The degree of LL.D. was conferred upon Professor Albert Hoffa, the professor of orthopedic surgery in the University of Berlin. The address was delivered by George F. Baer, president of the board of trustees of Franklin and Marshall College, and president of the Reading Railroad.—A report summarizing the result of the medical inspections of the schools, which was recently sent by Director Martin to the committee on hygiene of the Board of Education, showed that out of nearly 200,000 children examined but 5 were unvaccinated and only 1 had tuberculosis. Six cases of diphtheria, 11 of scarlet fever, and 30 of measles were also discovered, and those suffering from them were sent home. Defective eyes and ears were the main causes of pupils being sent home. During the month 4,956 children were excluded from schools because of minor ailments, and the medical inspector visited upward of 200 homes where school children were detained because of some slight affliction.—Dr. J. L. Faure, the distinguished Paris surgeon, conducted the clinic at the Jefferson Hospital, May 24.—Dr. Albert Hoffa, the famous orthopedic surgeon, of Berlin, conducted clinics at the Jefferson Hospital, May 26 and 27.

Conditions in the Philippine Islands.—The monthly report of the Manila Board of Health for January affords some interesting glimpses of physical and social conditions in the capital of the Philippines. The board estimates the population of Manila, basing its figures on the preliminary rough count of the census of 1903, at 219,941. The Americans number 4,389; the Spaniards, 2,528; other Europeans, 1,117; Filipinos, 189,782; Chinese, 21,230; all others, 895. The deaths in the month covered by the report numbered 826, of which 443 were without medical attendance. Infant mortality appears to reach a startling proportion in Manila, being 59.6% of the whole number. Our surprise disappears, however, when we turn to the summary of the sanitary inspection service and find that from the office of the sanitary engineer 178 orders were issued for the amendment of conditions of dwellings, while in the suburban districts the inspectors carried on a most vigorous overhauling of houses. In Manila there appears to be a contest in progress between modern sanitation and oriental fatalism, which must have great influence for good on the future of the Filipinos. How great is the need of autocratic supervision of people who never knew what sanitation was before we came appears from the record of the health board's fight against the cholera. In Manila in the calendar year 1903 there were 5,574 cases of cholera, and 4,378 deaths. In January, 1904, but four cases of cholera were reported in the city.—[*Boston Transcript*.]

EASTERN STATES.

Additional Hospital Buildings in Boston.—Two new buildings have been opened at the Boston City Hospital. One contains the surgical out-patient departments and the other contains three wards for patients who, because of the nature of their disease, need special treatment in isolated wards. The new surgical out-patient building contains a surgical service for men and boys, a surgical service for women and children, a surgical service for genitourinary diseases, a gynecologic service for women, a throat service and an eye and ear service. The building was laid out with the cooperation of the gentlemen composing the medical and surgical staff, and is well adapted for the treatment of different diseases by modern scientific methods. The upper story is occupied by bedrooms and sitting-rooms for the junior members of the house staff and subordinate officers, orderlies and other employees. The lower floor of this building is quite important, as it affords some additional means never before at the Boston City Hospital's command, such as admitting wards where suspicious cases of eruptive diseases may be cared for without risking the infection of a ward; rooms for the reception and treatment of cases of sunstroke, as well as lockers, toilets and robing rooms for physicians, house staff, nurses and orderlies. The surgical out-patient department building, with its substantial equipment, cost \$140,000, and Wards K, L and M, inclusive of furnishings, \$130,000.

NEW YORK.

Blood Poisoning an Accident.—Death from blood poisoning, following the cutting of a corn, is as much an accident as if the victim had died as the result of any other unforeseen catastrophe, according to Judge Buffington. He rendered an opinion to this effect recently in the United States Circuit Court, when he refused a new trial in the case of Katherine Nax against the Travelers' Insurance Company, in which Mrs. Nax recovered judgment on a \$5,000 accident insurance policy on the life of her husband, Leonard Nax. Nax, who lived at 1515 Diamond street, made a fortune in the manufacture of wooden pipes. In April, 1902, he pared a corn on his right foot. He cut too deep, blood poisoning resulted, and he died on June 22, 1902. Three months after his death, Mrs. Nax, in going over his papers, found an accident policy for \$5,000, issued by the Travelers' Insurance Company, and pressed her claim as widow. The company contested the claim, on the ground that Nax's death was not due to an accident. When the case was tried before a jury, in the Circuit Court, a verdict was returned in favor of the widow.

Would "Corner" Opium.—One of the firms in New York city which deals in opium and essential oils has sent out letters to rich men and those who are supposed to be interested in anything that permits of a corner, explaining that the supply of opium is far below the normal. The price per pound today is \$2.70, duty paid, while last year, when stocks were larger, the price was \$3.20 per pound. The firm does not believe that the demand has slackened sufficiently to warrant this drop in price, and expresses the belief that if any one cares to start to corner the market he would be successful. The firm says that a million or so in cash would not only suffice to control all the Turkey gum opium for two years, but would thereby enable the purchaser to put the price as high as the demand would permit.

New York's New Bath Houses.—The Milbank Memorial Baths, which will soon be open to the public, will provide the East Side with bathing facilities of almost Roman luxury. The abundant use of marble, the adoption of the most improved fixtures, and the greater provision for privacy render them superior to others. The flat dweller of 20 years ago would have envied those who are thus supplied free of charge with a convenience that can be obtained only at a high rental. Much has recently been done to remove from New York the reproach of inadequate bathing accommodations for the poor. We have been lamentably behind London, where the borough of Westminster provides its 185,000 residents with five large bath-houses and seven swimming pools with public laundries attached. The Milbank baths, on which \$150,000 has been spent, will accommodate 4,800 patrons a day. The bath in West Sixtieth street, on which work was begun in March, has room for about 5,000. The eagerness of the public to utilize free baths where they are made easy of access is indicated by the attendance of 1,500,000 at the five Brooklyn swimming baths during the three months of last summer. Mrs. Anderson's gift for the Milbank baths is philanthropy of an especially desirable kind, because of the sanitary form it assumes.

A Paradox in the Deathrate in Various Districts in New York.—By the last weekly report of the Board of Health the number of deaths in the Tenth ward was less than in the Eighteenth ward with its much smaller population, and in a year there are 1,200 deaths on an average in the Tenth ward and 1,500 in the Eighteenth. The same rule of disparity prevails generally through the wards of New York, the actual deathrate being least in those which are most thickly populated and largest in those less thickly inhabited. The Seventh ward includes the territory north of Catharine and south of Grand street between Division street and the East River. It has a present population of 90,000. Its area is 198 acres, or 450 persons to the acre. The Twentieth ward, on the West Side of town between Twenty-sixth and Fortieth streets, has a like population of 90,000, but in an area of 440 acres, or 202 persons to the acre. By the last published Board of Health report, for the third week of April, there were 30 deaths in the Seventh ward and 63 in the Twentieth. In a year there are 1,300 deaths in the Seventh ward and 2,000 in the Twentieth. Thus, while the overcrowding of population ought naturally to have the effect of increasing the mortality, and the absence of overcrowding ought greatly to improve hygienic conditions, the exact contrary appears to be the result.

PHILADELPHIA, PENNSYLVANIA, ETC.

Will We Have a New Insane Hospital?—It is stated that Director Martin will ask for \$1,000,000 to build a new hospital for the insane if a permanent loan for municipal improvements is submitted to the vote of the people next November. The item was included in the recent loan before it was cut to \$16,000,000. The State Hospital for the Insane at Norristown has 1,300 patients, for whom the city is paying \$1.80 each per week. Dr. Martin argues the city could save \$190,000 a year if it had hospital accommodations for them.

SOUTHERN STATES.

Smallpox and Vaccination in Baltimore.—Mayor McLane has agreed that extraordinary measures to stamp out smallpox in Baltimore be taken. Accordingly, Commissioner Bosley announced that he would engage 25 physicians to assist the 24 health wardens in vaccinating Baltimoreans. This extra force will be kept employed for at least 60 days. The 25 extra vaccine physicians will be selected from the ranks of the young members of the medical profession, who will be able to give their entire time to the work. These auxiliaries to the regular force of health wardens will be formed into bands and assigned at first to those sections of the city where smallpox has developed its presence. One of the greatest handicaps the Department has in its fight against smallpox is the indifference and unwillingness of the public to be vaccinated in advance of the disease making its appearance in their immediate neighborhood.—[*Baltimore News*.]

WESTERN STATES.

Doctors Advocate New Laws.—At a recent session of the Michigan State Medical Society a committee was appointed to act with the State Bar Association in its effort to secure State legislation for more desirable expert medical testimony in

courts. The Legislature also will be asked to establish a State sanatorium for the treatment of early stages of tuberculosis; to make a law to compel the registration of births as well as deaths; to pass a measure to prohibit the manufacture and sale of toy pistols; and a law to limit the times when suits may be started for malpractice to one year, instead of three, as at present, after alleged injury occurs, and that suits may not be started after the patient's death.

To Fight for Purer Milk in Chicago.—The Bulletin of the Chicago Health Department for the week ended May 21, states that the most frequently employed methods for the adulteration of milk are by skimming it, or diluting with water, or adding various adulterants for coloring the milk, and adding various preservatives, the most frequently used being formaldehyd, salicylic acid, or boric acid. Notes from the Laboratory: The success of the crusade for pure milk last summer has stimulated the Department to even greater efforts and energy this season. Not only the quality of the milk itself continues to be examined, but the inspectors also enforce the sterilization of bottles, etc., in accordance with sanitary regulations. What the Department is aiming at is the prevention of an increase of intestinal diseases among children during the hot weather. To this end the sterilization of all milk bottles is to be insisted upon. The city water is generally impure at present and if milk dealers are allowed to wash bottles in ordinary tap water an increase of intestinal diseases is very likely to result.

Decrease of Infant Mortality in Chicago.—The Bulletin of the Chicago Health Department, for the week ended May 21, says this is the most favorable season in the history of the city for the life and health of infants and young children. Since the first of the month there have been recorded 1,553 deaths at all ages, of which number 339 were of children under 5 years of age—a proportion of 21.8% of the total. During the corresponding period last year there were 1,922 deaths at all ages, including 510 under 5—a proportion of 26.5% of the total. These figures show a decrease of 17.7% in the deathrate of the under-5-year age group this year from that of 1903—which was about the normal. The cause of this condition is the phenomenal infrequency of the contagious diseases. At the close of the week a total of 599 deaths from the diseases most seriously affecting child life had been reported since the first of the year. For the same period of 1903 there were 1,169 such deaths reported—an excess of 570, or 95%. Among the most striking decreases are the deaths from diphtheria, measles, scarlet fever and whoopingcough—from diphtheria this year, 156, last year, 300; from measles this year, 9, last year, 190; from scarlet fever this year, 91, last year, 167; from whoopingcough this year, 8, last year, 186.

FOREIGN NEWS AND NOTES

GENERAL.

Japanese Military Hospitals.—News from Tokio, Japan, under date of May 25, states that Drs. Hashimoto, Sato, and Kikuchi, three of the most eminent surgeons of Japan, have been appointed superintendents, respectively, of the Tokio Hiroshima, and Matsuyama Military Hospitals. The government is securing the best talent available, and is carefully equipping hospitals for the treatment of both Japanese and Russian wounded. Dr. Hashimoto is the Emperor's physician.

Bovine Plague in Egypt.—In addition to bubonic plague it is reported that bovine plague is very widespread in Egypt. Severe precautionary measures are being taken, but owing to the nomadic character of the population the results, it is said, are unsatisfactory as far as the cattle disease is concerned. According to reports Egypt is also menaced this year with an invasion of locusts. In certain districts the government has ordered the destruction of the eggs left by the clouds of these insects that have already made their visitation. Under the direction of experts sent out by the ministry of the interior almost the entire population of some sections of Egypt are engaged in destroying the eggs.

World's Finest Hospital Train.—The Empress' hospital train started from St. Petersburg to the far East a few days ago. The train is the finest railway hospital ever constructed. The first section is composed of 14 ambulance cars, fitted with every appliance for the comfortable transportation of the ill and wounded. The second section contains two operating cars, supplied with every adjunct of the modern operating-room, with tiled interiors capable of instant cleansing, disinfectants, stores, instruments, bandages, and adjustable operating tables. There is also a library, chapel, and bath-rooms, including a special electric bath, a röntgen ray car, with dynamos and all apparatus, and a kitchen car, from which all the patients are fed. There are also cars containing a dispensary, sterilizing, and disinfecting apparatus, a water distilling plant, and ice manufacturing machinery. There went out with the train three doctors, four Sisters of Mercy, and three assistants. The Empress not only furnished the entire train, but furnishes \$500 monthly to aid in the purchase of delicacies for the sick.

Antivenomous Serums: Paris.—M. Calmette, of Lille, who has just been elected a corresponding member of the institute, read an important paper on May 5 before the Academy of Medicine upon the above subject. As is well known, the discovery of antivenomous serum is due to M. Calmette. But on continuing his researches, he found that the venoms of different serpents were not all of the same type. There are two main species to which all the others conform, cobra venom and viperine venom. The first is especially toxic, the second produces hemorrhages. M. Calmette has succeeded in preparing one polyvalent serum, which acts equally well in both kinds of poisoning. By studying the action of the neurotoxins, which serpent venom contains upon the globules of the blood and upon gelatin, M. Calmette has devised a method for standardizing the toxicity of venom with accuracy.

The Pestiferous Tramps.—According to accounts, recently, when disease was rife in England and Wales, inquiries were made by a medical officer as to the source of the infection, with the result of showing that tramps brought smallpox into 72% of the 63 large towns from which returns were received. More recently replies received from 125 cities and boroughs having populations of 20,000 or over confirm the conclusions drawn from the former inquiry. Of the 125 places, 111 had been visited by smallpox, and 51% of these places derived it from "the harmful and unnecessary tramp." Again and again when stamped out the disease has been reintroduced by the peripatetic loafer. "The disease," says the London *Telegraph*, "was introduced at least 305 times by vagrants into 58 places where it had already made its appearance. Twenty-three times it was carried into Sheffield in this manner, 24 times into Manchester, 31 times into Wakefield, and 34 times into Liverpool."

The Hygiene of Health Resorts, Berlin.—At a recent meeting of the Association of Government Medical Officers one of the subjects discussed was the hygiene of spas and health resorts and finally a series of definite recommendations was made, of which the following is an abstract. A sanitary commission ought to be formed in every spa and health resort. The notification of scarlet fever, measles, diphtheria, enteric fever, and pulmonary tuberculosis ought to be made compulsory. In the smaller spas and health resorts, where there is no hospital, arrangements ought to be made with a hospital of the neighborhood for the reception of patients, especially those suffering from contagious diseases. Ambulances and premises for the isolation of doubtful cases ought to be provided in every spa. The medical officers of health should be authorized to inspect the hygienic arrangements of dwelling houses and places of public resort at least once a year during the bathing season and to order unsatisfactory conditions to be corrected. In the ensuing discussion Dr. Behrend of Colberg rightly observed that not only the spa but also the public had obligations to fulfil in the interests of the general welfare; he especially drew attention to the fact that parents took their children when suffering from whoopingcough to crowded spas, although these children as a rule did not derive the least benefit from the change and were a source of danger to the healthy children whom they met there.

OBITUARIES.

T. M. Drysdale, at his home in Philadelphia, May 27. He had been ill for two weeks with pneumonia, and was 70 years of age. He was graduated from the Philadelphia Medical College in 1852. In 1856 he was made professor of chemistry of Wagner Institute of Science. In 1862 he was appointed a lecturer on microscopy for Franklin Institute. In 1863 he became a surgeon in the First Pennsylvania Infantry, where he served for the remainder of the Civil war. He was made consulting gynecologist at the Medico-Chirurgical Hospital, and in 1875 was elected president of the Philadelphia County Medical Society. He was one of the founders of the American Gynecological Society, and was a member of the International Medical Congress in 1876. In 1887 he was elected president of the Philadelphia Obstetric Society, and later vice-president of the American Academy of Medicine. He was a fellow of the College of Physicians and a member of the British Medical Society. He was the author of numerous papers on medical subjects.

F. Savary Pearce, at the home of his father, Steubenville, Ohio, May 27, aged 37; a graduate of the University of Pennsylvania in 1891. At the time of his death he was professor of neurology in the Medico-Chirurgical College, Philadelphia. He was the author of several works on nervous diseases, was a diligent student, and one of the most popular young physicians in Philadelphia. Dr. Pearce was a member of the American Medical Association, being secretary of the section on nervous and mental diseases. He was also a member of the County Medical Society, the Medical Club, the Neurological and Pathological Society, and a fellow of the College of Physicians. He belonged to the Pennsylvania State Medical Society, and was an honorary member of the Eastern Ohio Medical Association. He was also a member of the American Climatological Association, the Historical Society of Pennsylvania, the University Club, and the Loyal Legion.

Edwin Gallaird Mason, of New York, at the home of his father, Dr. A. S. Mason, in Hagerstown, Md., May 23, aged 39. He was a graduate of Bellevue Medical College, after which he was made assistant professor of nervous diseases of the Polyclinic School of New York. He was for several years editor of the *Gallaird Medical Journal*.

W. His, the noted professor of anatomy at Leipzig, in that city, April 30, aged 72; one of the founders of the *Archiv f. Anthropologie* and of the *Zeitschrift f. Anatomie*, of which latter he was editor until it was combined with the *Archiv f. Anatomie und Physiologie*.

Cornelius Van Evra, from apoplexy, at his home in Vineland, N. J., May 19. He was for a number of years a practitioner in Philadelphia and later in New York, where he retired from his profession, and moved to Vineland. He was married six times.

Peter F. Stokes, at his home near Branchville, S. C., May 16, aged 83; a graduate of the Medical College of the State of South Carolina, Charleston, in 1846; member of the South Carolina Legislature in 1852, and of the Secession convention in 1860.

Wm. A. McCoy, at his home in Madison, Ind., May 8, aged 60. He was a graduate of the Medical College of Indianapolis, Ind., in 1872; member of the American Medical Association and secretary of the Jefferson County Medical Society.

E. Duclaux, professor of biology and chemistry in Paris and director of the Pasteur Institute, May 3, aged 64. His work in biology, chemistry, physiology, bacteriology has made him famous all over the world.

Charles W. White, Jr., at his home in Fairhaven, Mass., recently. He was a graduate of Harvard College, and also of the University of Heidelberg. He was a member of the staff of physicians of St. Luke's Hospital.

Albert Nassau Cooper, at his home in Bisbee, Arizona, April 27, aged 25; a graduate of the College of Physicians and Surgeons, San Francisco, in 1901; member of the American Medical Association.

Henry H. Critchfield, of Hunter, North Dakota, at a hotel in Minneapolis, from heart disease, May 13, aged 43; a graduate of the Minnesota Hospital Medical College, Minneapolis, in 1885.

Daniel W. Tyndall, at his home in Taylor, Mo., May 16, aged 67; a graduate of the University of Michigan, Ann Arbor, in 1864; surgeon of the Federal army during the Civil war.

D. P. Jackson, at his home in Binghamton, N. Y., May 23, aged 63. He was one of the best known physicians of the city and at one time health officer in his home town.

Thomas J. Fitz Morris, at his home in New York, May 20, aged 35. He was a graduate of Bellevue Medical College in 1891, and at one time Alderman of the city of New York.

John N. D. Cloud, at the Duval County Hospital, Jacksonville, Fla., May 7; a graduate of the College of Physicians and Surgeons, New York city, in 1883.

Dayton R. Black, from pneumonia, at his home in Terre Haute, Ind., May 15, aged 55; a graduate of the Medical College of Indianapolis, Ind., in 1875.

Alvin Morris Woodward, at his home in New York, May 20, aged 68. He was a graduate of the New York Homeopathic Medical College in 1861.

A. Nash Johnson, at his home near Natural Bridge, Va., May 10, aged 55; a graduate of the Medical College of Virginia, Richmond, in 1878.

Hugh H. Davis, from heart disease, at his home in Sonoma, Cal., May 8, aged 62; a graduate of the University of Pennsylvania in 1878.

Benj. J. Clevenger, at his home in Red Key, Ind., May 10, aged 55; a graduate of the Medical College of Indianapolis, Ind., in 1873.

Cyrus Truman Meaker, at his home in Carbondale, Pa., May 9, aged 57; a graduate of Dartmouth College, Hanover, N. H., in 1887.

R. G. Coleman, at his home in Monarch, Mo., May 12, aged 60; a graduate of the Medical College of Ohio, Cincinnati, in 1897.

John F. LeRoux, at his home in Montreal, May 14, aged 55; a graduate of Laval University, medical department, Quebec, in 1883.

Henry W. Strong, at his home in Byron Center, Mich., May 9; a graduate of the University of Michigan, Ann Arbor, in 1864.

Elbert Wallace Clark, from paresis, at his home in St. Albans, W. Va., aged 55; a graduate of the Rush Medical College in 1871.

Wm. E. Garnett, of Cave City, Ky., at Stamford, Ky., May 4, aged 65; a graduate of the University of Louisiana in 1869.

Nelson Fanning, at his home in Catskill, N. Y., May 17, aged 63; a graduate of Albany, N. Y., Medical College in 1859.

Albert G. Pottle, at his home in Canaan, Vt., May 5; a graduate of the Medical College of Maine, Brunswick, in 1871.

John B. Curtis, at his home in Columbus, May 12, aged 83. He was a veteran of the Mexican and Civil wars.

W. O. Alexander, at his home in Washington, aged 58. He was a graduate of the Georgetown University.

Wilbur Flak Templeton, at his home in Glover, Vt., May 7, aged 68. He was of New York city.

J. A. Halteman, at his home in Espanola, New Mexico, May 6, aged 60.

SOCIETY REPORTS

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-ninth Annual Meeting, Held in Boston, Mass., May 24, 25, and 26, 1904.

[Specially reported for *American Medicine*.]

FIRST DAY.

The society met in the Boston Medical Library under the presidency of Edward Reynolds, of Boston.

An address of welcome was delivered by Charles M. Green, of Boston, and was responded to by Henry T. Byford, of Chicago.

Officers.—The following were elected: President, E. C. Dudley, Chicago, Ill.; vice-presidents, Henry D. Fry, Washington, D. C., and Henry C. Coe, New York; secretary, J. Riddle Goffe, New York; treasurer, J. M. Baldy, Philadelphia. Niagara Falls, N. Y., was selected as the place for holding the next annual meeting.

The Treatment of Gallstones Found as a Coincidence in Abdominal or Pelvic Operations.—JOHN G. CLARK (Philadelphia). This paper will appear in a future issue of *American Medicine*.

Discussion.—R. STANSBURY SUTTON (Pittsburg) said if gallstones were encountered during the course of another operation they should be removed, if the patient's condition warranted it. GEORGE M. EDEBOHLS (New York) operated on a woman at one time who presented marked dyspeptic symptoms. In addition she had movable kidney, chronic appendicitis, and induration in the region of the gallbladder. He anchored the kidney, removed the appendix through a lumbar incision, pulled the gallbladder into the lumbar wound, and found a stone about 4 cm. or 5 cm. in length, pear-shaped, and nearly filling the gallbladder. The attending physician was positive that the gallbladder did not produce symptoms of stone in it. He would not let him remove the stone from the gallbladder. A year later he opened the woman's abdomen for some other condition, making an incision near the gallbladder. He investigated the gallbladder, found it was healthy, and that the large stone had either passed or had been dissolved. The treatment after the previous operation consisted of the use of olive oil for about a month, and whether this had anything to do with the passage of the stone he did not know. A. PALMER DUDLEY (New York) believed that stones were formed in the liver ducts themselves, and that from a stagnant circulation cholesterol nuclei formed and that only a small proportion of stones was found in the gallbladder. He would not hesitate to explore the center of the liver in some instances. He cited a case in point. BROOKS H. WELLS (New York) said that in the last few years he had used practically the same measures as those outlined by the essayist. A number of patients coming under his observation had complained of obscure symptoms of so-called functional indigestion. In them he found either disease of the gallbladder, an over-distended gallbladder from obstruction elsewhere, or trouble referable to gallstones. By making a small or large incision, as seemed necessary, cleaning out the gallbladder and draining it, the patient had obtained remarkable relief from the symptoms that were supposed to be due to functional indigestion. SETH C. GORDON (Portland, Me.) said that when the abdominal cavity was opened for other purposes and he was quite sure the patient could stand it, he would examine the gallbladder thoroughly, and if gallstones were found he would remove them. HIRAM N. VINEBERG (New York) said that under the influence of the teaching of Kelly he had been in the habit of doing what had been advocated by the essayist, but after hearing a discussion on gallstones in the common duct and in the gallbladder by one of the Mayos, he had changed his method. Simply opening the gallbladder and removing the stones did not effect a cure, as was proved by three or four cases that occurred in his own practice. If the gallbladder was diseased, however, it should be removed. J. M. BALDY (Philadelphia) said that gallstones existed in the gallbladder for years without causing any material discomfort, but that when infection occurred trouble was liable to ensue. With reference to removing gallstones when operating for some other intraabdominal condition, the surgeon should consider the physical condition of the patient, the surroundings, etc., and as to whether the patient was willing to shoulder the additional risk of a second incision for the gallbladder operation. WALTER P. MANTON (Detroit) quoted Ochsner as saying that he had tried almost everything in so-called cases of chronic dyspepsia without affording relief; yet after opening the gallbladders of these patients and removing gallstones which were found, they were cured. Manton had seen a number of such cases and contended that the removal of gallstones, or the gallbladder if diseased, was the thing to do. He did not believe there was any solvent ever invented which would dissolve gallstones. BEVERLY MAC-MONAGLE (San Francisco, Cal.) stated that when the abdomen was opened for some pelvic or abdominal trouble the operator should investigate the gallbladder. If gallstones had been making the patient ill, or if there were adhesions around the gallbladder, one should operate. The conditions that arose in

the pancreas as a consequence of gallbladder disease and of gallstones were serious, and if the surgeon could do something of a prophylactic nature, without adding to the risk of the patient's life, it was a wise thing to do. CLARK, in closing, said the formation of gallstones through bacteria had been clearly demonstrated by experiment. He did not believe anyone would strongly advocate operation unless the gallstones were producing symptoms.

Ovarian Pregnancy.—J. CLARENCE WEBSTER (Chicago) reported a case in which there was a right ovarian irregularly rounded swelling, measuring 7 cm. by 8 cm. There was no evidence of rupture into the peritoneal cavity. The adhesions were recent. Sections of the ovarian swelling consisted mainly of extravasated blood and disseminated fragments of the chorion. No evidence of transformation of ovarian connective tissue into decidua was noted. It was certain that the pregnancy did not start in a Graafian follicle.

Discussion.—J. WHITRIDGE WILLIAMS (Baltimore) said ovarian pregnancy was the rarest of all forms of extrauterine pregnancy. While there was no doubt that Müllerian tissue might be found in the ovary, as mentioned by the essayist, and confirmed by numerous observers, it was going too far to advance that view in explanation of every case of ovarian pregnancy. JOHN T. THOMPSON (Portland, Me.), referred to a case of ovarian pregnancy he had reported at a previous meeting of the society, and called attention to the nature of the structures in which pregnancy occurred, and to the frequency with which rupture might occur in the early days. EDWARD P. DAVIS (Philadelphia) removed an ovarian pregnancy about a year ago. The indications were that the pregnancy did not originate in the Graafian follicle. LAPHORN SMITH (Montreal) had diagnosed ectopic pregnancy by the clinical symptoms, had operated, and found hematoma of the ovary. He had said to students that his diagnosis was wrong, because authorities maintained that there was no such thing as ovarian pregnancy, but after hearing what had been said he was convinced there was.

Uterolithotomy.—J. WESLEY BOVEE (Washington, D. C.) gave the history of this operation, discussed the size and number of calculi, and the routes for reaching and extracting uterine calculi. All uterolithotomy wounds should be drained, because the urine was practically never normal, therefore rendering wound infection probable. The possibility of urinary leakage subsequent to operation afforded another positive indication for drainage.

Nephrectomy for Primary Tuberculosis of the Kidney.—HIRAM N. VINEBERG (New York) said that tuberculosis of the kidney, both primary and secondary, was more frequently met with in women than in men in the proportion of about two to one. It was different from what occurred in man; renal tuberculosis in women was rarely associated with tuberculosis of the genital organs. A cystitis in women that resisted the topical applications of the silver nitrate solution by the Kelly method should be looked upon with marked suspicion as being of a tuberculous character, even though repeated examinations of the urine should show an absence of the tubercle bacillus. The differential diagnosis of a nontuberculous from a tuberculous cystitis with the aid of the cystoscope was not as reliable as the therapeutic test outlined in the preceding sentence. Pronounced reddening of ulceration about the mouth of one of the ureters, with absence of other bladder changes, was held by some authorities as pathognomonic of tuberculosis of the corresponding kidney; while the sign was an important one, too much weight should not be attached to it in women. In most cases the removal of the diseased kidney would bring about practically a cure of the descending cystitis. He doubted the wisdom of the advice to cure the cystitis before undertaking the removal of the kidney. The prognosis of nephrectomy in renal tuberculosis in women was very good. Of the writer's four cases operated upon, seven, five, two, and one and a half years ago respectively, all were alive and in good health.

Discussion.—JOSEPH E. JANVRIN (New York) reported the case of a woman who had been ailing for two years with what was supposed to be a renal calculus. The kidney was removed, and it was found that its pelvis was infiltrated with tuberculous deposits in the very early stage. She made a good recovery and was well today. J. WESLEY BOVEE said, as to the indications for operation on tuberculous kidney, the surgeon should be sure that the opposite kidney was capable of carrying on the function of excreting urine for the whole body before he decided to remove one tuberculous kidney. A nephrotomy might be done, and the kidney most markedly diseased drained, without taxing the other kidney to a great extent. PHILANDER A. HARRIS (Paterson, N. J.) said that in cases of tuberculosis of the kidney it was difficult, where the bladder was corrugated and changed by the pathology present, to find the urethra; but by painting the entire field of the bladder with some solution, as Prussian blue, he had succeeded in finding the ureters, in the case of a girl, which he could not otherwise locate. SETH C. GORDON operated on a man, removing a kidney, which was situated low down in the abdomen, painful, and bound down by adhesions. The patient died 11 days after the operation, and postmortem examination revealed that the man had no other kidney. Two years afterward he removed a very large kidney from a woman, who lived 28 days after operation. For 12 hours she did not have a single uremic symptom, nor was a drop of urine secreted, and

she died in full possession of her faculties. Postmortem examination revealed that she had no other kidney. J. M. BALDY said it was not uncommon to have practitioners ask if the ureters had been catheterized in cases of supposed kidney disease, and not infrequently a healthy kidney was palpated and found on one side which utterly failed to secrete with the patient under an anesthetic or without it. In some instances this failure on part of the kidney to secrete was undoubtedly brought about by the influence of the anesthetic. He had had exactly the same experience a number of times in patients whose ureters he had catheterized, but to whom no anesthetic had been given. GEORGE M. EDEBOHLS advocated that before removing a kidney, an incision should be made on the opposite side to determine by actual inspection and palpation the presence of another kidney and its probable health, so far as could be determined macroscopically, before removing the diseased kidney. He had adhered to this rule in all nephrectomies performed since that time, and in one case he had saved a woman's life by so doing. J. RIDDLE GOFFE, (New York) reported a case bearing on the removal of the ureter in connection with tuberculosis of the kidney, the patient having been operated on by him in 1896. She was a woman of 22, who had a very large tuberculous abscess of the right kidney. He removed the kidney and three inches of the ureter. She made an excellent recovery. The patient was now a graduate nurse and in perfect health. EDWARD REYNOLDS (Boston) gave his experience of 10 nephrectomies for tuberculous disease, seven of them being complete nephro-ureterectomies, all successful, so far as operative mortality was concerned.

Hypertrophies and Inflammations about the Urinary Meatus.—ROBERT L. DICKINSON (Brooklyn) said that their frequency, and the suffering caused, gave them an importance out of all proportion to their minute size. They were overlooked because hidden among folds of mucous membrane. They were explained by embryology. A tiny ribbon ran from the rear of the vaginal opening forward, on each side of the vaginal and urethral openings, across the vestibule to disappear beneath the clitoris. This fold was persistent in those cases where the hymen ran forward of the meatus, or the meatus seemed to open on the anterior vaginal wall. This fold was enlarged by friction or traction to produce flaps or labia hanging out each side of the meatus. They were found only with corrugated labia. Dilated or dilatable urethra often accompanied them. The urethral glands opened near the apex of the flaps. They were long, running down into the anterior column of the vagina. Swelling from infection differed from hypertrophy. The cure of chronic inflammation was only feasible by obliteration of the glands. A fine probe passed to the bottom of the gland rendered the vestibulovaginal surface tense; the cautery wire cut out the probe. For piles of the meatus, the cautery wire was used after cocaine. For prolapse or dilation of the urethra, resection of the anterior vaginal wall or paraffin injections into the urethrovaginal septum produced a sigmoid profile.

Surgery of the Female Urethra.—ELY VAN DE WARKER (Syracuse, N. Y.) said the term sacculation was regarded as better than urethrocele. Its major cause was mechanical, as inflammation alone was not adequate to its production. The urethra might be said to belong to the perineal rather than the pelvic zone of organs. The walls of the canal depended in a measure upon the support of the perineal body. It was often associated with long standing rupture of this part. Restoration of the perineum was therefore essential to treatment of the sacculation. When large, an elliptic flap of the walls of the urethra was removed, and the edges brought together by fine silk sutures. Prolapse of the mucous lining of the urethra the author had generally associated with long standing urinary troubles of various kinds. After removing the prolapsed portion there was a marked tendency to recurrence unless the conditions which gave rise to it were treated and cured. Bladder incontinence and dribbling were often life-long conditions. That this was due to a defective action of the sphincter vesicae was more than doubtful. Dribbling was one of the symptoms of hysteria, of which a striking case was given in illustration. Stricture of the urethra was common in women. Any condition that tended to produce linear or annular thickening led to stricture. Specific urethritis might produce stricture, but it was not the frequent cause alleged by some writers. Stricture of large caliber might be located and measured by the Otis bulbs, but never by the sound, as recommended by old systematic writers. Annular stricture of the meatus was the form most commonly met with. These strictures ought to be incised and made to heal in an open condition by the frequent passage of the sound. Dilation alone was too painful and required too much time. The prototype of eversion of the mucous membrane at the meatus was the fusiform stricture of Otis, and its surest cure was by dilation. Caruncle of the urethra was common. Removal, involving the whole thickness of the mucous membrane, being careful not to leave a stump, was an effectual cure.

Pyelitis Complicating Pregnancy.—EDWIN B. CRAGIN (New York) said the occurrence during pregnancy of a marked rise of temperature, with pain and tenderness on the right side of the abdomen, was always a source of anxiety to the obstetrician. Although several able articles describing the condition had appeared, it was not generally recognized that pyelitis was

a not infrequent cause of the above symptoms. It might be confused with appendicitis, typhoid fever, or salpingitis. It occurred almost, if not quite, invariably on the right side. It was due to pressure on the ureter by the pregnant uterus plus an infection. This infection was usually descending, and was usually due to the colon bacillus. The urine was acid, contained at first albumin and perhaps a few casts, soon followed by pus and bacteria. The prognosis was usually good. Induction of labor was seldom indicated. The medical treatment by urotropin, or allied drugs, with ice-bag over the kidney; fluid diet, and large draughts of water was usually sufficient.

A Second Case of Puerperal Eclampsia Successfully Treated by Renal Decapsulation.—GEORGE M. EDEBOHLS (New York) said the first case, reported to the society a year ago, illustrated the immediate cure by renal decapsulation of puerperal convulsions, recurring with great and increasing violence after the birth of the child, a period at which the hitherto final resource of forced delivery was, of course, no longer available. In presenting the case the opinion was advanced that resort to renal decapsulation in the undelivered woman suffering from puerperal eclampsia might obviate the necessity of forced delivery. The case now reported illustrated the correctness of that opinion. Renal decapsulation was performed upon a woman pregnant near term, suffering from puerperal eclampsia, and almost complete suppression of urine. The convulsions were arrested, the flow of urine was reestablished, and a threatened death from uremia was averted. Two days after all this had been accomplished, labor began spontaneously and living twins were born. One child died soon after birth. The second child and the mother were in perfect health four and a half months after the termination of pregnancy. Renal decapsulation thus became a rival of forced delivery in cases of puerperal convulsions of renal origin in the undelivered woman. In puerperal convulsions, occurring or recurring after delivery, it constituted the final resort when all other measures had failed.

SECOND DAY.

Primary Repair of Lacerations of the Cervix Uteri.—EDWARD P. DAVIS (Philadelphia) read the first paper of a symposium on this subject. The number of cases under the author's observation was 53. In these, good union occurred in 45; fair union in 6; no union in 7; while infection developed in none. In 84.9% the operation was successful; in 11.3% it was moderately successful; and in 3.8% the operation failed. The percentage of infection was *nil*. He pointed out the objections which were commonly urged against this operation, after which he said that in appropriate cases in his experience immediate closure of the cervix had given no inconvenience to the mother, and had been followed by excellent results. This operation was not advised for those who did not practise obstetrics with good surgical technic, and who were not competent to operate on the genital tract.

The Practice of Cervix Suture on the Fifth Day after Delivery.—ROBERT L. DICKINSON (Brooklyn) said that no complicated or considerable perineal injury should be repaired at the close of labor, but three to five days later. This had an important bearing on lacerations of the cervix, as this was the ideal time to restore such injuries. Whenever possible, the cervix should be sewed on the fifth day. The author described the conditions under which the cervix should be repaired at the close of labor, and also the conditions under which it should be repaired several days after labor. He drew attention further to the alterations produced by granulation and contraction in these wounds when left alone, so that the scarred, swollen, everted, or cystic cervix months or years after injury gave uncertain indications for accurate restoration to the original condition.

General Considerations of Laceration of the Cervix Uteri.—J. M. BALDY (Philadelphia) stated that as a matter of clinical fact, let the cervix uteri be torn deeply, and if the parts were preserved from infection, the greater part of the wound would heal spontaneously, and the rest of it would remain perfectly healthy. The lips would remain uninfiltated, of normal size and thickness, with no eversion and no erosion of the lining mucous membrane. In such a case, there would be no untoward symptoms and no bad effects whatever. There was a tendency among obstetricians to repair these lacerations primarily. The objections to such practice were manifold, and these he pointed out. Whatever might be ideal surgery under the exigencies of actual practice, the treatment for recent lacerations of the cervix remained, and he believed would remain, namely, rigid local cleanliness, excepting where there was sufficient hemorrhage to demand a ligature. There was one belief prevalent which would warrant, nay, demand, a repair of every lacerated cervix—the belief that lacerations of the cervix produced carcinoma. In this belief he took no part, and no one had, to his knowledge, as yet brought forward a scientific fact which would uphold such a theory. In 20 years' work he had not seen a single case of cancer develop in a laceration of the cervix which he had refused to repair.

Intrapelvic Hematoma.—J. WHITRIDGE WILLIAMS (Baltimore) reported a case of intrapelvic hematoma following labor, and made some remarks on the treatment of incomplete rupture of the uterus.

President's Address.—EDWARD REYNOLDS (Boston) stated that the use of the printed abstract published beforehand had of late become increasingly prominent in many societies,

and in the British Medical Association this use of the abstract had reached its highest point. It was seldom wise to adopt wholesale the regulations of other organizations. It was usually better to let changes follow a more gradual and natural evolution under the needs of the individual assembly, but the methods of the English association were worth a passing consideration. He said that a Fellow of the British Medical Association who desired to present a paper at one of its meetings must put it in the hands of the secretary complete and in the form in which he desired its publication, a number of weeks before the meeting, and the communication might be of any length he chose. A paid secretary, a qualified and experienced medical author, then abstracted each paper in the form and length which he considered best fitted for its public delivery. This official then read the abstracts to the society as they called on the program. Such a reading inaugurated each discussion, and the member whose ideas had been thus succinctly set forth before his associates, took part in the discussion and closed it. The ideas of individual members by this method were better and more intelligently presented than if they had read their complete papers. Time was economized, full debate was encouraged, and the members had the advantage of publishing to the world, papers in which their points were set forth at the fullest length and without time limitation. He recommended that the society give this method or a modification of it a year's trial.

Symposium on Injuries to the Perineum: The Preventive Treatment of Pelvic Floor Lacerations.—J. CLIFTON EDGAR (New York) said that the factors which tended directly or indirectly to produce pelvic floor lacerations might be arranged, for the sake of convenience, in three major classes, namely, (1) too rapid expulsion of the fetus, so that tearing instead of stretching resulted; (2) relative disproportion in size between the presenting part and the parturient outlet; (3) a faulty mechanism of labor, whereby the larger circumference of the head and shoulders than necessary passed through the parturient outlet. From an extended clinical experience, the author could speak most enthusiastically of preliminary digital stretching of the vulval outlet in primipara, and especially in elderly primipara, as a prophylactic measure in perineal protection. He then discussed episiotomy, head delivery, and cleidotomy. He had been most successful with the following method of shoulder delivery, and either the lateral or dorsal posture of the patient could be used at will. This method was not new: 1. The delivery of the shoulders was delayed, if possible, until nearly complete rotation of the bisacromial diameter had taken place. 2. The fetal head was taken in the hand and gently raised or pushed, so as to bring the anterior shoulder well up behind the symphysis, thus giving the cervicoacromial diameter of the fetus at the outlet instead of the bisacromial. 3. The posterior shoulder was now allowed to pass out spontaneously and whenever possible manual extraction should be avoided, as this increased the risk of perineal rupture. 4. During the detention of the anterior shoulder behind the symphysis, the fetal hand of the opposite arm lying across the fetal chest would usually soon appear in the vulva. He had found that delivery might be safely assisted by slowly flexing this forearm and arm out through the vulva, and thus delivering the posterior shoulder by slight traction on the posterior arm. 5. Should the foregoing be impracticable and delay in the expulsion of the posterior shoulder occur, he had found gentle traction upon the head, the fingers encircling the neck, to be preferable to traction with a finger in the axilla. 6. Should there be delay in the delivery of the anterior shoulder, after expulsion of the posterior, it was best remedied by making traction directly downward, with the hands placed on the sides of the head, taking care not to make too great pressure on the perineum. As a last resort, traction might be made by a finger in the axilla.

Immediate Repair of Lacerations of the Perineum, with Special Reference to Placing the Sutures before the Lacerations Occur.—LAPTHORN SMITH (Montreal). This paper will appear in a later issue of *American Medicine*.

Immediate Repair of Injuries of the Pelvic Floor.—HENRY C. COE (New York) said that he had selected this topic in order to emphasize the fact that by careful attention to puerperal lesions at the time of their occurrence, the patient could be spared much future trouble. He assumed that it was the usual practice of modern accoucheurs to repair injuries to the pelvic floor at once, but it was one thing to suture visible tears and another to repair deeper lesions. Even when perfect union of the lacerations was obtained the occurrence of prolapsus, cystocele and rectocele months afterward proved that there had been some fault in the technic. The fact of the separation of the fascia and levatores ani muscles must be recognized as well as the superficial tear, especially after difficult instrumental deliveries. An illustrative case from the writer's practice was cited. The tendency of the accoucheur after a tedious instrumental case, in which both physician and patient were exhausted, was to spend as little time as possible in repairing lesions of the soft parts, trusting to aseptic technic to insure perfect healing. The writer was firmly of the opinion that it paid to do the work thoroughly at the time unless the patient's condition was such as to render delay advisable. He had had such good results from immediate operations that the intermediate did not appeal to him.

[To be concluded.]

CLINICAL NOTES AND CORRESPONDENCE

[Communications are invited for this Department. The Editor is not responsible for the views advanced by any contributor.]

A MODIFIED AND IMPROVED METRANOIKTER.

BY

B. C. HIRST, M.D.,
of Philadelphia.

Although Schatz presented his metranoikter at a meeting of the Leipsic Obstretical Society as long ago as the autumn of 1881, it has apparently found little favor in his own country, and is scarcely known elsewhere. It is not mentioned in the index of Veit's Handbuch, and is dismissed in a paragraph in the "Encyclopädie der Geburtshilfe und der Gynäkologie" by a writer who disapproves of it. My attention was called to the instrument by an article by Daniel and Schneidersievers,¹ who recommended it highly. In a number of cases in my hospital service this winter I have found that the dilator accomplished all that its inventor and advocates claim for it, but as the four-branch principle has proved its superiority in all metal dilators

for the cervix, I had an instrument maker construct a dilator on the Schatz model, but with four instead of two blades. With this instrument a wider and more permanent dilation of the cervix can be secured than with any other that I know of. If the dilation is performed for dysmenorrhea and sterility, I have used (1) a Baer's modification of Goodell's dilator; (2) a heavy Wathen's dilator; (3) the four-branched Cleveland dilator; then have curetted the uterus, washed out the cavity, inserted the metranoikter, and packed the vagina with sterile gauze. The metranoikter remains in the uterus 24 hours. If the instrument is used for diagnostic purposes, only enough dilation is secured with a light dilator to permit its insertion. In multiparas no preliminary dilation at all may be required. At the end of 24 hours, when the metranoikter is withdrawn, it is possible to insert the forefinger to the fundus uteri, and to palpate with perfect ease the whole uterine cavity. The metranoikter does more than uterine tents can do, without danger of infection and without pain.

A METHOD OF NATIONAL RECIPROCITY.

BY

JAMES L. TAYLOR, M.D.,
of Wheelersburg, Ohio.

To the Editor of *American Medicine*:—With regard to the subject of reciprocity discussed in last week's editorial columns, the statement there made that the Federal Government has no jurisdiction in the matter is certainly true. But might not the Federal Government initiate action within the

constitutional prerogative that would eventually lead to reciprocity? The Federal Government has no authority for naming a certain day of the year to be observed as a general Thanksgiving. Yet, in a matter pertaining much more to sentiment than to practical politics, the mere recommendation of the President is promptly followed by executive adoption in all the States. Suppose the Federal Government should prescribe a certain examination or a certain diploma as a condition for appointment to medical positions in the Army, Navy, and Marine-Hospital Service, would not the State Medical Boards promptly recognize such a Federal license without examinations, whether the holder was engaged in the public service or not? A definite professional standard being thus recognized for government service, would not a practical basis for reciprocity result, eliminating the multitude of standards now held to by the various State Boards? Great Britain concedes to the possessor of a certain London diploma, granted on examination independent of any particular medical school, the right to practise in any part of the British Empire. Would not the adoption of a definite professional standard here for federal purposes easily lead to general uniformity for such as desire it,

and be sanctioned by the different States as a happy solution of a problem now impossible to work out with our existing dissimilar standards?

[Why may not the different States now sanction each other's definite professional standards, whenever they are equally high? Why not actually reciprocate? The power to do so usually lies in the hands of the profession.—Ed. *Am. Med.*]

PERVIGILUM.

BY

JAMES A. SPALDING, M.D.,
of Portland, Me.

To the Editor of *American Medicine*:—As I was reading your article on "Pervigilium," published April 30, an old gentleman came to consult me. After the consultation we entered into conversation and I asked him if he ever knew of any one going long without sleep and in reply he told me of the following case:

The subject was a very old man who lived to be 90, and he was very proud of telling about a saw mill which belonged to several people, each of whom took turns in using it according to the money they had contributed toward its purchase, for village uses. The old man happened in this way to obtain the use of the mill for a week and when his turn came he decided to make the most of it. So he hauled from his wood lot an abundant supply of lumber and began sawing at one minute after midnight on Sunday and he operated the saw until the following Saturday at midnight without sleeping. He never suffered from any trouble afterward and as before stated he lived to be over 90.

I must admit that I am surprised that he did not suffer from tinnitus the rest of his life.

¹ Journal of Obstetrics and Gynecology of the British Empire, 1902, p. 280.

ORIGINAL ARTICLES

THE CONSERVATIVE TREATMENT OF ACUTE APPENDICITIS.

BY

A. W. MORTON, A.B., M.D.,
of San Francisco, Cal.

Professor of Surgery, College of Physicians and Surgeons; Surgeon-in-Chief, Morton's Hospital; Visiting Surgeon, City and County Hospital; Consulting Surgeon, California General Hospital; Consulting Surgeon to German Hospital; Surgeon to the Santa Fe Railroad.

The subject of appendicitis has been more thoroughly discussed by medical men and the laity during the past decade than any other medical topic. Regardless of this, there still remain a wide difference of opinion as to the treatment, and a grave mortality, which is evidence that we have not thoroughly mastered the subject.

The disease is far more prevalent than is generally supposed. Observers have found in postmortem examinations that from 30% to 40% of the subjects give evidence of having had appendicitis during life.

I do not bring this subject before the profession because I have any thing new to offer, but to make an appeal to be more conservative in the time selected to operate.

The disease of the appendix was observed by many writers during the past century, but was not accepted by the medical profession until 1886, when Dr. Fritz of Boston convinced it that most of the cases of peritonitis were caused by appendicitis.

The appendix is located in the right iliac fossa and seldom wanders from that location. It is attached to the lower end and back part of the cecum and is very similar in structure, except that it is poorly developed on account of not having any special function, and a poor blood supply. Its location corresponds to a point about two inches from the anterior superior spine of the ilium directed to the umbilicus—McBurney's point.

The causes of appendicitis have varied to suit the opinions of different authors, from foreign materials to a meat diet. The most rational cause is that of defective drainage from mechanical obstruction, or preexisting disease, which leaves the appendix in an unhealthy condition, making a proper soil for *Bacillus coli communis*, or some pus infection, which under ordinary conditions would be harmless. Typhoid fever, dysentery, indigestion, and many other diseases may act in preparing the way for the germ, which is always associated with the disease.

Appendicitis is generally divided into various classifications which simply represent different stages of the disease, whether it be catarrhal, suppurative, or gangrenous.

The symptoms of acute appendicitis are of such marked character that any one who has had any experience with the disease should readily make a diagnosis. The four cardinal symptoms—pain, tenderness, gastrointestinal disturbance, and rigidity of the muscles, in conjunction with the constitutional symptoms, will be of great value. The pain is generally acute and first felt in the region of the umbilicus and radiating over the entire abdomen. After the pain lasts a few hours it becomes more fixed in the region of the appendix. The tenderness soon becomes localized at the region of the appendix. The disease is often ushered in by vomiting, the vomitus consisting of the food in the stomach, and later the secretions from the upper part of the intestinal tract. The rigidity of the abdominal muscles over the appendix is a very valuable symptom, not only for diagnosis, but because it differentiates it from other abdominal lesions. The pulse and temperature are valuable signals as to the condition of the patient, but only in conjunction with the cardinal symptoms are they valuable in arriving at a diagnosis.

The leukocytes are of importance in conjunction with

the other symptoms, in not only arriving at a diagnosis, but in differentiating it from other diseases, as typhoid fever. It is of much value in indicating the severity of the disease. J. DaCosta¹ claims when it reaches 20,000 or more, that pus has formed and immediate operation is required. I believe that 20,000 or more not only indicates that pus has formed, but in conjunction with other symptoms, that it has passed beyond the confines of the appendix, and that there is an effusion into the peritoneal cavity, and that it is one of the symptoms that not only confirms the diagnosis, but should deter the surgeon from operation as long as the count remains above 20,000; the pulse remaining above 116, and the other symptoms exaggerated, are special indications that operation should be postponed until the general condition is better. This is the hopeless class of patients which give the ever ready surgeon his mortality. The surgeon generally says he will give the patient the last chance (operation), which is too often true.

Operation at this stage will generally find the pus free in the peritoneal cavity. You may succeed in removing the ruptured or gangrenous appendix, but not the infection, as it is now a constitutional sepsis, and not local. The infection has not only spread over the abdominal cavity, but the operation produces trauma of the peritoneum and omentum, which are the life preservers of the abdominal cavity, and it inhibits their action in antagonizing the infection, to say nothing of the depressing effect of the anesthetic.

Many of our best medical men and surgeons, as Osler, Deaver, Price, and Murphy, have considered appendicitis a surgical disease at all stages, and have recommended operation as soon as diagnosed, regardless of the stage. I believe such teaching as this has done, and is doing great harm. Many physicians under unfavorable circumstances, and without the proper amount of experience, and often at the time the case becomes very serious, will operate, because they have been led to believe that surgery offers the only hope of relief. There is possibly no place where this advice has been more used or abused than in this country.

I believe all surgeons agree, that to operate early in the disease and under favorable circumstances offers more hope than any other form of treatment, and that it is the only method which will cure the disease. The mortality at this time should be very low, as there is practically no danger of infection so long as the pus is confined to the appendix. I believe in not limiting this period to 24 or 48 hours, which is the preferable time in acute cases, but if the patient's condition is reasonably good, judged by the pulse, temperature, leukocytes less than 18,000, and general symptoms, which convince me that the pus is confined to the appendix, I always operate. If the patient has passed into the stage of sepsis, when the pus is no longer confined to the appendix, and it is impossible to remove the sepsis, the pulse is rapid, the abdomen tympanitic, there is vomiting, with all the local symptoms exaggerated, and leukocytes above 20,000, I do not operate, as it is this class of patients from which we get the heavy mortality. McBurney has said, "often the surgeon is called too late for an early operation, and too early for a late operation." The statistics of Richardson² in operation for acute appendicitis show a mortality of 18%; Deaver,³ 16%; Broca,⁴ 33%.

If the experienced surgeons under favorable surroundings have this mortality, may we not expect even a heavier mortality with the less favored ones, if acting under the same teachings? Surgeons seem to be a unit in the belief that acute inflammation should be treated by rest in every part of the body, except the abdominal cavity, and here under all conditions we are to give cathartics, such as magnesia, which keeps up the peristaltic action of the bowel, and constantly irritates the inflamed appendix, which not only keeps the effusion from becoming walled off, but may carry it over the general peritoneal cavity, and even break down

adhesions which have formed. In my opinion rest is especially indicated in the treatment of appendicitis, and I believe that all acute cases could be carried through the attack and the patients operated on in the intervals with a mortality of less than 4% which has been the statistics of Ochsner.⁶

This treatment is to give the patient nothing by the mouth in the way of food, or cathartics until his condition makes the operation safe. All forms of food administered by the stomach have a tendency to start peristaltic action of the bowels; water can generally be administered in small doses, per mouth. If the patient is vomiting, gastric lavage should be used, which will stop the vomiting and relieve the pain and distress. Nourishment is kept up per rectum by using salt solution or some predigested foods in small quantities every few hours. If the lower bowel is full I generally empty it by enema. I have seldom found it necessary to keep up rectal nourishment longer than a week, as the patient's pulse, temperature and general vitality improve by this time. During this period the patient is rendered more or less immune to the infection, and the pus is not so virulent, as it has been walled off, and the patient has passed beyond the condition when operative procedure gives such mortality.

During the past two years I have treated 45 patients with acute appendicitis (not chronic or recurrent cases), and 27 of the patients were operated upon during the first to the fifth day, with one death. Two were treated through the attack and refused operation. Sixteen of the patients were treated from four days to two weeks, and then operated on, with one fatality.

The first fatality occurred in a young man of 22, who had been sick 3 days when he entered the hospital with acute appendicitis; pulse 116; temperature 103.5°; leukocytes 27,000, and with all the local symptoms exaggerated, with vomiting. The consultant demanded immediate operation, which was done. We found a ruptured appendix, with a small amount of pus which was not walled off. The appendix was removed and drainage established; the patient died 5 days later with general peritonitis.

I am confident that if this operation had been delayed and the patient treated by rest, he would have been saved.

The second fatality was in Mr. D., aged 45. I saw him the second day of the attack in consultation; he was suffering with all the symptoms of appendicitis. Immediate operation was advised, but refused. He was placed under the rest treatment and improved by the end of the first week, when we insisted on operation, but were again refused. Patient was started on a liquid diet per mouth, but immediately began to grow worse; the food was stopped and rectal nourishment resorted to again; but his symptoms continued to grow worse. On the twelfth day of his illness I opened the abdomen and found the pus from an appendix abscess had burrowed beneath the liver. This is a type of case in which the patient was in excellent condition for operation when first seen, and again at the end of the first week; after that the abscess began to wander which was indicated by the renewal of the acute symptoms with an increased leukocytosis. This is one of the dangers we may meet in this form of treatment.

I take one history from the cases in which operation was delayed on account of the severity of the disease:

Miss M., aged 21, had suffered several attacks of appendicitis, and had been sick three days when I was called in consultation. She had suffered very severe pain the night before and had been given a dose of morphin to relieve her; temperature was 105.5°; pulse 125. The abdomen was very sensitive, especially over the region of the appendix; leukocytes, 27,000; hemoglobin, 80. The patient was sent to the hospital, placed on rectal nourishment and a little water was given per mouth. On the fourth day of the treatment her pulse was 84; temperature 99°; leukocytes 10,500. Patient's condition was so much improved that consultant thought we had been mistaken in the diagnosis. One day later the abdomen was opened and we found the abscess walled off with the entire appendix sloughed; this was removed *in toto* and the cavity drained. Patient made a complete recovery.

In all cases in which operation was done after delay, the diagnosis was confirmed. Before adopting this method of selecting the time for operative cases, I followed the accepted teachings, to operate when the diagnosis was made, and especially when the case appeared hopeless. When I found the appendix gangrenous, or a

large quantity of pus free in the abdominal cavity, and following this a heavy mortality, I satisfied my conscience with the thought that the patient could not have recovered with any other form of treatment.

I am now convinced that the rest or Ochsner treatment will assist the surgeon in carrying his delayed acute cases to a safe period for operation. The medical man can safely treat his cases until he has proper surgical assistance.

THE LEISHMAN-DONOVAN BLOOD PARASITES (A SYNOPSIS).*

BY

JOSEPH McFARLAND, M.D.,
of Philadelphia.

The specimens that I have the pleasure of presenting to the society this evening were sent to me by Dr. Low, of the London School of Tropical Medicine, at the request of Sir Patrick Manson, to whom I had previously written, stating that our hematologists, having no opportunity to see them, were nevertheless much interested in the Leishman-Donovan blood parasites. Assuming that the honorary members of our society would be sufficiently interested in its work to make occasional contributions to its meetings, I begged Sir Patrick Manson, should it put him to no personal inconvenience, to send us some stained specimens showing the parasites, and I am glad to say that my request met prompt and generous response.

In order that the best possible use may be made of the specimens, I have thought it appropriate to synoptize briefly what is known about the interesting objects, in order that their examination may be profitable to all.

They seem to have been first described by Major W. B. Leishman,¹ professor of pathology in the Royal Army Medical College, London, in a paper entitled, "On the Possibility of the Occurrence of Trypanosomiasis in India." The parasites were first observed in cases of what Leishman called "dumdum fever."

Dumdum is a station about seven miles from Calcutta, and is notoriously unhealthy, malarial fevers of all types, dysentery, and enteric fever being rife. It is excessively damp, and, in the rains, is practically a morass from the fact of its lying so low; it is said to be even a few feet below the level of the Hoogley, which flows within a mile or two of the cantonments.

Leishman had a short personal acquaintance with this station in 1890, and the memoranda contained in his first paper, refer to the features of this form of Indian fever as represented by soldiers invalided on account of it from Dumdum to the Royal Victoria Hospital, Netley, during the past three or four years.

"The cases were, as a rule, regarded as having been malarial in origin, and on admission to Netley, the patients presented an extreme degree of cachexia; it was, in fact, the severity of this cachectic condition and the frequency of its association with Dumdum—and, more rarely, its immediate neighbors, Calcutta and Barrackpore—which gave rise to the idea that we were dealing with a specific type of fever, whose cause was unknown. Clinically, these cases presented no very definite features distinguishing them from other and commoner forms of tropical cachexia, the chief symptoms being an irregularly remittent type of fever, grave anemia, progressive muscular atrophy, and great enlargement of the spleen. Digestive and bowel derangements were frequent, the latter often a legacy of previous dysentery. In none of these Netley cases were malaria parasites found in the blood, nor were there any records of their having been found at an earlier stage of the disease. The difference then between these cases of dumdum fever and other cases of tropical cachexia, associated with a low form of fever, was chiefly one of degree, and this was so marked that one of the first questions one asked a patient suffering from a particularly severe

* Paper read before the American Society of Tropical Medicine, at its meeting on March 21, 1904.

form of cachexia was as to whether he had served recently at Dumdum."

On making smear preparations from the spleen pulp, in one of his cases of dumdum fever, Leishman was struck by the curious appearance among the spleen cells and red corpuscles

"of enormous numbers of small round or oval bodies, two or three microns in diameter, which corresponded to nothing I had previously met or had seen figured or described. They stained faintly with methylene-blue and with hematin, showing with these stains a sharply contoured circular or oval shape, but no detailed structure; but on staining them by Romanowsky's method, they were found to possess a quantity of chromatin, of a very definite and regular shape, which clearly differentiated them from blood-plates or possible nuclear detritus. This chromatin appeared in the form of a more or less definitely circular mass or ring, applied to which, though apparently not in direct connection with it, was a much smaller chromatin mass, usually in the form of a short rod set perpendicularly or at a tangent to the circumference of the larger mass. The outlines of the sphere or oval enclosing these masses of chromatin were only faintly visible by this method of staining. These little bodies were scattered freely among the cells, as a rule isolated one from the other, but here and there aggregated into clumps composed of 20 to 50 members."

The bodies were not present in all cases, as Leishman mentions two fatal cases of dumdum fever in which he was unable to find anything of the same nature in the spleen. The original article continues with a speculation as to the nature of the parasites, in which Leishman unfortunately falls into error, and supposes the bodies to be degenerating trypanosomes.

On July 11, 1903, the *British Medical Journal* published a letter from Captain C. Donovan, Second Physician, Government General Hospital, Madras, regarding the bodies just described. In this letter he says:

I wish to state briefly that I have noted bodies similar to those described by him (Leishman) in smears taken postmortem from enlarged spleens of patients—natives of India—said to have died of chronic malaria. I obtained them in three consecutive cases on April 9, 23, and 24, 1903. In the first instance, I thought I had discovered the long sought for resting-stage form of the malarial parasite in man, but could not compare them with any analogous stages in the sporozoa. However, on again procuring the same bodies in the two other cases, I changed my views, and considered they were probably postmortem degenerations of the nuclei of the splenic pulp cells. On reading Major Leishman's paper, I at once recognized the similarity of his so-called degenerations of the trypanosomes to those found by me in the spleens of the cadavers mentioned. Yesterday (June 17) I had occasion to puncture *intra vitam* the spleen of a native boy, aged 12, suffering from irregular pyrexia, with no malarial parasite in his peripheral blood (careful examination of stained films on four several occasions), and found identical bodies in the blood from the spleen, thus removing any doubt there was as to the products being due to postmortem changes. It is unwise to theorize on the insufficient grounds at present in hand. I hope to contribute something more definite on the subject after further and more prolonged study of these organisms. My films were stained by the Maurer-Romanowsky method. I am familiar with the appearance of trypanosomes—*T. evansi*, *T. lewisi*, and a doubtful species occurring in the blood of the common Indian squirrel (*Sciurus palmarum*). There was nothing resembling trypanosomes in the peripheral blood of the boy in question.

Major Ronald Ross,² professor of tropical medicine, University of Liverpool, published a paper entitled, "Note on the Bodies Recently Described by Leishman and Donovan." Having obtained some stained specimens of the bodies from Captain Donovan, Major Ross examined them with great care and publishes the following brief notes in verification of the previous papers:

All these preparations contain bodies agreeing exactly with Leishman's description, and he himself admits the similarity after having been so kind as to examine the specimens.

In Donovan's specimen of April 9 (postmortem) the bodies number about 30 in a field and measure about 2.5 microns. They are disconnected from each other, but often lie fairly close together in groups of 10 or more. In the specimen of June 17 (*intra vitam*) they number only about 1 in 12, they are in fields, but are slightly larger—up to 3.25 microns. In that of July 4 they are also large, and number about one in every field or so; while groups of from 2 to 12 of them can often be found embedded in what seems to be some kind of matrix which stains a faint bluish-gray color, and which has an oval contour measuring up to 8 microns in the long diameter. Some of the bodies

appear even to be intracorpuscular, but this may be due to accidental superposition.

Both large and small nuclear masses are almost invariably present, and both are always stained a deep vivid crimson. The smaller one is very often rod-like and pointed at the large one, just as Leishman describes, and stains somewhat deeper than it. The bioplasm is generally colorless, but its contour is reddish in the specimens made *intra vitam*.

In none of the specimens can I find either entire trypanosomes or the remains of dead ones, such as the characteristic flagella.

Major Ross finds it difficult to adopt Leishman's view that the bodies are involution stages of trypanosomes in the postmortem spleen, believing that the stained flagella are always to be seen in degenerating trypanosomes yet are never to be seen in the Leishman's bodies.

If, then, these bodies are nothing but disintegrating trypanosomes, we should certainly find a few of the flagella among them. Then, again, neither the large nor the small nucleus in the preparations seems to me to recall those of trypanosomes; and they are, moreover, approximated in a much more regular manner than, I think, we observe in dead trypanosomes.

Lastly, as Donovan observes, his two preparations made *intra vitam* exclude postmortem changes altogether, and should, therefore, contain some unaltered trypanosomes. *Prima facie*, then, I am strongly inclined to think that we have to do with some quite novel organism. As it has already been found in eight cases of fever and cachexia, it promises to be a common and important one.

The next note seems to have been published by Laveran,³ to whom Captain Donovan also sent specimens. He admits that the bodies are parasites, but does not regard them as either trypanosomes or hematozoa, but believes that they belong in the genus to which he has given the name *Piroplasma*, and which includes such parasites as *Piroplasma bigeminum*, which causes Texas fever in cattle, and the recently discovered *Piroplasma hominis*, causing the tick fever of the Bitter Root Valley.

According to Laveran the bodies are found contained in the red corpuscles, and are sometimes pyriform. No one else seems to have observed the parasites in the corpuscles.

Major Ross⁴ published a paper entitled "Further Notes on Leishman's Bodies." In this contribution Ross calls attention to the very important fact that in preparations of the Leishman's bodies made *intra vitam*, the organisms appear under two distinct conditions, *viz.*, free, and embedded, to the number of one up to twelve in a matrix. In the majority the contour is elliptic, but it is occasionally nearly circular. The two chromatin masses are generally situated at the extremities of the minor diameter of the elliptic cell. The larger mass often seems to bulge beyond the cell wall. He thinks that both masses are always present, but that the smaller one may be occasionally hidden by the larger. All of the free forms seem to have a most definite size and structure. The bodies embedded in a matrix are found only in preparations made *intra vitam*. They are much less numerous than the free forms. However, the contour of the little cell is generally much less distinct in the embedded organisms than in the free ones, although the chromatin is stained just as deeply and the two chromatin masses bear just the same relations to each other as regards position and distance. What he calls the matrix is always stained very faintly in these specimens, much more faintly than the red or white corpuscles. In Romanowsky specimens, the tint is violet, or more rarely mauve. The structure appears cloudy, or perhaps granular, or even stromatic; but is too delicate for expression in the drawings. The form is generally a more or less regular oval, but sometimes the mass appears to be shapeless or torn. The outline is sharp, but it is important to note that there is never any contour line suggestive of a cell wall, as with the Leishman bodies themselves. Also there is never any suggestion of the hemoglobin of the red corpuscles, or the nucleus of the white corpuscles, to be seen in this matrix.

The size varies in my specimens from about three microns to eight microns in the long diameter, and there is a rough but only a rough correspondence between the size of the matrix and the number of Leishman bodies it contains. Sometimes a considerable part of the matrix is empty, and sometimes a rather large matrix holds only one of the bodies. It may contain as many as twelve.

In discussing the nature of the bodies, Ross says that after having examined some thousands of them, he has seen only two or three lying in contact with red blood-corpuscles, and therefore believes the cases mentioned by Laveran, in which they were found in the red blood-corpuscles, to have depended upon accidental superposition. He did not find any distinctly pyriform bodies in his preparations. The matrix of the embedded forms does not present any of the characteristics of a red blood-corpuscle altered by parasitic infection.

Instead of accepting Laveran's classification of the organism among the piroplasmas and accepting the name given—*Piroplasma donovani*—Ross believes the parasite belongs to another new genus, for which he suggests the name *Leishmania*. Should this name be accepted, the full name of the parasite would be *Leishmania donovani* (Laveran).

In the same number of the same journal, we find an additional note by Donovan, stating that up to November 5, 1903, he had found these parasites in 16 cases, in all of which they were obtained by punctures in the spleen and liver during life.

Briefly synoptized, the symptoms with which the parasites were associated were enlarged spleen and liver, irregular pyrexia, paroxysmal edema of the feet, congestion of the lungs, occasional subcutaneous hemorrhages, and cancrum oris. Medication by quinin, arsenic and sodium salicylate proved ineffectual.

The most recent contribution appears in the *British Medical Journal* for January 23, 1904, under the title "The Leishman-Donovan Body and Tropical Splenomegaly," by Sir Patrick Manson and George C. Low, of the London School of Tropical Medicine. In this paper the writers notice that over and above the malarial cases and those of leukocythemia, cirrhosis of the liver and other well-recognized pathologic conditions associated with enlargement of the spleen, there is a considerable residuum of cases of tropical disease in which enlargement of the spleen is a prominent feature, and which hitherto have not been adequately recognized or explained.

Clinically these cases fall into two categories, the subacute and the chronic. In the more acute forms there is a history at first of a malaria-like condition with recurring attacks of high fever, which after some months, and in spite of liberal dosing with quinin, leads to the development of a very definite cachexia. This cachexia is characterized by quotidian fever, afternoon chill, followed by high temperature and profuse sweating, and terminating by the following morning in a subnormal temperature and anemia. Although in some instances there may be intervals of apyrexia of several weeks' duration, in others there is little variation in the quotidian recurrence of fever, which is absolutely uninfluenced by quinin. In time the spleen enlarges, and the anemia becomes intense. According to their experience, the patients die in a few months. The fatal event is brought about sometimes by pure asthenia, sometimes by cerebral thrombosis, sometimes by diarrhea, sometimes by other intercurrent disease.

The second type of febrile splenic enlargement to which they refer, resembles the foregoing, only the fever is much milder, rarely exceeding 101° F., the splenic tumor and the anemia being less pronounced. There is, however, always a malaria-like initial stage, and just as in the other type, this and the subsequent course of the disease are unaffected by quinin. What the ultimate fate of these more chronic cases may be, is not known,

but it seems probable that these patients drift along as valetudinarians until they are ultimately cut off by some other affection, to which their persistently enfeebled state renders them specially liable.

In both types of the disease the tongue is clean, the appetite good, and, but for weakness, the patient feels fairly well. Occasionally, as might be expected, in persons coming from malarial localities, attacks of genuine malarial fever may be interpolated. In this event there may be considerable gastric derangement, and quinin may be of temporary service.

In certain instances the skin becomes deeply and fairly uniformly pigmented. Owing to this latter circumstance, and because most of the cases which have passed under the observation of Manson and Low, have come from Assam and the Indian Terai, they have arrived at the conclusion that the disease is none other than what is known by the natives in Assam and India as kala-azar or kala-dunkh. They have seen an exactly similar condition in a patient from South Africa, but whether his case and the Indian disease are identical, they are not prepared to say.

Manson and Low were fortunate enough to be consulted by a patient from the neighborhood of Darjeeling, who was persuaded to enter the tropical wards of the Seamen's Hospital. From the enlarged spleen of this patient two tapings were made. In the material thus secured, microscopic examination revealed a great number of the Leishman-Donovan bodies, many fields of the microscope showing dozens of them.

Their studies of the bodies confirm and supplement the descriptions of the earlier observers, and seem to disprove completely Laveran's statement that the bodies are parasites of the red blood-corpuscles, and a species of piroplasma; although the parasites were frequently encountered superposed on or underlying a red blood-corpuscle, nothing was at any time seen to suggest that they were inside the corpuscle. The Romanowsky stain gave by far the best results. Fuchsin was a complete failure. The somewhat lengthy description of the different appearances presented by the parasite adds very little to what had already been described. Different-sized, oat-shaped, elongate and spheric bodies with a nucleus and centrosome (?), arranged as described by Leishman, similar bodies enclosed in rounded, zooglea-like masses, sometimes singly, sometimes in large clusters, and zooglea masses containing no parasites were found. They do not doubt that the frequency with which the body was found by Donovan and the frequent occurrence of chronic febrile splenomegaly, indicate that this parasite is important in tropical pathology.

Judging from the appearances met in our preparations, it seems fairly safe to assume that once in the spleen it multiplies by simple division. Certain of the parasites, after being liberated from the zooglea masses, are destined for passage into another phase outside the body, others for endogenous multiplication. The latter on becoming free in the splenic pulp probably conjugate, and throw out a material which ultimately forms the matrix of the zooglea masses within which the parasites divide for some five or six generations. This goes on indefinitely, apparently.

Thinking that the blood might be the medium by which the parasite travels toward its exogenous phase, we made repeated and prolonged examinations of peripheral blood obtained from the patient at regular intervals of two hours during the day and night. Although two expert assistants worked at these films for several days, no Leishman-Donovan body, with one doubtful exception, was ever found by them or by ourselves. Neither in these examinations of the peripheral blood nor in those of splenic or hepatic blood did we ever encounter malarial parasites or malarial melanin.

It is evident that the parasite must get out of the body somehow, and that the blood is the most probable channel. We thought that possibly the parasite was filtered out from the splenic blood as the latter passes through the liver in the portal circulation. Accordingly, we tapped our patient's liver, and found in the small quantity of blood so obtained, numerous single or double parasites, but no zooglea masses. This discovery seems to point to the biliary ducts as the channel through which the parasites escaped to gain subsequent freedom by passing out of the body with the feces, but repeated examinations of the feces were negative. Similarly, centrifuged urine

also yielded no parasites. A curious feature about the parasites from the liver was that in quite 90% of them the nucleus was either extruded and swollen, or was in process of extrusion. Possibly this phenomenon was owing to the blood having been diluted with normal salt solution. An attempt to cultivate the parasites in blood agar failed.

VARICOCELE.¹

BY

HENRY DAWSON FURNISS, M.D.,

of New York City.

Instructor in Gynecology, New York Postgraduate Hospital.

The structures which form the spermatic cord, namely, nerves, lymphatic vessels, a thin fibrous cord (the remains of the peritoneal pouch), arteries (the spermatic, the cremasteric, and the artery of the vas), and veins, converge at the internal abdominal ring and together pass down the inguinal canal to the testis and epididymis. The spermatic artery, a branch of the aorta, passes down in the inguinal canal with the vas; it divides into several branches, two or three of which accompany the vas and supply the epididymis, and anastomose with the artery of the vas; other branches supply the testis after piercing the tunica albuginea. The cremasteric artery, a branch of the deep epigastric, accompanies the cord, supplies the cremaster and other coverings of the cord, and anastomoses with the spermatic artery. The artery of the vas, a branch of the superior vesical, accompanies the vas, ramifying upon its coats, and anastomoses with the spermatic near the testis. Thus it is seen that there is a free communication between the three arteries of the cord.

The lymphatic vessels of the scrotum terminate in the lumbar glands.

The nerves supplying the cord are from the spermatic plexus of the sympathetic, joined by filaments from the pelvic plexus, which accompany the artery of the vas. The spermatic veins, which are numerous, emerge from the back part of the testis, receiving tributaries from the epididymis, to form the pampiniform plexus of veins, which constitutes the chief mass of the cord. These veins ascend the front of the cord, and below the external, or superficial abdominal ring, unite to form three or four veins; these then pass upward along the inguinal canal, and after entering the internal, or deep abdominal ring, unite, forming two large veins, which join to form a single vein. On the right side the vein enters the inferior vena cava at an acute angle, while on the left the venous blood is carried to the left renal vein, the junction here being at a right angle. The spermatic veins throughout their course are provided with valves. Rivington has demonstrated that there is usually a valve at the orifices of both spermatic veins. On the left side, when no valve is present at the junction of the left spermatic vein with the left renal vein, valves are generally present in the renal vein on the vena cava side within a quarter of an inch of the junction.

The disease known as varicocele is a varicose condition of the veins of the spermatic plexus. Without going into the question, it is sufficient to say that an analogous condition occurs in the veins of the broad ligament in the female. Upon examination it will be found that not only are the veins in this condition, but also all the other structures of the cord are thickened. After the dilation has become at all marked, there is a relative incompetency of the valves of the veins of the plexus; when this occurs, the back flow of the blood is augmented, with consequent further dilation. In marked cases there

is adhesion between the different veins of the plexus; sometimes a communication between two or more branches, and occasionally the formation of a thrombus. The thrombus may be the source of emboli, infected or noninfected, dependent upon whether the thrombus has been infected or has remained sterile; it may organize, and if it has been an occluding thrombus and a sufficient number of branches have been involved, may cause a spontaneous cure of the varicocele; the organized thrombus may become calcified, giving rise to a phlebolith. A phlebolith through erosion of the veins may cause a large extravasation of blood into the scrotum. Fortunately, thrombus formation, with its sequels, multiple emboli and phleboliths, is rare.

Some authorities contend that varicocele may be due to a congenital weakness of the veins, or an abnormality in the number and size of the veins that go to make up the pampiniform plexus. Anatomically, there are several reasons for the frequent occurrence of varicocele, namely, the imperfect support afforded the veins by the loose structure of the scrotum; their great length; their vertical course; their dependent position; their plexiform arrangement in the scrotum, with their termination in one small vein in the abdomen; their few and imperfect valves; the fact that they may be subjected to pressure in their passage through the abdominal wall; that in the scrotal region they are not surrounded by muscles whose contractions may assist in the return flow of the blood; the feeble *vis a tergo*, since the spermatic artery is of small size. On the left side are additional anatomic reasons for the occurrence of varicocele, namely, that in the passage of the left spermatic vein under the sigmoid it is liable to pressure, especially in constipated individuals; that on the left the spermatic vein empties into the left renal vein at a right angle, this giving a greater hydrostatic pressure on the vein than on the right side, where the junction with the inferior vena cava is at a lower level, and the angle of the convergence of the two veins is here acute; the left side of the scrotum is usually longer than the right; that in right-handed individuals the contraction of the abdominal muscles is greater on the left side. Lately it has been asserted that the left spermatic veins in the fetus and the young child are more numerous than on the right side. Treves states that the left side is affected 25 to 30 times oftener than the right, and that both sides are affected in about 7% of cases. On the right hand, Pick, and other authorities, state that varicocele of the right side alone is almost unknown.

Varicocele is a disease usually of puberty and early manhood, most of the cases occurring between puberty and 30. It rarely originates after 35, and in a large proportion of the cases it disappears spontaneously after this age. As a reason for its occurrence at puberty, is ascribed the naturally greater varicosity, due to developmental changes physiologically present at this age. Unsatisfied sexual desire is given a place in the etiology, because of the greater frequency of the trouble in unmarried persons, and the disappearance of the varicocele after marriage. Often varicocele, with a long and relaxed scrotum, seems to be part of a general lack of muscular tone or development. For some reason it is less frequent in the negro; some contend that his relative immunity is due to the fact that he does not have to contend with unsatisfied sexual desire; yet it may be due to the fact, that generally, the muscular tone of the negro is better developed than that of the white man.

The diagnosis of varicocele is usually easy, but sometimes its association with inguinal hernia and hydrocele may render the diagnosis more difficult. The enlarged veins may be seen through the scrotum, forming an irregular mass. To the touch they feel like a bunch of worms; to this mass an impulse on coughing is imparted. Upon assuming the recumbent posture the veins slowly empty, to refill again upon regaining the erect position; this occurs, but more slowly, even after

¹ Read at the February, 1904, meeting of the New York Postgraduate Hospital Alumni Association.

pressure of the arteries at the internal, or superficial abdominal ring.

The large majority of people with varicocele, present no subjective symptoms, and the presence of the large mass of swollen and tortuous veins is the only noticeable feature. Next in frequency are those individuals who are made aware of the trouble by a sense of weight and dragging in the scrotum. In a very neurasthenic individual this causes marked mental distress, though assured by competent authority that this is of little or no consequence; in these the mental impression made, with ideas of approaching impotency and sterility, is the chief symptom. As is often the case, the softening of the testicle on the affected side, and its being smaller than its fellow, lends weight to their fears. With some the pain is actual, extends along the cord into the inguinal region, and often causes backache, and a feeling of weakness in the lumbar region. This pain is made worse by long continued standing. Occasionally, as mentioned before, there may be thrombus formation with its sequels, and the symptoms dependent upon this will be, according to the termination of the thrombus, multiple emboli, infected and noninfected, in different portions of the body, and hemorrhage into the scrotum from erosion of a vein. The varicocele in nervous patients may cause impotency, which is not always amenable to treatment, encouragement and suggestion. Should atrophy not occur at puberty, or early thereafter, it is improbable that it will.

Treatment.—In a palliative way, in suitable cases, the improvement of the general muscular tone of the body, by good food and plenty of outdoor exercise, combined with cold baths may be effective. The baths, beside their general tonic effect, act locally as a stimulant to the scrotum, causing contraction; with the shortening consequent upon the contraction, the veins are relieved of much of the backward pressure of the column of blood, and more readily empty themselves. In cases of varicocele, in which the dragging is not marked, and there is no pain, it is doubtful if it is advisable to wear a suspensory, as the scrotum would become too dependent upon this support, and upon discontinuing the use of the support the subsequent condition might be worse than primarily. In summer the use of the suspensory is very uncomfortable, and absolute cleanliness is necessary to prevent chafing; yet this is the time of the year when varicocele is most troublesome. As a palliative measure when there is pain and dragging the suspensory is very serviceable.

Operation should not be undertaken except for good and sufficient reason, for it is more dangerous than is generally supposed. Those desiring to enter the army, the navy, the police and the fire services are required to be rid of varicocele, though causing no symptoms, by operation. Operation is not advisable unless the mental condition is distressing, or there is beginning atrophy of the testicle (and not for this unless there are other good reasons), or the dragging sufficient to cause marked inconvenience, or the pain actual and not relieved by palliative measures, or both sides affected. In the event of thrombus formation, when there is reason to expect more serious trouble dependent thereon, operation is not only justifiable, but is indicated. This conservative stand in regard to the operation for varicocele is taken, because I have seen more bad results from it than from any other one operation of election. It may be urged that the bad results are due to improper technic, but these mishaps have occurred in the hands of men regarded competent by the profession. This should lead the inexperienced to regard the operation with some apprehension, and make the experienced more careful. Fortunately, up to the present time, I have escaped having any bad consequences from the operation.

The report of the following cases will show that the operation is more dangerous than generally supposed, and will also illustrate some valuable points.

CASE I.—Varicocele, left side. Open operation with incision over left and front side of scrotum. Veins isolated and separate branches tied with seven ligatures of No. 2 chromic catgut, after resecting about one inch; ends of upper and lower mass united; wound closed with plain catgut; wound broke down and testicle sloughed out; under treatment five weeks before recovery; here there were too many knots, the catgut too large, and chromicized.

CASE II.—Double hydrocele and varicocele on left side. Sac on each side opened through incision over side and front of scrotum; sac sutured to margin of wound and packed with gauze. On the left side, a portion of the veins was resected. Wound broke down on left side, and the greater portion of the testicle sloughed away. It was five weeks before the wound was completely healed.

CASE III.—Varicocele, left side. Incision over side and front of scrotum, veins isolated from vas, and 1½ inches resected. In dividing the veins the vas with its blood supply was severed. Wound closed with plain catgut. On the tenth day the wound broke down, and the testicle sloughed. This illustrates the fact that after the blood supply of the testicle has been destroyed, it should be removed. If desirable, a celluloid testicle may be inserted at the time of operation.

The following cases I did not see, but they have been reported to me by friends who knew I was interested in this subject:

CASE IV.—In this case the subcutaneous method of operation was chosen, and the vas accidentally ligated. Necrosis of the testicle necessitated its removal.

CASE V.—Varicocele, redundant and relaxed scrotum (left). Ablation of scrotum, and resection of varicose veins by open operation. After the operation there was considerable hemorrhage from spermatic artery of the left side, necessitating opening of the wound. Testicle sloughed, and convalescence was protracted.

CASE VI.—Varicocele, left side. Resection of veins by open operation. After the patient had been put to bed there was considerable hemorrhage into the scrotum, necessitating opening of wound and ligature at bleeding point. (History does not give source of hemorrhage.)

CASE VII.—Redundant scrotum. While this is not strictly relevant to the subject of varicocele, it is included, for the operation for redundant scrotum is often undertaken at the same time as one for varicocele. Under the anesthetic the proper amount seemed to have been ablated. Wound closed with plain catgut. In 36 hours the scrotum had so contracted that the sutures gave away, there not being sufficient scrotal tissue to cover properly the testicles. These became exposed and the patient was under treatment five weeks before the granulating wound healed.

In consideration of the lessons taught by these cases, and from other experience, the following conclusions have been deduced:

Asepsis should be as complete as possible, and greater care is required in asepsis here than in other operations of seemingly greater importance. Operate with as little traumatism as possible, and ever be careful not to injure the vas and its blood supply, the testicle, and the epididymis. The subcutaneous ligation of the veins is objectionable, for a thickened vein may be isolated under the impression that it is the vas, and the vas be ligated with the other veins. The swelling is greater than after the open operation. A small vessel may be punctured, giving rise to an extravasation of blood into the scrotum that would necessitate incision and evacuation of the blood and ligation of the bleeding point. Such an extravasation, if left alone, forms an admirable culture medium for the development of pyogenic organisms.

The open operation is the operation of choice, and the high operation is better than the one in which the incision is made through the scrotum, for the following reasons: At the external or superficial ring the veins have united to form two or three large trunks, and the isolation from the vas is easier in this situation than in the scrotum (the higher one begins, the easier will be the isolation). By resecting the veins in such a manner that after the joining of the several ends this juncture will lie under the aponeurosis of the external oblique muscle, the pressure of the muscle will prevent the swelling that would occur if the resection had been made in the scrotum. In the scrotum this swelling lasts for a considerable time, and produces an unfavorable impression on the patient. Another good reason for the high operation is that there is less danger of the production of

traumatic hydrocele, a not infrequent sequel of the operation in the scrotum. Again, high up there are fewer veins to ligate; it is not necessary to ligate all of the branches that come from the testicle, but the main branches formed by their coalescence. This is analogous to the ligation of the saphenous vein for cure of varicose veins of the lower extremity.

In cases in which the veins are greatly enlarged with a patulous external abdominal ring, and in which it is supposed that there is a predisposition to hernia, Dr. W. B. DeGarmo advocates, beside the resection of the veins, the performance at the same time of the typical Bassini operation for inguinal hernia. The patient is in bed only a few days longer, and after the operation his abdominal wall is certainly stronger with than without the hernia operation. As a matter of technic after removing the portion of the veins between the double ligatures, the performance of the hernia operation is easier, if these are not united until after the transversalis and internal oblique have been sutured to Poupart's ligament.

In the ligation of the veins No. 2 plain catgut is sufficiently strong and lasts long enough to secure good results, while with the chromic there is more danger of infection, as it remains in the tissues longer as an irritant.

When the scrotum is very long, rather than resect a portion, I would prefer to make the cavity smaller by uniting with sutures of plain catgut the inner surfaces of the lower portion of the scrotum. This will decrease the size of the interior of the scrotum, and leave a redundant portion that will in time atrophy more or less. This can be done so that the redundant portion, which will be more or less flattened, shall run in a direction from before backwards and from left to right (it is here considered that the operation is on the left side), this allowing it to fit the thigh more comfortably, as most men dress on the left.

Operation.—The operation I prefer is a modification of the one described by Kocher in the "Vierte Auflage" of his "Chirurgische Operationslehre."

An incision over the external or superficial abdominal ring just above Poupart's ligament 2 inches long is made, the incision being parallel with Poupart's ligament, this extending through skin, superficial fascia, the process of fascia over the cord known as Cooper's fascia, and the fibers of the cremaster. The cord is then isolated and the enlarged veins separated from the vas with its vessels, the higher the better. An inch to 3 inches of the veins are resected after isolating them. The veins should be isolated for a greater distance than the amount of vessels to be resected, so that when the divided ends are united, there is not too great a kink in the vas. The veins are ligated with No. 2 plain catgut in two places, the distance between being proportionate to the amount to be resected. After resection the ends are united by tying the ligatures which have been left long for this purpose and with one or two stitches. This should be done as high as possible, so that the united ends will then slip up under the fascia of the external oblique. When the operation is done high, fewer vessels have to be ligated, and the mass included in the ligature is not so great. It is not necessary to ligate all of the vessels entering into these veins, but only the main trunks high up. This is analogous to the ligation of the saphenous vein for varicose veins of the lower extremity. All bleeding points should be controlled by ligature. The wound should be closed with a subcutaneous suture of plain catgut, and dry sterile gauze dressings applied. A point of great importance in the after-treatment, while the patient is in bed, is that the scrotum should be well supported by a good suspensory bandage. Perfect asepsis must be observed in this operation.

Effect of Rest in Bed on the Fever of Tuberculosis.—All tuberculous patients who have fever should remain in bed; experience shows that the fever is often lowered by this simple procedure in the early stages of this disease. Pickert, after studying the effect of the dorsal posture on the fever of tuberculosis, concludes that it is the congestive element which controls the fever. As in osseous tuberculosis we find local hyperemia provoked by the Esmarch bandage, so in pulmonary tuberculosis the blood stasis caused by the recumbent posture arrests the proliferation of the bacillus. This shows, according to Pickert, that it is the blood stasis and not the rest alone which influences the temperature. This is why the temperature rises if the patient is kept absolutely quiet, but is allowed to sit up with the legs elevated.—*Journal des Praticiens.*

THE RESULTS OF THE RÖNTGEN METHOD IN THE DIAGNOSIS OF RENAL CALCULUS.

BY

CHARLES LESTER LEONARD, A.M., M.D.,
of Philadelphia.

In order to be recognized as a valuable method of physical diagnosis, it was essential that the röntgen method should produce not only better results, but also results that could not be secured by any previously known method of diagnosis.

This has been accomplished. Greater accuracy and detail have been obtained earlier and with less inconvenience, pain and injury to the patient. This has been demonstrated in the diagnosis of fractures, dislocations and osseous deformities. It has gone far beyond other methods in localizing foreign bodies that have entered the tissues, and calculi that have formed within.

The application of the röntgen method of diagnosis to the detection of various concretions or calculi, that form in the hollow viscera, has been attended with marked success. These calculi are principally formed of inorganic salts, that ordinarily pass in solution through the organs in which they are found. Some slight derangement of function is apparently responsible for their formation, as a consequence they do not give rise to characteristic symptoms until they interfere mechanically with the function of the organ in which they are situated, or infection follows their depressant action. This is entirely in accord with nature's tolerance of all sterile foreign bodies. Such quiescent calculi are, however, a menace to the functional life and vitality of their host. The presence or absence of such concretions should be determined as soon as they are suspected. The indefiniteness of the symptoms does not always permit this to be done, but the present röntgen technic makes it possible in renal and ureteral lithiasis, and an improved technic will make it equally possible in other calculous conditions.

The absolute negative and positive diagnosis of calculous nephritis and ureteritis can be made with an error of less than 3%. This is greater accuracy than has been obtained by any other method, in this, one of the most obscure fields of surgical diagnosis.

The result has been felt in altered indications for operation, and modifications in operative procedures, that have rendered them more accurate and comprehensive, while lessening the danger and necessary operative trauma. These advantages, and others that follow the employment of this method in calculus diagnosis, will be realized more fully after a review of the results obtained in 320 cases that have been referred to me for röntgen diagnosis between March 15, 1898, and May 1, 1904.

Many of these cases have been reported or referred to in papers previously published, in which detailed descriptions of technic, the indications for operation, and the influence of this method upon treatment may be found.

A statistical study of the 320 cases examined shows that calculi have been found in 93 cases, or a little less than a third of the cases examined. In many of the cases in which a negative, or exclusion diagnosis was rendered, the patients had such slight symptoms as to render the presence of calculi possible, but not probable. In 47 cases the symptoms demanded operative intervention, and in all but one, the accuracy of the negative diagnosis was proved by the operation, as no calculi were found. In many of the cases of negative diagnosis in which there was no operation, the subsequent development of other conditions showed that the diagnosis had been correct. In three cases of negative diagnosis small calculi that had escaped detection were subsequently passed. Thus there has been a total error of but four cases in the negative diagnoses: One due to defective technic, and the others to inaccurate reading of the plates.

Of the 93 cases in which calculi were found there were four in which calculi were present in the kidney and ureter of the same patient. Including these cases, there were 33 renal calculi found and 64 ureteral.

Of the renal cases, 27 were removed by operation; four patients refused operation, and in two cases operation was not advised on account of the age of the patient and the chronic character and mildness of the symptoms.

Of the 64 ureteral, 26 have passed the calculi after expectant treatment (*American Medicine*, November 30, 1901) had been adopted as the result of the röntgen diagnosis. The ureteral calculi have been removed by operation in 15 cases. In the remaining 23 cases the patients have not had sufficiently grave symptoms to render operation necessary or advisable. Among them are many recent cases, in which the expectant line of treatment has been adopted, until further symptoms make operation advisable.

To the total of 93 cases in which calculi were found by the röntgen diagnosis should be added the four cases of error in the negative diagnosis, making a total of 97 cases in which calculi were present, in 320 cases examined.

The total amount of error, including these cases, has been nine cases, or less than 3%. There have been five cases of doubtful and positive diagnosis, which are included among the errors, in which the operator failed to find a calculus.

The patients were some of them exceedingly stout, and an absolute diagnosis had not been rendered; in others, the operation for a small stone was delayed a sufficient length of time for the calculus to have changed its position. In one case a large calculus was not found by one operator, but was subsequently removed by another, and the accuracy of the röntgen diagnosis confirmed. This case and others in which calculi have been missed by expert operators, and subsequently found by the röntgen rays, and later removed, show how readily the surgeon may overlook a small calculus. The greatest care must, however, be taken in reading the negatives in this diagnosis. The negative must first be recognized as having sufficient detail to show all calculi, as clear definition in bone shadows is not sufficient; contrasts must show in soft tissue shadows.

The negative diagnosis is based upon the axiom that "where shadows of tissue less dense than the least dense calculus are shown, no calculus can escape detection." In order, however, to be accurate, the negatives must be carefully studied, and experience in reading them increases the accuracy of the diagnosis.

The greater accuracy of this method over other methods of diagnosis, and even over operation, has been repeatedly demonstrated. In two cases calculi were found in a kidney that had previously been operated upon and a small calculus removed. In three other cases calculi were found in the ureter, blocking it and producing a urinary fistula from a kidney that had previously been operated upon. Again in three cases calculi were found in the second kidney, after the other had been operated upon and calculi removed.

Such cases as these illustrate the greater accuracy, precision and completeness of the röntgen diagnosis. They show that it renders the operative intervention thorough and complete, while reducing to the minimum the amount of operative trauma. They guard the patient from the danger of operation upon the wrong kidney; of operation upon the kidney when it is the ureter alone that is involved; and of any calculi remaining behind to necessitate a second operation. The accuracy of this method localizes to the exact seat of the calculus the operative intervention, decreasing the trauma and necessary shock.

One of the gravest complications of nephrolithiasis is anuria. Unilateral anuria threatens the functional activity of the kidney involved. Bilateral or complete anuria threatens the life of the patient. Both demand

immediate operation to remedy a most serious condition. The question in complete anuria was, formerly, which kidney to operate upon, and how to find and relieve the obstruction? This query can now be answered accurately by the röntgen diagnosis. But a condition almost as serious, and more difficult to diagnose is present in unilateral calculous anuria. The great danger and difficulty lies in the insidiousness of the symptoms. It is a condition that threatens the functional life of the kidney involved, because it totally obstructs the urinary flow, this finally leads to degeneration of the secreting substance of the kidney. The symptoms are not open and frank, they simulate recovery, while they actually mean destruction. When the ureter is completely blocked, the intrapelvic urinary pressure soon equalizes the intranephritic blood-pressure, the kidney ceases to act, there is no longer distention of the pelvis of the kidney, and of the ureter above the calculus and hence no more pain. The patient has apparently recovered from the attack. Unless a calculus has been passed and detected, or the presence of a bilateral urinary flow has been proved, the patient, after the cessation of symptoms following an attack of renal or ureteral colic, is in grave danger. This cessation of symptoms may mean total obstruction of the ureter. The röntgen diagnosis renders it possible to relieve such a situation of all its danger, and renders rational and safe an expectant line of treatment, that will often result in the passage of a calculus by natural channels, avoiding the necessity and dangers of an operation.

Every patient who has suffered from an attack of renal or ureteral colic, unless a stone has been passed, should be examined by the röntgen method. If the symptoms have entirely subsided and a calculus is present, the existence of a bilateral urinary flow ought to be ascertained.

The value of this diagnosis, and of the expectant line of treatment that can be based upon it, is illustrated by a series of 26 cases, in which this line of treatment had been suggested, after the detection of small calculi in the ureter. It is not wise, in any application of this method of diagnosis, to depend entirely upon it in shaping the course of treatment. All the knowledge that can be gained by every possible method of diagnosis should be employed in each case. In no class of cases is this more true, than in calculous nephritis and ureteritis. The study of the symptomatology, combined with the findings of the skiagraph, have led to this more rational and safe method of conservative treatment, and these 26 patients may be said to owe their recovery without operation, to the röntgen method of diagnosis.

In only three cases in which this conservative treatment has been suggested, have the symptoms become so severe as to demand immediate operation. In all, the accurate localization of the calculi facilitated the operation, rendering it successful, and aided materially in producing in each case a favorable termination. Purely medical, or expectant treatment is unwise and irrational without the aid of this method, which safeguards the integrity of the kidney and makes accurate, effective operation possible when the symptoms demand it.

Beside forming the basis for new indications for operation, and rendering the operation more complete, it has freed it from some of its graver dangers. Multiple and bilaterally situated calculi are detected, and the operation freed from the danger of overlooking them, or of operating upon one kidney or removing it, when the other is the seat of calculous disease. That these dangers are real ones, is shown by the detection of multiple calculi in 12 cases.

The accuracy which has been secured in the negative diagnosis leads to the opinion, that when an operator has attained the essential accuracy, and his skiagraphs show no calculi in the kidney, an incision into the kidney in the search for calculi is not justifiable, unless

some macroscopic pathologic lesion is present as an indication.

In favorable cases greater detail can now often be obtained that suggest greater possibilities in renal diagnosis. Thus pyonephroses and hydronephroses, displaced kidneys, tuberculous kidneys, and surgical kidneys have been demonstrable or suggested in some negatives, and have afterward been found at the operation.

The röntgen method has been of great advantage in differentiating calculous nephritis and ureteritis from other conditions in surrounding organs or in the kidney itself, that simulate the symptomatology of renal lithiasis so closely as to render a differential diagnosis very difficult.

Thus a calculus lodged in the right ureter, where it crosses the iliac artery, a very common seat for impaction, may suggest appendicitis or ovarian disease. The appendix has been removed, when the true condition was an impacted ureteral stone, by some of our best surgeons, who afterward removed the calculus. The ovary has undoubtedly been removed or operated upon in a similar way. This possibility is easily conceivable when we consider that the röntgen method of diagnosis has shown that more than half the calculi that form in the kidney do not give rise to symptoms of moment until they reach the intrapelvic portion of the ureter.

I have recently examined two patients whose cases forcibly illustrate this point. In the first, appendectomy had been performed by one surgeon, and nephropexy by another. The symptoms still persisted, and were shown by the röntgen diagnosis to be due to a small calculus in the juxtavesical portion of the ureter, where it was found and removed by operation. In the second case the appendix had also been removed. Here a small ureteral calculus was found in the parasacral portion of the ureter.

The results of the röntgen method of diagnosis in conditions of renal lithiasis have, therefore, been the more ready differentiation of calculous conditions from other pathologic processes in the kidney and surrounding organs, by a method that is more accurate, precise and comprehensive, while it is without danger, inconvenience or pain to the patient. It has facilitated operation by giving the exact size, location, and number of all calculi, thus confining the operation to the position of the calculus and decreasing the operative trauma and shock. It has freed operation from the danger of doing unwittingly a nephrectomy upon the kidney, or other serious surgical intervention, while the second kidney is the seat of calculous disease: The wrong kidney cannot be operated upon for calculus, or calculi left behind when multiple calculi are present.

It affords a solution for the grave problems of complete and unilateral calculous anuria, and has rendered rational and safe a conservative expectant line of treatment, that without it would be dangerous. It has already saved many patients from the dangers of operation, guaranteeing their safety until they have been restored to health.

The negative diagnosis has been proved to be as accurate as the positive. It renders unnecessary any incision into the kidney during exploratory or other operations, unless there is some further visible pathologic lesion to justify it.

These demonstrated results make the use of this method imperative in all cases in which calculus is suspected. After an attack of apparent renal colic, no course of treatment can be correctly or conscientiously undertaken, without the determination of the presence or absence of stone. It must be employed before every nephrolithotomy or ureterolithotomy to determine whether operation is, or is not indicated, to free it from as much danger as possible, to localize and limit the operative trauma, and finally to render the operation comprehensive and complete.

NEUROSES OF NASAL ORIGIN.¹

BY

G. HUDSON-MAKUEN, M.D.,

of Philadelphia.

Professor of Defects of Speech in the Philadelphia Polyclinic and College for Graduates in Medicine; Laryngologist to St. Mary's Hospital and the Frederick Douglass Memorial Hospital, Philadelphia.

In attempting to discuss so comprehensive a subject in the brief time allotted to me (10 minutes) it will be necessary to take many things for granted. I may say that my conclusions are based not alone upon rhinologic work, both in private practice and in 2 dispensaries, but also upon a careful study of the nasal conditions found in about 1,000 purely neurotic subjects. The fact that these latter patients consulted me not on account of nasal, but of nervous diseases, makes them peculiarly appropriate as a basis for these remarks.

There are 2 ways in which the nervous system may be affected by intranasal diseases: (1) By interference with normal respiration, and (2) by peripheral nerve irritation.

Free nasal breathing over normal mucous membrane is exceedingly important as a means of keeping the entire respiratory tract in good condition, and indirectly of giving tone to the general nervous system by the proper aeration of the blood; and perverted nasal breathing and mouth breathing are frequently causal factors in many grave neuroses and psychoses. Deviations and obstructions of the inspiratory air current caused by structural irregularities within the nasal chambers, and the vitiated air supply that results from breathing over diseased mucous surfaces are responsible in my opinion for quite as many nervous symptoms as accrue from peripheral irritation within the cavities of the nose.

The various sensory neuroses, such as disturbances of olfaction (parosmia, hyperosmia, and anosmia), many neuralgic pains of the head, pharynx, ear, and face, and some of the diseases of the eye, as for instance epiphora and conjunctivitis, can best be explained on the theory of interference with normal respiration by obstructive nasal lesions and catarrhal conditions. In a similar manner we may account for all those psychic phenomena, to which Guye, of Amsterdam, gave the name *aprosxia*. It was his opinion that intranasal and postnasal obstructions interfere by direct pressure with the normal cerebral circulation, and thus give rise to such psychic disturbances as listlessness, inattention, and incapacity for intellectual work. It is quite possible also that toxic disturbances of the cerebral functions may result from absorption of catarrhal and septic material within the nostrils and accessory cavities. If this theory is the correct one, and it is now pretty generally accepted, I see no reason why it should not be carried a step further and thus used to explain some of the more serious functional, and even organic diseases of the brain and nervous system. *Aprosxia* is a condition present in almost all cases of stammering and allied disorders of speech, and as I generally find the aforementioned nasal conditions associated with it, I have come to look upon them as a probable causal factor.

With reference to the reflex theory of nasal neuroses, I have always been more or less sceptical, and have felt that the rhinologist, like his neighbors, the ophthalmologist and gynecologist, has allowed his enthusiasm to carry him rather too far along these interesting lines. However, it must all result in much good by calling attention more emphatically to the importance of nasal conditions in general as possible factors, either causal or casual, in the diagnosis and treatment of nervous diseases.

Of all the peripheral and vesicular regions of the body, excepting only the eye, the nose is probably the most sensitive and susceptible to irritation. By means

¹ Read before the Medical Society of the County of New York, January 25, 1904.

of its own copious nerve supply and through the sphenopalatine, the gasserian and the superior cervical ganglion of the sympathetic, it has direct connection with the pneumogastric, and when we recall the wide distribution of this latter nerve throughout the thoracic, abdominal and pelvic viscera, we can well understand the possibilities of nervous disturbances in these regions due to peripheral nasal irritation, and we can also understand the rationale of their treatment by the removal of this irritation.

I should as soon think of treating dyspepsia without examining the tongue as I should of treating hay fever, spasmodic cough, asthma, cardiac insufficiency, albuminuria, dysmenorrhea, and certain diseases of the brain and spinal cord without examining the nose. Notwithstanding all this, we must keep in mind the fact that we are dealing in many instances with nervous phenomena that have no demonstrable anatomic or pathologic foundation, and because we know so little about them we call them neuroses, a term that is as indefinite as the conditions for which it stands. Who of us can define a neurosis? Is it not often a mere symptom of some hitherto undiscovered disease?

To illustrate, I have a boy of 12 under my care at the present time who has suffered with cough and asthmatic breathing for 3 years. About 8 weeks ago I removed a small exostosis of the nasal septum, and cauterized a single follicle on the pharyngeal wall, and he has had scarcely any cough or asthmatic breathing since that time. I cannot claim in this case to have cured a disease, but rather to have removed a symptom. If there is a disease I do not know what it is.

I have another patient, aged 7, that had severe choreic twitchings of the orbital and facial muscles until after the removal of adenoid vegetations and the resultant nasal catarrh, when the symptoms promptly ceased. Whatever of disease the patient had before my operation he still has, as is shown by the fact that the twitchings recur, to some extent, with every exacerbation of the nasal catarrh.

Another patient aged 26, has stammered during the greater part of his life, and under the usual treatment, which consisted in his case in the removal of a septal ridge causing slight intranasal pressure, and appropriate psychophysical training, his general condition improved satisfactorily and he acquired perfectly free speech; but as in the 2 cases cited before, we did not cure a disease, but simply removed temporarily a symptom, as was shown by the fact that when the crucial test came some weeks later, which chanced to be an attempt to read the scriptures at a church service, his tongue seemed to cleave to the roof of his mouth and although pregnant with words he was unable to deliver himself.

I have cited 3 typical cases, one of asthmatic breathing, one of choreic twitchings, and one of stammering. The patients are all of the so-called neurotic temperament. There is a general tendency to be irritated, and this tendency characterizes all cases of so-called reflex neuroses of nasal origin. It often takes the form of neurasthenia, hysteria, or aprosexia, and it may be the direct result of the nasal conditions which I have described, but it is almost never itself of purely reflex origin. To be quite sure of our diagnosis we must have, as Friedrich has aptly suggested, absolute clinical proof that the symptoms can only come from the nasal mucous membrane, that they can be completely arrested by anesthesia of the parts, and that they can only be finally cured by direct treatment of the offending area. A careful application of these 3 diagnostic tests would make it necessary to transfer many neuroses from the long list of those supposed to be of purely reflex origin, to the list of those having their origin in the interference with normal respiration, including intranasal pressure and toxic conditions resulting from the absorption of septic material.

To sum up briefly, I beg to offer the following con-

clusions: 1. It is reasonable to suppose, though not absolutely proved, that some of the more serious mental and cerebral diseases may be of nasal origin. 2. Many of the so-called reflex nasal neuroses may best be explained on the theory of faulty respiration and impaired cerebral circulation, due to direct intranasal pressure and the absorption of toxic catarrhal products through the blood and lymph circulation. 3. A careful examination of the nose is imperative in all doubtful cases of diseases of the nervous system.

THE IMPORTANCE OF A CORRECT DIAGNOSIS IN THE TREATMENT OF DISEASES OF THE STOMACH, WITH A SUMMARY OF 30 CONSECUTIVE CASES.

BY

ALBERT WOLDERT, M.D.,

of Tyler, Texas.

Both in hospital work and in private practice I have found that patients afflicted with diseased stomachs constantly present themselves for treatment.

While acting as assistant physician at the Howard Hospital, Philadelphia, where upwards of 10,000 patients were treated annually, and while in charge of the clinic for diseases of children at the St. Joseph's Hospital in the same city, I learned that a large proportion of patients who came to the clinics suffered from gastric trouble.

I learned, also, that some patients who complained of symptoms referable to the stomach, when a careful chemic examination of the gastric contents was made, little could be found that was wrong, while in other patients, with few such symptoms, a thorough examination of the stomach would show a considerable degree of abnormality.

Formerly I endeavored to arrive at a diagnosis, by depending upon the complete history of the case and by the clinical symptoms presented. My experience was that many of these patients would disappear, and later I would learn that some of them were being treated by other physicians; then they would reappear, complaining of the same symptoms as formerly.

I began to consider whether or not some of these cases had been diagnosed properly, and why the prescription of hydrochloric acid and pepsin, or of sodium bicarbonate and peppermint had not brought about the hoped for relief.

In one instance there would be a patient complaining of eructation of gas, or of sour or bitterish food; in another a complaint of a "bloated" feeling in the region of the stomach, a burning pain in the pit of the stomach; some complained of a thickly coated tongue, others of headache, and a great many of constipation.

Purgative medicines would sometimes ameliorate the symptoms, but I observed that such medication had a very transitory effect.

The question as to whether or not one should in any given case administer hydrochloric acid and pepsin, or adopt the opposite line of treatment of sodium bicarbonate, is encumbered with multitudinous chances, when one depends only upon the clinical symptoms and uncertain histories. Should one depend alone upon such evidence, he will surely go wrong in a very great many instances.

As to the administration of hydrochloric acid and pepsin in cases of stomach trouble, or what was formerly called "dyspepsia," it is only necessary to state that in this series of 30 consecutive cases of gastric trouble treated in private practice, 21 patients or 70% were secreting too much hydrochloric acid originally.

In order to overcome many of the fallacies which surround this subject, I think it will be admitted that the best way to secure competent evidence in the case would be to give a light test-meal to the patient, draw

off the gastric contents, filter, and proceed with the proper tests.

We have not yet learned all that is to be known in regard to the subject of gastric analysis, but I believe that if *labor omnia vincit* applies to other problems it also applies to this one.

It seems to be the current idea that because a patient suffers from a "bloated" feeling accompanied by eructation of "sour" food, that an alkali is needed to neutralize the excess of acid *presumed* to be present. To illustrate this point, the following case may be cited:

Mr. —, a patient of 42, had for years occasionally suffered from bilious spells, dizziness, and what he thought was "malaria." He had suffered from indigestion, following an attack of typhoid fever 4 years previously. At times he would have a sense of fullness in the region of the stomach, accompanied by the eructation of "sour" food. During these spells of gastric distress he would have a more or less depressed feeling, or a feeling of prostration, and a fear that "something was going to happen." A microscopic examination of the blood was made in this case, and showed that the patient did not have malaria, while the gastric examination showed *not even a trace* of hydrochloric acid present. I believe that the quinin and calomel which the patient had taken at intervals for his "touch of malaria" also did harm. Proper treatment in this case soon brought the free hydrochloric acid up to the normal of .073%, and the total acids up to 56%, and a relief from the symptoms enumerated.

The question of the administration of any drug directed to the relief of any diseased condition, depends upon the condition present. In many instances, the proper use of the stomach-tube, together with lavage, will do more genuine good than will drugs. The following case will illustrate this point:

A patient aged 23, had for 3 months suffered from eructation of gas (belching every minute or two), and from a "drawing" sensation with pain in the region of the stomach. At times he would awake at night with a sense of "smothering," accompanied by palpitation of the heart, and a fear of impending death. The heart and lungs were found normal, while a thorough gastric examination showed the hydrochloric acid to be totally absent. Lavage, with alternate douching of hot and cold water, within 3 days, and without the use of any drug for this condition, restored the free hydrochloric acid to .058%, and the total acids to 48%, or a normal percentage of each.

Recently it has grown to be the fashion for patients afflicted with diseased stomachs to go to certain health resorts, and to drink the mineral waters at those places. In fact, some of these patients after returning home have such mineral water shipped to them to be placed upon the table and taken *ad libitum*.

No one can doubt that a change of climate and relaxation from business cares will frequently accomplish more than drugs.

"And Certynly wher nature will not wirche,
Then farewell physik."

The fact should be impressed upon patients who go to "mineral" resorts, that they are simply taking drugs which may be purchased at the drug stores, and that such drugs when taken into the system produce definite results.

For instance, at Mineral Wells, Texas, there are located some wells, the waters of which contain as much as 306 gr. of glauher salt and 18 gr. of epsom salt per gallon. There are mineral wells at Sour Lake, Texas, which are surcharged with sulfuric acid; a mineral water at Saratoga, New York, which contains 143 gr. of calcium bicarbonate per gallon; a spring in California which contains 107 gr. of ammonium bicarbonate and 103 gr. of borax per gallon; one in Bohemia which contains 79 gr. of epsom salt and 17 gr. of glauher salt per gallon. Having an assortment of springs and wells containing such large quantities of drugs per gallon, some alkaline, and others acid, how is one able to decide by clinical symptoms alone where any given patient with gastric trouble should go? The following case will illustrate this point:

A man of 27 had for 5 or 6 years suffered from indigestion, accompanied by "soreness" on pressure over the region of the stomach; this was worse in the morning hours on awaking. He complained of eructation of gas after eating and suffered

from "biliousness" almost constantly, and from a bad taste on arising. He had suffered from constipation for years, and had taken all kinds of purgative medicines. During the year 1901 he had made 2 trips to one of the health resorts named, and had drunk the alkaline purgative waters there with temporary relief, but on returning home the bowels again became constipated, and soreness of the stomach returned. A gastric examination was made October 14, 1901, and the hydrochloric acid was found diminished to .01022%, or a fifth of what it should have been; the total acids were 40%. The stomach was greatly dilated (gastroptosis), the motor and absorptive powers deficient, and the gastric contents had a Paris-green color, indicating mold (gastrosia fungosa). He did not keep up the stomach treatments. Two years later the patient made 2 other trips to the same resort as before and drank the alkaline purgative waters there, but after returning home the old trouble returned, and mold was still present in the stomach. Restriction of the diet, with douching of the stomach with a weak solution of silver nitrate (1 to 1,000, as recommended by Einhorn), together with intragastric faradization, relieved the symptoms.

In a case of this kind it is evident that an alkaline purgative water might do harm, for the patient was originally suffering from a lack of acids in the gastric secretions.

The question of "what to eat" and "what not to eat" in a case of indigestion also demands close attention and study. Probably there is no other condition of the system on which the average person among the laity feels more competent to give a positive opinion and to prescribe a proper diet slip than cases of indigestion. And yet how such advice proves utterly valueless and tantalizing. Can the medical profession be blamed for the *opprobrium medicorum* heaped upon it by those who follow such advice?

Frequently, one sees patients who begin the circle by first denying themselves of this kind of food, then of that kind of food, finally reaching such a stage that they become afraid to take sufficient food of any kind to nourish the body, in consequence of which anemia comes on, soon followed by a collapse of the system generally.

In one case among this series it required considerable persuasion to get the patient's consent to eat a small amount of meat, although she was informed that the acids had been restored to normal, and that she could digest it.

It is clear that the best variety of food to be given in any particular case of gastric trouble necessarily depends upon the condition present and as determined by a thorough examination of the gastric contents.

One common symptom of gastric indigestion is summed up in the word "biliousness." This condition is more commonly met in the South than in the North. In the South it is frequently diagnosed "malaria," and in the North "abortive" typhoid fever. It is nearly always ushered in with loss of appetite, vague pains, thickly coated tongue, disagreeable taste in the mouth, headache, eructation of gas and food, and general restlessness. Slight fever may or may not be present. I have found that biliousness may occur both in patients who have not a trace of hydrochloric acid in the gastric contents, and in those who already secrete 2 to 3 times too much hydrochloric acid.

Method Used in the Treatment of These 30 Patients.—I endeavored to conform to a strict plan of examination (modified after Ewald) as follows: (1) To secure a complete and accurate history of each patient; (2) to determine the percentage of free hydrochloric acid; (3) to determine the percentage of total acids; (4) to determine the motor power of the stomach; (5) to determine the absorptive power of the stomach; (6) to determine the digestive power of the gastric juice on albumen (meats); (7) to determine the digestive power of the gastric juice for starch (bread); (8) the milk curdling ferment (rennin); (9) the presence or absence of bile; and (10) the size and position of the stomach.

To determine the percentage of free hydrochloric acid I used the decinormal solution of sodium hydrate. And to be sure that this solution was accurate I first standardized it with a decinormal solution of oxalic acid. The indicator used for the free hydrochloric acid was the

Töpfer reagent, in nearly every instance being confirmed by the tropeolin (heat) test. For the total acids I used the phenolphthalein test; for the digestive power of albumen, white of egg; for digestive power of starch, Lugol's solution; for the motor power in a few instances I used the salol test, but finding it inaccurate I used lavage. In one instance in which the salol test was used, no reaction with ferric chlorid could be obtained at the end of 75 minutes, while lavage 4 hours after a small breakfast showed rice and bread particles unchanged. For the absorptive power potassium iodid was used; for the milk curdling ferment (rennin) 2 or 3 drops of the fresh gastric juice to about 8 cc. of fresh milk; and for bile the nitrous acid test. The size and position of the stomach were determined by inflation with air, combined with gentle percussion.

In nearly every instance I procured a complete history of the case, and made a thorough examination of the heart, lungs, liver and renal excretion, and in some cases supplemented this by testing the eyesight, and by microscopic examination of the material withdrawn from the stomach.

ANALYSIS OF THE CASES.

Entire number of cases in the series, and treated in private practice, 30.

Free HCl normal (.040% .073%), 2.
Free HCl diminished (below .040%), 5.
Free HCl increased (above .073%), 21.
Free HCl totally absent, 2.

THE PERCENTAGE OF FREE HYDROCHLORIC ACID.

Free HCl above .073% in 21 out of 30 cases.
Free HCl above .10% in 16 out of 30 cases.
Free HCl above .15% in 6 out of 30 cases.
Free HCl above .20% in 2 out of 30 cases.

PERCENTAGE OF TOTAL ACIDS.

Total acids above 50% in 16 out of 30 cases.
Total acids above 65% in 4 out of 30 cases.

MOTOR POWER OF STOMACH.

Motor power of stomach was tested and found deficient in 16 cases or 53%.

Motor power of stomach was not tested in 14 cases or 47%.

The number of cases tested by lavage, and considerable amount of food remnants found 3 to 4 hours after a light meal, was 13 cases or 66%.

Salol test was given in 3 cases.

ABSORPTIVE POWER OF STOMACH.

Absorptive power of the stomach was found deficient (over 15 minutes) in 15 cases or 50%.

Absorptive power of the stomach was deficient (over 10 minutes, but time not determined) in 14 cases or 47%.

The absorptive power was not determined in 1 case.

The average length of time required before the iodine could be detected in the saliva was 24 minutes. The longest time required in any case was 40 minutes (in a case in which the HCl was totally absent); and the shortest time in which the iodine was detected in the saliva was 15 minutes.

DIGESTIVE POWER OF GASTRIC JUICE FOR ALBUMEN (MEATS).

The number of cases of hyperchlorhydria (?) (free HCl above .073%)¹ in which the digestion of albumen (meats) was good, was 20 cases out of 21.

Hydrochloric acid was diminished (though not absent), and the digestion of meats was good in 4 out of 5 cases. In one case the digestive power of albumen was not determined.

In the 2 cases in which the hydrochloric acid was totally absent there was no trace of digestion at the end of 3 hours, and in one of these no digestion at the end of 3 days.

DIGESTIVE POWER OF GASTRIC JUICE FOR STARCH (BREADS).

The number of cases of hyperchlorhydria (free HCl above .073%) in which the digestion of starch (breads) was good was 9 out of the 21 cases or 43%.

Hydrochloric acid was diminished (though not absent) and the digestion of starch (breads) was good in 2 out of the 5 cases. In one case the reaction was not determined.

In the 2 cases in which the hydrochloric acid was totally absent, the digestion of starch (breads) was good.

TESTS FOR MILK CURDLING FERMENT (RENNIN).

The milk curdling ferment (rennin) was active in 22 cases out of 25 or 80%; inactive in 3 cases or 12%. The reaction was not determined in 5 cases.

In the 2 cases in which the hydrochloric acid was totally absent the rennin ferment was active in one, and absent in the other case.

¹Some authors consider the free hydrochloric acid normal when considerably above this figure.

REACTION FOR BILE.

Bile was tested for in 29 cases out of 30, but was never present.

SIZE AND POSITION OF THE STOMACH.

The number of cases in which the stomach was found dilated (that is in which the fundus was found to project below the navel after dilation had been done) in a series of 27 cases, was 19 or 70%.

Hyperchlorhydria (free HCl above .073%) with dilation of the stomach was found in 12 cases or 44%.

HCl was diminished—hypochlorhydria (that is free HCl below .040%), or entirely absent with dilation of the stomach in 6 out of 7 cases.

Of the 2 cases in which the free hydrochloric acid was found to be totally absent, the stomach was found dilated in both instances, in one only slightly, in the other it was greatly dilated.

The size and position of the stomach were not determined, mainly on account of irritability in 3 cases.

SEX OF PATIENTS.

Of this series of 30 cases, 25 were males, and 5 females.

AGE OF PATIENTS.

Between 20 and 21 years (inclusive) there were 3 cases or 10%.

Between 22 and 35 years (inclusive) there were 10 cases or 30%.

Between 36 and 50 years (inclusive) there were 14 cases or 46%.

There were 3 cases in patients over 50 or 10%.

SEASON OF THE YEAR.

Of the series of 30 cases, 15 or 50% occurred during the fall months; 6 or 20% during the spring months; 5 or 16% during the summer months; 4 or 13% during the winter months.

Constipation occurred in 13 cases or 43%, and diarrhea occurred in 4 cases or 12%. The number of male patients who used tobacco in excess was 15 or 60%. Of 30 patients there were 2 who suffered from mold in the stomach (gastrosia fungosa). Of the 30 patients treated, 18 have been greatly benefited; 10 have been cured; and 2 have not reported.

MANIFESTATION OF NERVOUS SYMPTOMS.

Of this series of 30 cases nearly every patient suffered more or less from nervous symptoms, provided one includes actual pain under this heading. The symptoms most commonly met were as follows: Pains in region of stomach before or after eating, an uneasy feeling in the region of the stomach early in the morning on arising; pains in the back near the shoulder blades or spinal column, "smothering spells" principally coming on during the night, a "sinking" feeling on lying down at night, dizziness, fear as though "something was going to happen," symptoms of angina pectoris, a feeling of lassitude or "don't care what happens," a sense of uneasiness or self-conscious fear in appearing in public as at an opera house, or church, "intense" sick-headache, sleeplessness, frightful dreams, fainting spells, a "swelling up" or tightness about the stomach, and palpitation of the heart.

In studying this series of cases I have been impressed with the frequency with which nervous symptoms have been associated with gastric trouble. But whether or not the stomach disorders were a result of derangement of the nervous system or whether the nervous symptoms arose primarily from a disordered stomach I am not prepared to say, but this I do know, that frequently when the stomach was restored to a more healthful condition the nervous symptoms disappeared.

INFLUENCE OF OLD AGE, DIABETES, ARTERIAL SCLEROSIS, AND GOUT ON THE HEALING OF WOUNDS.¹

BY

WELLS P. EAGLETON, M.D.,

of Newark, N. J.

The subject matter of this paper was suggested by the following case:

Mr. W. H., aged 74, was a persistent drinker until within the last few years; he had frequent attacks of gout. He had general edema of the legs and abdomen 15 years ago. For the past three months he has had uninterrupted otitis media, with suppuration of the right ear, associated with vertigo, and pain in the head and back of the neck. Temperature was never above 99.3°. When first seen there was a profuse discharge from the right ear, coming from an opening in the posterior wall of the external auditory canal, through which a probe

¹Read before the Newark Medical and Surgical Society, November 19, 1903.

could be passed into the mastoid cells, and in which dead bone could be felt. The drum membrane was intact. The patient was almost entirely deaf on the affected side. There was no tenderness over the mastoid, but an almost incessant pain during the night. Temperature 99°. There was arthritic enlargement of several joints of both hands and feet. Urine examination was negative.

Operation.—The anesthetic used was ether. On exposing the mastoid the cortex appeared healthy, but on removing it the mastoid cells were found thrown into one large cavity, extending from the lateral sinus behind to the posterior wall of the canal in front. The entire cavity was filled with pus and granulation tissue, in the center of which was a rather large sequestrum perfectly detached. The granulation tissue was firm and offered an effectual barrier against the extension of the pus inward toward the lateral sinus.

The patient was catheterized on the following day because of retention of urine. Day succeeding, temperature 102.3°. Pulse was slow, urine somewhat cloudy, with a slight quantity of sugar. Within a few days, temperature became normal.

On the fourteenth day after operation, he was discharged from the hospital in good condition, except for pain and a slight edema of the right leg. *The wound, however, although clean and free from pus, did not granulate, and this unfortunate condition continued until his death.* Temperature varied but slightly from subnormal to normal, with the exception of one day, following a chill. On this occasion it rose to 103°. Eyesight failed gradually, he could not read, but ocular examination was negative. Seven weeks after operation gangrene of the ball of the great toe occurred, but not of the toe itself. Slight rise of temperature occurred, three days later, followed by unconsciousness, and death.

Diagnosis.—Either abscess of the cerebellum with septic thrombosis, or diabetic coma and gangrene.

Why did not the wound granulate? Was it due to his age, gout, arterial sclerosis, or diabetes? Or to the combination of them all? Each condition being, as it were a part or sequence of the other.

In the era which preceded aseptic surgery, the general recuperative powers of the patient were regarded as the important factor in determining upon the advisability of operating, but with the advent of Listerism, and the knowledge that nonunion of wounds was due to infection, the pendulum swung too far in the opposite direction. Now again we are becoming conscious that natural recuperative power plays a most important part in a small, but, as yet unsettled class of cases. Examination of the standard textbooks throws but little light on this subject.

The influence of age is generally dismissed with the statement that infants and old people stand operations badly. But why, how, or in what proportion, is not explained. Do wounds in old people heal slowly? The experience acquired in every eye hospital in regard to cataract extraction bears evidence that so far as corneal wounds are concerned, the union is as rapid, if not more so, in aged than in young persons. One of the first questions invariably asked, by friends of elderly patients on being informed that an operation for the removal of a cataract is necessary, is if the extreme age of the patient will not militate against him, and a negative reply is received with more or less incredulity.

Again, notwithstanding that failure to obtain a good result is usually attributed to the patient's age, it is a recognized fact that every ophthalmic surgeon approaches the extraction of a cataract in a young patient with much greater dread than he entertains when operating on an extremely old one. If then, this is the universal experience in ophthalmic surgery, why should it not also apply to operations on other parts of the body? The general experience with nonunited fractures of the head of the femur, in old people is, in a large measure, the cause of the belief that injuries to old people do not heal rapidly.

In 1884 Humphry maintained that granulation proceeds more rapidly in old people than in young, provided the tissue does not slough. He states, "The apparently opposite tendencies exist at this time of life; namely, the tendency to slough, and the tendency to heal quickly." He contends, and proves, by the report of 14 (?) cases and several specimens, that fractures of the head of the femur do unite in a small proportion of cases, and that when they do not unite it is not on

account of the age, but on account of the anatomic relations of the parts, the inability to coaptate the fractured surfaces, or to the inadequate treatment.

Gibson compiled statistics of 65 major operations on patients over 70, operated upon at St. Luke's Hospital, from 1860 to 1893, or during a period of 33 years, the mortality was 24.5%. This apparently high mortality is somewhat accounted for by the fact that many of these operations were performed in preaseptic days. Of the deaths 50% resulted from uremia after operation, the patients living from 11 to 37 days, or an average of 15 days. A large number of the operations were for the relief of suppurative diseases of the genitourinary tract, with diseased kidneys, a condition followed by a high rate of mortality at every period of life. Excluding the deaths from uremia, we have in Gibson's cases a mortality of about 12%. The majority of these patients died from shock.

Humphry says in 1886, "I think we must notice the difference manifested in the old between the little power they show of bearing up against the first impulses, or initial shocks of disease; and their power of recovering from its effect; between the power to withstand the tidal flow of disease, and the power of repair during its ebb. The depression associated with the oncoming malady is illy borne by the aged."

Can we not recall instances from our own experience of very elderly people rapidly sinking in a few hours, or even minutes, to the verge of death, and in a comparatively short time, returning to a normal condition? Humphry thinks that this inability to withstand shock, with rapid repair, may be accounted for by the "lowered irritability, or the lessened nerve susceptibility, which is a wellknown factor of the senile frame." Repair progresses best in quiet, and where there is but little excitement. The mental torpor, freedom from responsibility, and absence of worry in the aged, are the great factors. The essential consideration, then, in operating on old people, aside from damaged kidneys, heart, etc., is to guard against shock. This being eliminated, we can anticipate quite as rapid union as in younger patients.

Until recently the presence of diabetes was almost a positive barrier to operative interference of any kind; not only because diabetic patients are very apt to pass into coma following the anesthetic, but having passed that, the wound itself has not a tendency to heal, especially if repair is by granulation. That such instances do occur, there can be no doubt, but the danger of both complications has been greatly exaggerated.

Durham and Smith, Fisk, Phillips and Noble, have all compiled numerous cases, proving that, in a very large percentage of operations, both major and minor, union is as prompt in diabetes as in other diseases; and that in the cases in which union does not take place infection is the cause, coming from without, as in ordinary wounds. The evidence that the addition of microorganisms is necessary is furnished by the results obtained in the treatment of fractures.

Phillips says: It has been affirmed "that in diabetes, fractures do not unite properly, nonunion or delayed union being the rule." But his investigations contradict this statement, as he found only five such cases reported. This is a very small number indeed, when it is remembered how common diabetes is, and the frequency with which such fractures occur.

While the presence of microorganisms is necessary for nonunion of wounds in diabetic patients, the tissues are of a low grade of vitality, react but slowly to a stimulus, and consequently offer but slight resistance to infection. Why this is has not been fully explained, but possibly the reaction of the wound itself has something to do with it, although there is no evidence that such is the case. Stoker, in 1898, observed that nonhealing wounds were highly alkaline in reaction, in which condition wound-bacteria, *Bacillus fluorescens*, especially was present, while staphylococci had disappeared. But

on the wounds assuming a healthy granulation, their reactions were found to be but *slightly* alkaline, and this to be the normal state in all healthy wounds examined.

The influence of the actual presence of sugar on the growth of bacteria has been the subject of investigation by Bujwid, Nicholas, and Kurlinski. Their experiments demonstrate that while the presence of sugar increases the pus-producing properties of the microorganism of suppuration, it diminishes their virulence. Both of these deductions are entirely theoretic.

That trauma to the tissues makes them more liable to infection has been recognized for a long time, but this is frequently forgotten as the vitality of healthy tissue allows of frequent handling in retracting, sponging, etc., without injury. In diabetes, however, slight trauma is often the factor that prevents union. That avoidance of all trauma but what is absolutely necessary, results in as good union, as in nondiabetic subjects, is exemplified by the excellent results obtained in the extraction of cataract in these patients.

The nerve degeneration, and arterial sclerosis, both of which so frequently follow diabetes, add further to the liability of infection. The influence of nerve degeneration has received but little attention. This is shown by the omission to state the condition of the reflexes in the reports of patients operated upon although the frequent absence of the patellar reflex in diabetes has been observed for a long time.

On the other hand the danger of a complicating atheroma has been recently fully demonstrated, chiefly in causing, what was formerly called diabetic gangrene, but which is now recognized to be ordinary senile gangrene, in a diabetic patient. This has led to the adoption of high amputation far above the site of obstruction.

Wallace reports atheroma in 23 out of 24 cases of diabetic gangrene. He says: "It cannot be that the poison in the blood directly causes gangrene, for if this were the case we should expect to see gangrene in young subjects in whom diabetes is most active."

In approaching a case for surgical operation in a diabetic subject, what extra precautions are necessary to insure union? Paying less attention to the presence of sugar in the urine and more to the technic:

1. By remembering the especial liability of the tissues to infection and so practising absolute asepsis. Antiseptics have no place here.

2. By remembering the extremely low vitality of the tissues. All trauma not absolutely necessary should be avoided.

3. By remembering the frequent association of arterial sclerosis. Interfere as little as possible with the blood-supply.

4. By remembering the liability of nerve degeneration and preventing the possibility of even slight pressure over the site of operation.

The foregoing are simply the rules of aseptic surgery and admit of slight infringement in healthy individuals, but any violation whatever in a case of diabetes would probably terminate disastrously.

Epidemic of Diphtheria on U. S. Steamship Buffalo.—George E. H. Hermon reports that this vessel left the Navy Yard at Norfolk with some 750 men aboard, in October, 1902. A few months later an epidemic of diphtheria appeared on board and the vessel put in at Port Royal, S. C., where the men disembarked and the vessel was fumigated. Those who carried germs of diphtheria in their throats were treated with various local disinfectants, such as Löffler's and Dobell's solutions. The tenacity with which some of the cases held on under treatment was remarkable. In 12 patients the germs persisted for several weeks and these men were left at Port Royal because they were considered unsafe to take aboard. They developed no general symptoms of diphtheria, remaining apparently in perfect health while their throats contained abundant microorganisms. Antitoxin was employed in upward of 80 cases. The disease was not contracted by any man over 30, yet 18% of the ship's company were affected, while out of 137 cases there were but two deaths, and not a single death after antitoxin treatment was begun.—*Jour. of Asso. of Military Surgeons.*

SPECIAL ARTICLES

THE CARE OF THE INSANE.

BY

W. J. HOWELLS, M.D.,

of Medical Lake, Wash.

It is to be greatly deplored that the general public is so poorly informed regarding the actual needs and requirements of the insane. As a consequence, they often forget the duty they owe these unfortunate ones and supply their needs with a grudging and parsimonious hand, often feeling they have been unjustly imposed upon. Having once contributed to their support, many feel relieved of any further obligation toward them or interest in their welfare so long as they are kept out of their way. There has always been a feeling of superstition and dread in the minds of the more fortunate toward the insane, and as a result of this attitude, the insane have suffered much.

Up to the time of Hippocrates all was confusion regarding insanity. The belief that persons acting in a peculiar manner were possessed by spirits (good or bad, according to the actions of the afflicted person), resulted in the care and treatment of the insane being vested in the hands of the ecclesiastic authorities. The priests treated their charges by prayers and religious ceremonies to the different deities, the Egyptians going so far as to build a temple to Saturn for the purification of the possessed. The patient had to undergo purification, expiation, exorcism, and ablution with lustral waters or the blood of a sacrificed victim. Occasionally some hygienic practices were added to these religious ceremonies, such as promenades, a sojourn at the baths, and exercise in the gymnasium. It thus happened that some of the patients recovered, and as this was attributed to the appeasement of the malignant spirit, it necessarily involved the giving of valuable offerings to the priests.

About 435 B. C., Hippocrates, then about 25, began the study of the insane, his writings and studies earning for him the title "The Creator of Mental Science," as well as "The Father of Medicine." He advanced the theory that "mania," "melancholia," and "sacred disease" were due to overheating the bile and the whole body. He therefore combated the religious practices, and substituted in their place phlebotomy, purgation, baths, special diet, exercise, music, traveling, and the use of a few drugs, which included all the medical appliances available at that period. Very little advance was made during the Alexandrian period which followed, except in the study of anatomy and nerve physiology. However, from 80 B. C. up to 473 A. D. (the Grecian-Roman period) some advance was made in the treatment of the insane, although none of the noted teachers of this time got further than locating the seat of the disease in the different viscera, the majority believing it to be in the spleen and liver. Asclepiades divided mental disorders into acute and chronic, and treated them by the institution of a general intoxication. In 5 A. D., Celsus cast the first shadow on the treatment of the insane by advising the use of hunger, chains, and chastisement as measures to subjugate those whose acts and words were due to a want of reason. Galen, a celebrated physician of Pergamus, who followed him, confined himself to putting in form what had already been written about the disease, and recommending, in direct opposition to Celsus, that treatment be humane in the extreme, with exercise and the proper administration of medicine, and as little restraint as possible. From his time until the middle ages very little advance was made.

During the middle ages the study of insanity lost itself in the general chaos of the period; the return of superstitious beliefs, the reign of sorcery and treatment by exorcism and ceremonies, frequently ended in the condemnation of the unfortunate person and his punishment by torture or execution. Thus most of these unhappy victims of popular prejudice atoned with their lives for their loss of reason, not a single voice being raised in their behalf. During the sixteenth century there was a lessening of the prejudice which had governed the treatment of these unfortunates through so many centuries. The writings of Paul Zacchius, Sydenham, Bonel, and others exposing the fallacy of superstitious beliefs, placed the treat-

ment of insanity on a more substantial basis. Still the treatment could hardly be called humane, and it was not until 1660 that the French Parliament passed an act reserving two wards in the Hotel Dieu for the treatment of the insane. And even then, if they did not recover in a few weeks, they were called incurable and sent to the jails and placed in so-called asylum additions, where they were confined in cells and dungeons, clothed in rags, poorly fed, no attention paid to personal cleanliness, and the restless loaded down with chains and irons. About the only fresh air they received was when they were placed in iron cages and exposed to the view of the public, who, on the payment of a fee, were admitted on holidays to "view the sights" and tease them like wild animals through the bars of their cages. This continued until the time of Philip Pinel, who, in 1793, became Physician to the Insane at Bicêtre, where the male insane of Paris were kept. With his entrance upon the scene, a new era in the treatment of insanity began, which carries up to the present time. His first step on assuming charge was to remove the chains; substituting for bad treatment, violence and blows methods of repression and firmness combined with mildness and patience, thus laying down the first basis of the moral treatment of the insane. He demonstrated the necessity of creating special establishments adapted for their treatment, pointing out the principles that ought to govern their construction and management, suggesting the separation of the patients into different quarters according to the nature of their mental disease, or in other words, drew up the first rules for the hospitalization of the insane. Pinel met strong opposition in many quarters, and it was only by his persistent and earnest protests that he succeeded in the rehabilitation of the insane, and their elevation to the dignity of sufferers from disease, thus accomplishing what many centuries had vainly sought to do. While this was going on in France, similar efforts were being made in other countries, prominent among them being that of William Tuke, of York, England, who, witnessing the abuses that prevailed in the so-called asylums, influenced his coreligionists in the Society of Friends to found an institution where all severe measures and bad treatment should be abandoned. As a result the first stone of the York Retreat was laid in 1792, and this was the starting point of the humane treatment of the insane in England. Chiarruggi, in Italy, and Daquin, in Savoy, were also working along the same lines. But in all this work, Pinel stands out as the central figure, not only as a result of his persistent efforts, but also from his most excellent work as a result of his studies, which he published in 1809, and which is not only a medical work, but also a masterly discourse on philosophy and morals. From the time of Pinel there was a rapid improvement in the care and treatment of the insane, until at the present time the treatment of insanity has become one of the prominent branches of medicine. Hospitals for the care and treatment of the insane are now found in every country, and in our own country, in every State in the Union. With the continued study and observation of the insane, and the knowledge of the different forms of insanity, the treatment of each form has improved and broadened, until at the present time the care and treatment of the insane is more humane and more advanced than it has ever been in the history of the world.

The treatment of insanity at the present time is divided into the prophylactic or preventive, and the direct or curative. The prophylactic treatment aims to remove as far as possible all the exciting causes of the disease from the lives of the predisposed. The curative treatment is indicated for those who are already insane. The treatment of these sufferers is divided, first, into general agents, and second, into special agents. The general agents consist in (a) isolation either on farms or in hospitals for the insane where they may have as much freedom and fresh air as possible, with quiet and rest, both mental and physical; (b) travel to divert the mind; and (c) short residences at hydrotherapeutic establishments, etc. The special agents consist of (1) hygienic measures, including sanitation, habitation, raiment, food, sleep, etc.; (2) psychic measures, including moral influence, forbearance, suggestion, kindness, amusements, etc.; (3) physical measures, including hydrotherapy, electricity, massage, etc.; (4) surgical

measures, including operations on the brain and other organs, and last, but by no means least (5) medical measures, including the administration of such drugs as may be required in each individual case.

Before considering the responsibility of the State toward the insane, it might be well to bring to your attention some of the conditions that have to be met in the care of this class of patients. Insanity is now recognized as a disease. Many attempts to form a concise and complete definition of insanity have been made by alienists, but as yet none has been accepted as complete or satisfactory to all. Still all carry the fundamental principles, namely, that insanity is a disease of the brain, affecting the mental faculties to such an extent that the ability to reason and distinguish between right and wrong is partially or completely destroyed. It may be either acute or chronic. In the acute form, statistics show that from 70% to 80% recover. In the chronic form none recovers. The proportion of these forms admitted to institutions for the insane is such that about 33% of all those admitted recover. Of these, about a fourth return at a later period, thus giving 25% of permanent recoveries of all the patients admitted to our institutions for the insane. Very few, except those who have actually been in contact with the insane, understand their requirements and needs. In the first place, owing to a perversion of the mental faculties or a loss of the reasoning powers, or a complete loss of the mental faculties, which makes them unable to care for themselves in any way, they develop ideas which, while they seem perfectly normal to them, to the sound mind are not only absurd, but impossible for one living in the present era of civilization, to hold. Being controlled by these ideas, they act upon them and become a menace to society, at times going so far as to endanger the lives of others as well as of themselves. Many of them, through their perverted sense, imagine they hear voices, which they are unable to distinguish from real voices. They frequently think that these voices come from the Lord, and attempt to obey his directions. Others, through a perversion of their other special senses, imagine that things are being done to them by others to persecute them, and as a result they are liable to do injury to those whom they believe responsible for these persecutions. Some, owing to ideas of personal unworthiness which they develop, attempt to make way with themselves; while others, owing to their confused mental faculties, are unable in any way to care for themselves, and unless cared for by others, would wander off, become lost, and die by the roadside. Not being able to appreciate their condition, they naturally feel that they have been unjustly treated by being deprived of their liberty and placed in institutions where they cannot carry out their false ideas, which they frequently believe would revolutionize the world. So long as their mental faculties remain astray, they hold to their persecutory beliefs that they have been unfairly deprived of their liberty and legal rights, and unjustly compelled to lead a life of quiet away from the busy world, and would, if they had the opportunity, return to that life. It is therefore necessary to make provisions to prevent them from doing so. On the other hand, as patients who have been mentally afflicted recover their reason, they realize the conditions which have been, and feel very thankful, and appreciate the care and treatment they have received while suffering from this disease. Partly owing to hereditary tendencies, and the strenuous life that is being led in the large centers of population, there has been a gradual increase in insanity during the last century. With this, the steady increase in the number of chronic cases necessitates the building of frequent additions to the institutions already in existence, and new hospitals more conveniently located. As these unfortunately afflicted persons are a menace to society, it becomes necessary that laws be passed to protect sane individuals from the insane; and it is necessary to provide and maintain institutions for their care and treatment. This duty devolves upon the State as a natural consequence of the conditions which give the people the right to govern themselves that the law of this country gives to each State in the union. It is therefore the duty of each State to provide as many institutions as may be necessary for the care of the insane, and to appropriate and supply such money as shall be necessary to run these institutions and give the patients in them

all the care and treatment it is possible to give with the advanced state of medical science. The number of institutions and their size should be designated by the natural law of demand and supply, but unfortunately, as a rule, the demand has to become very urgent before the answering supply is received. As a consequence, in most institutions of this sort the cry of overcrowding and insufficient funds arises. While economy should be advocated, it should not be practised to such an extent as to deprive anyone so unfortunate as to become mentally unbalanced of any service, care, attention, or equipment that would facilitate recovery to a normal state of mind. Hospitals for the insane should be equipped with every appliance known to medical science for their care and treatment.

Hospitalization of the Insane.—By this term is meant the housing of the insane in specially constructed institutions, on the plan of a hospital, and adapted to their requirements, and where they can be treated as sick persons, and not as criminals. While we recognize the necessity of building institutions which will prevent those inmates who are not willing patients from escaping, the architecture and construction should be such as to emphasize this point as little as possible. The old asylum idea, with its four bleak walls and gratings on every hand, has given place to the modern cottage plan, which with its variety of design and embellishment, does away, as far as possible, with the prison appearance and surroundings. In planning an institution of this sort it is necessary to take into consideration the class of patients: (1) Whether acute or chronic cases; (2) the condition of the patients, excited, quiet, or infirm; and, (3) the equipment. It is generally recognized by alienists that it is desirable to separate the acute from the chronic cases. This can be done in two ways. 1. By separate departments in each hospital; these should be far enough apart to prevent the two classes from coming in close contact. 2. By the construction of smaller hospitals for the acute insane near the large cities, and a large hospital for the chronic insane centrally located.

If the first plan is carried out, it would be desirable to select a site which would be central, and where plenty of adjacent land for farming purposes could be secured. Having selected the site, the arrangement of the buildings follows. The group for the acute cases should be so situated as to have as good a perspective as possible. The grounds around the buildings should be parked, and with flowers and shrubs, made as attractive to the eye as possible. The group for the chronic cases should be located near the farm proper, and the grounds immediately surrounding the buildings parked. The farm should be large enough to supply all the fruit and vegetables needed by the hospital. As it would be worked by the chronic male patients, it would be run at a minimum cost. The group for the acute cases should be on the cottage plan, as this allows of better segregation. The construction should be separate cottages, planned according to the requirements of the class of patients; the variety of architectural style, design, and embellishment should give as little the appearance of an institution as possible—rather a group of homes. If desired, the buildings might be connected by one-story corridors. The cottages should not be more than two stories. Amusement grounds and groves should be within easy reach. This arrangement prevents the mild and excited patients being thrown together and a deleterious influence thereby exerted on the milder patients. The equipment of the group should be as complete as possible, as it is at this period, if at any stage of the disease, that a cure is effected. Every convenience and apparatus known to medical science for the treatment of the insane should be supplied, as well as games and amusements of all sorts to occupy the patients; also reading, billiard and music rooms, bowling alleys, entertainment and dance hall, gymnasium, plunge, etc. A larger corps of nurses is needed for the acute than for the chronic cases. As I said before, the group for the chronic cases should be located near the farm. It may be built on the same plan as for the acute. The buildings may be grouped closer together and be of larger dimensions. With this class of patients, having become incurable, the requirements are different. All that can be done is to make them as comfortable and their lives as pleasant and useful as possible. For the feeble and infirm, one-story buildings with

large verandas are better. A large proportion of the male population could be employed in the different departments and on the farm, where, under the directions of the employes, they would carry on the work, the women being employed in the laundry, sewing-room, and similar departments. This would mean not only a great saving of labor, but would give occupation to the patients, thereby making their lives useful as well as more contented, and it would also lessen their destructiveness. The farm, orchard, and berry patches would supply vegetables and fruit for the institution, and thereby materially reduce the cost of running it.

We now come to the question of separate institutions for acute and chronic insane. The fundamental principles of both plans are the same, with the exception that the second plan goes a step farther and draws the line of demarcation more sharply. The location of the different institutions is also important. The idea being to locate the hospitals for the acute insane within easy reach of the larger cities, and the hospitals for the chronic insane in a farming section, where the soil and climate meet the requirements of this class. The advantages of having the hospital for the acute cases near the large cities are, the resident staff could make arrangements with specialists and prominent physicians of the city to pay weekly visits to the institution, for consultation and assistance in operations, the convenience in securing talent for entertainments, etc., nearness to the base of supplies, besides the cheapness of transportation of patients to and from the hospital. The same considerations should govern the location, construction and equipment of the hospital for the acute insane as mentioned for the acute department in the hospital for both classes. The equipment should be absolutely complete in every detail. The grounds should be ample to allow sufficient exclusion, as well as room for the raising of plenty of fruit, a small farm and pasturage for a herd of cows.

Having located the acute hospital, we will now consider the selection of a site for the hospital for the chronic insane. The prominent points to be considered are the climate and hygienic advantages, the fertility of the soil, central location and accessibility. As I said before, all that can be done for this class of patients is to make their lives comfortable, pleasant and useful; therefore, the climate should be considered first. A mild, sunny climate, such as is found in the southeastern part of Washington, with its long summers and short winters, allows the patients to be out in the fresh air a greater part of the year, which is a great advantage in the treatment of these patients, and adds greatly to their enjoyment of life, there is also the advantage that less fuel is required to heat the institution. Many of this class of patients can be employed on the farm, thus rendering their lives more pleasant and useful. While their work is, as a rule, purely mechanical, and consequently has to be supervised by trained attendants, considerable work will be done by them under the directions of tactful employes. It would therefore seem advisable to select a site having a large area of fertile land which could be farmed by the patients. A large herd of cows could be kept and the other institutions supplied with butter made here, and a hennery could be made to supply fresh eggs to the other institutions. Owing to the large amount of supplies used in these institutions, it is necessary to have easy access by rail and road, yet, at the same time, enough isolation to prevent the idle, curious and meddlesome from bothering or making sport of the patients. Having selected the site, the construction and equipment must be considered. As stated before, comfort and convenience are the essentials; with suitable arrangements for passing the idle hours as pleasantly as possible. The grouping of the buildings should be so arranged that the noisy and restless patients would not disturb the old and feeble or the workers; enough space should be allowed between the groups for each class. In an institution of this kind there can also be a department for insane epileptics and mentally defective children. The grounds surrounding the buildings should be parked and made attractive to the eye.

Management.—Each institution for the insane should be in charge of a superintendent. This man should not only be a capable physician, but one who has had several years' actual experience in the care and treatment of the insane in a hospital. In his hands should be the entire management of the hospital,

both executive and medical. He should have a sufficient and efficient corps of medical men and trained attendants especially fitted for this work. The attendants should be of a kind and considerate disposition with an even temperament, patience, forbearance and a great deal of tact. They should also be intelligent and quick of observation. They should be responsible to the superintendent for the care of the patients in the departments under their charge, and should hold their positions only so long as their services would be satisfactory to him. The mechanical, culinary, and agricultural departments should be in charge of experienced men. Each employe should be responsible to the superintendent for the condition and efficiency of the department under his charge. These departments to include the engineering, carpentry, general workshop, laundry, kitchen, bakery, stock, farm, etc. The employment and discharge of all employes should be vested in the hands of the superintendent. It seems hardly necessary to speak of the pernicious influence of politics in the management of these institutions, for it is well known that when politics step in, efficiency, thoroughness and the humane treatment of the insane step out. In fact, all the abuses which occur in institutions of this sort are due directly or indirectly to political influence in the management. If there are several hospitals for the insane in a State, the general supervision of all should be in the hands of a Central Board of Lunacy, providing all political element could be eliminated from its formation and operation. This board should be composed of men selected because of their familiarity with the needs and requirements of the insane and their fitness for this work, and not because of their political standing and following in the State. The chairman should be, by preference, a physician who has had a number of years' experience in the care and treatment of the insane and a recognized authority on this subject, preferably an alienist. The advantage of having a central board composed of the right class of men is that they can bring the different superintendents together, and thus secure uniformity in the management of the different institutions, as well as stimulate the management of each institution to increased effort, thereby improving the treatment and giving the patients the benefit of every advance made by medical science in the care and treatment of the insane. At the same time they could purchase supplies in bulk, and thus furnish the needs of the institutions at minimum cost. The superintendent of each institution should be responsible to this board for the general management of the institution under his charge, and should make regular reports to it, including a discussion of the treatment of the patients under his charge and any recommendations as to the instigation of new special treatment, etc., as well as to changes in the construction and equipment of the hospital. It would also be advisable for the board to make arrangements for each superintendent to make a trip with it to the other institutions at least once a year, thereby observing the management of the institutions in charge of his colleagues, exchanging ideas and discussing the care and treatment of the insane with them. The salaries paid the members of the board, the superintendents, and assistants in the different hospitals should be large enough to secure the ablest men that can be found.

Vaginal Section for Delivering Child.—A. Dührssen reports a case of vaginal section for placenta prævia, and also discusses at length its use in eclampsia recommending it when there is immediate danger to the life of mother or child. He holds that the metreurynter with its constant pressure is the best method in all cases in which one can await delivery some hours, since the metreurynter, especially with the Champetier balloons, stimulates a kind of labor activity, widening the os sufficient for the passage of the child's head. If immediate delivery is indicated by danger to either life, Dührssen advises first the metreurynter if it is practicable, drawing the bag as quickly as possible through the cervix, the balloon being filled to the size of a child's head. But if this does not succeed the indication is for vaginal section when the cervix is not obliterated. The leading motive must always be the delivery of a living child without danger to the mother. In his opinion one is not justified in letting the child die because on account of obstruction from the soft parts it cannot be spontaneously born. In the hands of a modern gynecologist the conservative or radical vaginal section is a relatively safe method of delivery.—[*Zentralblatt für Gynäkologie.*]

THE WORLD'S LATEST LITERATURE

Journal of the American Medical Association.

May 28, 1904. [Vol. XLII, No. 22.]

1. Physical Signs of Pleural Effusions. WILLSON O. BRIDGES.
2. The Prevention of Typhoid Fever. RUFUS L. COLE.
3. The Abuse of Drugs. JOHN V. SHOEMAKER.
4. Prostatectomy: Report of 51 Cases Operated on from May 6, 1901, to February 28, 1904. (Continued.) JOHN B. MURPHY.
5. The Cultivation of the Surra Trypanosome of the Philippines. FREDERICK S. NOVY, WARD J. MCNEAL, and CHARLES E. HARE.
6. A Consideration of Speech Defects. JAMES M. BROWN.

1.—Physical Signs of Pleural Effusion.—W. O. Bridges reports cases diagnosed as tuberculosis, uncompensated mitral disease, etc., illustrating the importance of thorough chest examinations. The signs are less apt to be typical in inflammatory than noninflammatory cases. Two of importance in diagnosis are the bulging of the intercostal spaces in phonation and the absence of the phrenic shadow. Displacements of the heart must be differentiated from hypertrophy of the right or left ventricle. Absence or enfeeblement of vocal fremitus is said to be the rule, but vocal fremitus may be pronounced over a large effusion in children, and has occurred several times in the writer's experience over purulent effusions following pneumonia. The percussion note varies according to the amount of fluid. Alterations with change of posture are more noticeable in moderate accumulations, and may be absent on account of adhesions. The exploring needle clears up uncertainty. None but the largest should be used. Even this may sometimes fail, only a good-sized trocar demonstrating the fluid present. [H.M.]

2.—Prevention of Typhoid.—R. L. Cole states that in the absence of specific treatment, to stamp out typhoid requires the recognition of all cases, and destruction of all bacilli as they leave the patient. Typhoid exists in greater proportion in the country than in the city and propagation is generally from the country to the town. One of the most common mistakes is failure to recognize typhoid in children. We should not wait for positive diagnosis before instituting prophylaxis. In this way half the cases could be prevented from harming others, and atypical cases would become rarer. Sterilization of the excretions is all that is necessary. Students are very careless in handling typhoid urine. Bacilli are occasionally present in the sputum, sweat, and expired air. The writer considers carbolic acid 1 to 20 or bichlorid 1 to 1,000 with 0.5 to 1,000 of sodium chlorid the best disinfectants. Of the first 1.5 liters or of the second 200 cc. should be kept in a jar into which the urine should be emptied during the 24 hours, thus permitting sufficient time for thorough disinfection. Urotropin does not kill bacteria, but simply inhibits their growth. For feces, carbolic or milk of lime is best. The latter should be mixed with 8 parts of water and thoroughly stirred with the excreta an excess being used. The buttocks should be wiped with bichlorid solution, and bath water should be sterilized with 250 gm. (½ lb.) of lime to 200 liters of water. Sputum should be burned, clothes be soaked in carbolic solution, and dishes boiled. The nurse should wear a rubber apron when giving tubs and wear gloves or soak her hands in bichlorid. There should be fly screens in the windows. The room should be disinfected. Precautions should be observed at autopsies as to the hands and as to permitting rinsings to enter the sewer. [H.M.]

3.—Abuse of Drugs.—J. V. Shoemaker thinks we too often use medicines in place of natural remedies, nursing, diet, hygiene, exercise, and the therapeutic properties of water, electricity, etc. The public have a widespread habit of using drugs on their own responsibility. Prescribing druggists are a prolific source of drug-taking. A common form of abuse is constant reliance on purgatives, weakening the intestinal muscular fibers, irritating the mucosa, and in some cases causing cardiac weakness and anemia. The effect of stomach bitters is often to set up the alcohol habit. Constant use of preparations containing ginger has caused loss of sight. The medicinal malts are generally much more powerfully alcoholic than beer. Evils from the use of coal tar products are particularly rife among anemic and neurotic persons, especially women. The invariable tendency is to increase the dose and shorten the intervals. Rheumatism cures are similarly objectionable. It

is by the analgesics, anodynes, and hypnotics that the worst human wrecks are made. Physicians should be wary in prescribing alcohol; indicating always the exact liquor, dose, and time of taking. [H.M.]

5.—The Cultivation of the Surra Trypanosome of the Philippines.—F. G. Novy, W. J. McNeal, and C. B. Hare have found as the result of recent experiments and investigations that the trypanosome present in the Philippine surra can be cultivated artificially. Attenuated cultures of this organism can be obtained as in the case *Tr. brucei*. This trypanosome is differentiated by its cultural characteristics from *Tr. lewisi* and *Tr. brucei*. The Philippine surra is therefore a distinct disease, different from nagana, and this observation confirms the work of Laveran and Mesnil on the nonidentity of nagana and the surra of Mauritius. The morphologic differences between the Mauritan and Philippine trypanosome suggest the probability that these organisms are distinct species, and hence that the term "surra" covers a group of closely allied diseases. [H.M.]

Boston Medical and Surgical Journal.

1. Sulfurous Acid and Its Salts as Food Preservatives, as Aids to Fraud, and as Possible Causes of Lesions of the Kidneys. CHARLES HARRINGTON.
2. Notes on Radium: Production of the Gamma Rays from the Beta Rays of Radium; Use of Radium in Some Diseases of the Eye. FRANCIS H. WILLIAMS.
3. Vaginal Section in the Treatment of Extrauterine Pregnancy. FRANK A. HIGGINS.

1.—Sulfurous Acid and its Salts as Food Preservatives.—C. Harrington states that these are used with fish, meats, sausages, fruits, dried vegetables, cider, and wines especially for their action in improving the appearance suggesting superior quality. Canned corn and asparagus are bleached to a uniform white and meats acquire the redness of arterial blood. The sodium salt is used chiefly in minced meat sold as "Hamburg steak" made from trimmings and inferior parts. It makes these look fresh even when swarming with bacteria and it acts as a deodorant. Stale specimens of meat however feel slimy and adhere to the fingers. Sodium sulfite as a preservative has little though appreciable influence. By itself at room temperature it has less effect than the low temperature of a refrigerator, but it can cause decomposing meat to have a normal appearance. For the desired effect 1% to 2% must be added, but often as much as 4% is found. Its use by meat dealers is the rule. The writer reports the percentage found in 50 specimens examined in Boston. It causes diarrhea, vomiting, eructations and general discomfort. Continued ingestion of small amounts causes serious injury to the organs without outward signs of sickness. Experiments on dogs and cats show nephritis as a constant result. [H.M.]

2.—Notes on Radium.—Francis H. Williams gives the technic for the employment of radium, particularly in the treatment of ocular affections. He states that it is hardly necessary to mention the great convenience of using radium as compared with the röntgen rays. The output of the rays from radium is uniform, and the rays may be easily applied. The greatest care should be employed when diseases of the lids or eyes are treated with this powerful agent. Radium is also of use as a test for determining whether or not the eyes of the practitioner are in a suitable condition for making fluoroscopic examinations. This test can be carried out by means of the spintharoscope, which contains a small amount of radium. If the scintillations appear bright to the practitioner, his eyes are ready for use; if dull, he must wait for a while longer in the dark room before attempting to make a fluoroscopic examination. 2.—The relation of the röntgen ray and radioactive solutions to examination of the stomach is discussed by Sinclair Tousey. All his work with radium and radioactive solutions has been with radium of twenty thousand radioactivity, and the amount used in each case has been one decigram. The radioactive solution has been prepared by immersing such a quantity of radium, enclosed in a hermetically sealed glass tube, for four weeks in 16 oz. of normal saline solution contained in a stoppered glass jar. The fluorescent solutions employed were made according to suggestions from Kemp. The quinin bisulfate solution contains 10 gr. of quinin bisulfate and 5 minims of dilute phosphoric acid to a pint of water. The fluorescent solution contains an eighth of a grain of fluorescein, 20 gr. of sodium bicarbonate, and a dram of glycerin to a pint of normal saline solution. Tousey says in conclusion, that radioactive and fluorescent solutions as prepared above, are innocuous when given by the mouth or subcutaneously. They do not produce either singly or in combination, sufficient fluorescence to be of value in the examination of the stomach, without the use of some additional light to excite their fluorescence. They will in some cases be of great assistance in the röntgen ray diagnosis of and in the treatment of stomach lesions. [C.A.O.]

3.—Congenital Hip Dislocation.—D. D. Ashley and Frederich Mueller, in their second article, give a more extended description of the different types suggested in the first paper, and the proceedings necessary to meet the indications in each type. The first type considered is that in which the head rests securely within the acetabulum, moderate resistance felt in attempting to correct to a better walking position. This group represents the so-called "normal cases," in which the after-treatment does not meet with any special difficulty. The second type is that in which the head is in the proper location, but easily dislocated. The indication here is for the renewal of the cast in a very slightly modified primary position, extending the time of treatment in this position. In the third group the head is in the right location, but considerable rigidity is encountered. This rigidity may be explained either by the shrinkage of the muscles, or by the retraction of the capsule, if a third eventuality be not considered—that is, that the femoral head becomes walled around by osteophytes of the acetabulum. [C.A.O.]

4.—Extraperitoneal Route to the Ureter.—T. C. Witherspoon reports a case in which he combined the intraperitoneal examination and extraperitoneal exposure of the ureter, so that both could be accomplished at the same time and through the same incision through the abdominal wall. An incision four inches long was made over the lower end of the rectus, beginning at a point over its insertion into the pubic bone, and extending upward in a direction parallel with its fibers. The opening is directly over the route of the ureter, and allows a good view of that structure through a very small cut in the abdominal wall. It allows of a thorough palpation, through the peritoneum, of both kidneys and ureters, and at the same time of an exposure of the ureter on the side of the incision for extraperitoneal operation upon its lower end. A thorough palpation of the entire urinary tract can be made, and may be of

value. The field of operation is bloodless, and no forceps are in the way. Drainage may be carried through the lower end of the rectus, and does not leave the bright prospect of hernia which a para-Poupart incision does. The dissection is not difficult, and can be carried out by any reasonably prepared surgeon. [C.A.O.]

6.—Diabetes Mellitus, Gangrene: Operation.—E. P. Stone reports the case of a man of 65 whose first symptoms were noticed 21 years ago. During this time the presence and quantity of sugar in the urine fluctuated, but it was present most of the time. He began to have pain in the right great toe, and a small spot of discoloration appeared there. In spite of all efforts, gangrene spread until it involved the whole of the foot, and extended a little above the ankle, where a line of demarcation developed. The process was a dry mummifying gangrene, and was comparatively painless. The leg was amputated at the junction of the upper and middle thirds, under chloroform anesthesia. The patient made a rapid and uneventful recovery from the operation, the wound healing almost throughout by first intention. [C.A.O.]

1.—Vocal Fremitus.—W. N. Berkeley states that the first and earliest sign of pneumonic consolidation, antedating bronchial breathing and pectoriloquy by 12 to 36 hours, is increase of fremitus over the suspected area. The oral resonance is greatest for tactile purposes when the sound of *oo* in soon or *oo* in foot is made or is sung in as bass a voice as possible, using words like good, boodle, rood, moon, avoiding combinations containing *p*, *ph*, *f*, *th*, *ch*, *sh*, or *s*, as these momentarily suspend the vibration of the chords. The patient should be told to speak in as deep a voice as possible and maintain the initial pitch and intensity. Palpation should be made with the hand most used and with the palmar surface of the four fingers. The side of the palm should not be used as its area is too small and it has fewer tactile nerve-endings. Fremitus is conveyed not only by the wind pipe and bronchi but also by the vertebral column and true ribs. Accumulations of fat and muscle on the exterior of the chest are not so destructive of fremitus as usually taught. It is larger over the right than the left side, especially from the tenth to twenty-fifth years. The ratio might be stated as 3 to 2 or 4 to 3. A greater than this is pathologic. Vibration over the larynx is to right subclavicular fremitus as 5 to 1 or 4 to 1. A wide variant from this is also pathologic. The causes of left-sided excess are left consolidation, any process on the right which dissociates the visceral from the costal pleura, obstruction of the right bronchus, or transposition of the viscera. Dilation of the air sacs with atrophy of their walls as in emphysema does not modify fremitus to any serious degree. [H.M.]

2.—Diffuse Septic Peritonitis Treated by the Reversed Trendelenburg Position.—R. S. Fowler and G. R. Fowler from October, 1899, to January, 1904, operated upon 100 well-marked cases of diffuse peritonitis, resulting from disease of the appendix. No case, however desperate, was refused operation. Of the 100 patients, 67 recovered. The technic is given in detail. The reversed Trendelenburg position was used in all instances after operation. The elevation should never be less than a foot. A folded pillow is placed against the buttocks, and through the fold of the pillow is passed a stout bandage, which is tied on each side to the head of the bed. This allows the patient to rest comfortably and maintains his position without exertion on his part. A saline enema is given every 3 or 4

hours for 4 to 6 times. Before their employment of the elevated head and trunk position in the after-treatment, they saved about 25% of this class of cases. At the German Hospital they operated upon 46 consecutive patients with but 9 deaths, 81.25% of recoveries; at the Methodist Episcopal (Seney) Hospital, 30 patients with 12 deaths, 60% of recoveries; at the Brooklyn Hospital, 22 patients with 12 deaths, 45.5% of recoveries. Of the 33 deaths, 17 occurred within 24 hours after the operation. The salient points in the treatment are as follows: 1. A small incision and the avoidance of eventration. 2. Thorough cleansing of the primary focus of infection and removal of the appendix. 3. Evacuation and cleansing of all accessory abscess cavities and the pelvis before washing out the peritoneal cavity. 4. A rapid systematic flushing of the peritoneal cavity with peroxid soda solution, followed by hot saline. 5. The continuance of the saline flushing until the sutures are placed, and for the most part tied. 6. The provision of proper drainage for the pelvis, either by means of a large glass tube containing a capillary drainage strip emerging through the lower angle of the wound or, in females, by a large caliber rubber tube filled with wicking passed through a posterior colpotomy incision. 7. The drainage of accessory abscess cavities with gauze or wicking. 8. The elevation of the head of the bed to accelerate the drainage of septic fluid into the pelvis, where it can be removed through the glass tube or, in case of a vaginal drainage, find a ready exit. [A.B.C.]

4.—Tuberculosis in New York.—J. A. Miller describes the institutions and agencies which influence the problem, showing how physicians may utilize them, and discusses the question of responsibility toward these patients. The institutions include those for education and prevention, and those for treatment. Among the former are the Health Department, the Charity Organization Society, the United Hebrew Charities, the Association for Improving the Condition of the Poor, the Diet Kitchen Association, the Nathan Straus Milk Depots, the Tenement House Commission, and numerous other smaller agencies. The various sanatoriums have a capacity for 640, hospital accommodations amount to 1,406 beds, and five dispensaries attempt a satisfactory treatment. The writer discusses the management of different classes of cases. The prospects of success in solving the tuberculosis problem are brighter than any other of the great problems of preventive medicine. The reduction of the deathrate in New York in 10 years by 40% has been largely due to Dr. H. M. Biggs and Dr. S. A. Knopf. [H.M.]

5.—Cancer of the Stomach: Gain in Weight before Death.—G. W. McCaskey reports the case. The patient was a man of 40 who had suffered with trouble in the gastric region for a year. This was characterized by pain in the region of the stomach, gas formation, pain between the shoulders, all of which became worse after eating. His normal weight was 220 pounds, but he had lost about 45 pounds. Test-meals revealed absence of hydrochloric acid and the presence of lactic acid. The liver was enlarged. Toward the end of his illness the stomach symptoms suddenly left him, his appetite became morbidly voracious, and he ate with impunity enormous quantities of meat, bread, potatoes and other solid food, and in three weeks his weight increased 35 pounds. There was no dropsy at that time and the phenomenal increase of weight was clearly due to tissue building. The gain did not last, however, the stomach symptoms recurring in three or four weeks; a little later marked jaundice supervened, and he died. At the autopsy the liver was found to be markedly enlarged, with a diffuse carcinomatous process, while the stomach was apparently normal, excepting in the pyloric and cardiac regions, where it was much thickened by malignant growth. The middle part of the lesser curvature was almost if not entirely free from the morbid process. [A.B.C.]

7.—Ethyl Chlorid as a General Anesthetic.—This is a very instructing article by A. F. Erdmann, in which he discusses the merits of ethyl chlorid as a general anesthetic, its relative safety, the proper method of administration, dosage, anesthetic phenomena, contraindications, etc. A short synopsis of the article cannot be readily given since it deals with various phases of a most important subject. [A.B.C.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

EDITORIAL COMMENT

Genital Herpes.—Genital herpes has recently been made the subject of an interesting and instructive investigation by Drs. Ravant and Darré.¹ They report the conditions found in two consecutive cases of genital herpes which occurred in young women. In each there developed a series of symptoms resembling those distinctive of ordinary zona, and, had it not been for the bilateral development, such would have been the diagnosis arrived at. In each of the cases there were acute lancinating pains in the whole perineal and anal regions—extending to the adjacent inner surfaces of the thighs—for some days before the appearance of the eruption; exactly comparable to those which usually usher in an attack of zona. At the same time—in one of the cases more especially—there was fever, general feeling of exhaustion, acute cephalalgia and rachialgia, with a furred state of the tongue. These symptoms appeared eight days before the development of the eruption, and subsided pretty rapidly after that event. The eruption itself disappeared after about 20 days, leaving depressions which became gradually defaced. In both cases the eruption consisted of confluent vesicles, which covered a great part of the perineal region and the posterior portion of the perivulvar—stopping just short of the mucocutaneous margin. There were some vesicles on the labia majora, and on the inner aspects of the thighs. The analogy of the symptoms to those of zona drew attention to the nervous system, and induced the physicians to perform lumbar puncture. This was done, in the first case, four days after the appearance of the first vesicles, while some of the phenomena of fever and general constitutional disturbance were still present. They were surprised to find marked turbidity of the cephalorachidian fluid. Centrifugation gave a pronounced clot, which proved to be formed of lymphocytes in considerable number, among which were found some rare polynuclear specimens. There were no microbes; and attempted cultures gave negative results. There was also an abnormal proportion of albumin present. An examination made five days later gave a clear liquid, with much fewer cellular constituents. The lumbar puncture had also the effect of causing disappearance of the cephalic symptoms. In the second case the lumbar puncture was made eight days after the appearance of the eruption; the liquid proved to be clear, but there was an evident “reaction cellulaire,” which was found to exist, in lesser degree, 20 days after. Since these experiences, the writers have practised in the same way on 12 patients affected with different varieties of genital herpes, and have in every one found numerous cell-elements in the cephalorachidian fluid. Their conclusion is that the number of the latter is in direct proportion to the extent of the eruption, and the early date of the examination. Also, that their research offers an additional argument in favor of the implication of the central nervous system in certain forms of genital herpes.

REVIEW OF LITERATURE

Test for Albumin in the Urine.—Charles Murray² calls attention to the fact, long ago pointed out by Bence-Jones, that if too little nitric acid be added to urine (2 to 3 drops to 10 cm. of albuminous urine), or too much (30 to 40 drops), one may fail altogether to detect the presence of albumin, though it is present in an appreciable quantity. On the other hand, if 10 or 12 drops are added and the upper stratum of the fluid rapidly heated the test is positive. Murray states that very few published works point out these phenomena, nor can he find any sufficient explanation for them. Various other tests for albumin

are discussed, and the writer states that in the laboratory of the University of Aberdeen the test for albumin, which has been used for a number of years, is the salicyl-sulfonic acid test. This is done by adding a few drops of a saturated aqueous solution of salicyl-sulfonic acid to a small amount of urine (20 m. or 30 m.) in a very small test-tube; if no precipitate occurs, there is no proteid present; if there is a precipitate, the tube is boiled to distinguish between albumin, which does not clear up on heating, but coagulates from proteoses (primary), which do clear up, to reappear when the fluid cools. In the absence of precipitation on the addition of the reagent, boiling is unnecessary. There is no need for care as to the exact amount of the reagent used, no danger of overacidulation, and the reagent is noncaustic and exceedingly stable. It can be used in the form of crystals, and when so used one should proceed as follows: Half a dram or less of urine is taken in a small test-tube ($\frac{1}{8}$ in. in diameter and 3 in. in length); a few crystals of the salicyl-sulfonic acid are dropped in, and boiling, if necessary, can easily be done over an ordinary lamp or candle. No substance in the urine, except those of the proteid class, has been found to cause the reaction, which is an exceedingly delicate one. [A.B.C.]

Value of Cryoscopy in the Prognosis of Chronic Pleural Exudates.—Kétley and Torday¹ determined the molecular concentration of pleural and other fluid exudates, by ascertaining the freezing-point. Fifteen cases were thus investigated, and it was found that absorption of the exudate could only be expected when the lowering of the freezing-point was less than that of the blood-serum. This only applies in those cases which exhibit no symptoms of active pleural inflammation; for in cases where inflammation is still present, further production of exudate is to be expected. In cases of pleural exudate resulting from nephritis, the functioning power of the kidneys must be considered in making the prognosis. The absorption of tuberculous peritoneal exudates depends upon the same factors as pleural exudates; but cryoscopy can be depended upon for the prognosis only in cases which offer no mechanical obstruction to the absorption of the fluid. In all cases of fluid accumulations the condition of the heart must be considered, as well as the cryoscopic findings. Cryoscopy offers no help in the differential diagnosis of exudates from transudates. [B.K.]

Etiology of Rachitis.—Rowland G. Freeman² summarizes the experimental work done on this subject and reports the results of personal observations on three small groups of infants from hospitals and tenements in New York. In one immaculately clean institution, with good general hygiene, where the babies were fed mostly on breast milk supplemented twice daily by condensed milk, 91% of the 66 inmates showed evidence of rickets. In a series of 38 babies just received into another institution from the tenements or which had been there for some time and were all bottle-fed, the percentage of rickets was only 70. Freeman does not agree with Morse that unhygienic surroundings is the only influence in common in all cases of rickets. Experiments and clinical observations indicate that unsuitable food, and possibly bacteria or intestinal toxins, are capable of producing the condition. [A.G.E.]

The Fight against Malaria in German East Africa.—The draining of the swamps and the extermination of the mosquitoes is a thing well nigh impossible in East Africa, and knowing the insufficiency of such measures, the German physicians there have initiated a fight against the malaria organism itself. Souls³ studied their methods and reports concerning them. At the commencement of the campaign 50 out of every 100 Europeans were malarial, and all the European children had hematozoa and enlarged spleens. The plan of campaign was the following: The blood of all inhabitants, Europeans and natives, is examined for the organism, and whoever has it must submit themselves to systematic treatment with quinin until further examinations show the absence of the organism. For 2 days out of 10 quinin is given in daily doses of 1 gm. (15 gr.) and the blood is examined every 8 days. After the expiration of the first year many of those treated had lost the organisms; those still harboring them were treated the second year

¹ Gazette des Hôpitaux, October 15, 1903.² British Medical Journal, April 16, 1904.¹ Deut. Archiv f. klin. Med., Bd. lxxix, p. 563.² Archives of Pediatrics, April, 1904.³ Archives de Médecine Navale, 1904, lxxxI, 81.

on 3 days out of 10. The sexual forms of the organism are the most resistant, and are often found in latent malaria. The work is performed with a surprising regularity and simplicity and mostly by a few natives. After 2 years of treatment, cases of malaria among Europeans have fallen from 50 out of 100 to 10 out of 100, and no grave forms of the fever are now observed. [E.L.]

Coexistence of Typhoid and Scarlet Fevers.—F. Farnarier¹ has been able to collect 75 cases of typhoid and scarlet fevers occurring simultaneously in the same patient. In the vast majority of cases the typhoid infection preceded that of the scarlatina, the latter infection occurring either during the incubation or the course of the typhoid fever. The scarlatina may make its appearance during convalescence from typhoid, or the symptoms of the two diseases may be mingled with each other. In some cases the scarlet fever may make its appearance first, the fever may never fall to normal, and the typhoid symptoms develop after the disappearance of the scarlatinous rash. In a few cases the symptoms of both diseases seem to develop at about the same time. In making a diagnosis, the two sources of error are the scarlatiniform rashes of typhoid fever, and scarlet fever of a typhoid type. The prognosis of the combined diseases is remarkably favorable. The mortality in the collected cases was 10% less than the average mortality of the separate diseases. [B.K.]

Myelopathic Albumosuria.—Bruce, Lund, and Whitcombe² report the case. A woman of 51, by merely assuming a stooping posture, suffered a fracture of the left femur, which, after two months under proper treatment, had united; while in bed in consequence of the first fracture, a nurse, merely lifting the patient with the hand in the axilla, caused a fracture of the left clavicle. Somewhat later the patient, in endeavoring to reach something lying beneath her, fractured the left humerus; later there was fracture of the rib on the left side from muscular action. The patient was spare, anemic, debilitated, complained of pains in the chest, the back, right side and left hip; these were often severe and neuralgic in character, and nothing seemed to relieve them. During the eight months she was under observation her weakness increased, became extreme with marked anemia and emaciation, and death followed. A previous examination of the urine, the results of which are given in detail by the author, showed the case to be one of albumosuria. The interesting points in connection with the case, aside from the urinary condition, are: (1) The fragility of the bones; (2) extreme anemia and lassitude; (3) pains of neuralgic character varying in intensity and situation, aggravated by movement and accompanied by local tenderness; the presence of a semifluctuating tumor over the acromial end of the clavicle in connection with nonunion of that bone. The peculiarities of the case are: (1) The fractures occurring solely on the left side; (2) the occurrence of the disease in the long bones—humerus and femur; no disease in cranial bones; (3) absence of any prominence of the bones; (4) a sharp grating crepitus of the fractures resembling that produced by old dried museum specimens; (5) the fact that a firm union took place in the fractured femur although infiltrated with disease of a malignant nature; (6) the female sex of the patient, most reported cases being males. [A.B.C.]

The Relation of Typhoid Fever to Tuberculosis.—J. M. Anders³ quotes statistics from the Philadelphia, Episcopal, and Johns Hopkins hospitals to show the rarity of combined typhoid infection and acute tuberculosis. Only cases of typhoid coming to autopsy are included; of these 1.6% had associated acute tuberculosis; 7.6% had chronic tuberculosis. The notes of several cases are given. The clinical phenomena of the combined diseases are difficult to interpret; all of the cases coming to autopsy showed an incomplete or erroneous diagnosis. The typhoid symptoms are usually manifest before those of the tuberculosis; the temperature curve resembled closely that of typhoid, the pulse that of acute tuberculosis. Anders says that while the rarity of the combined diseases makes recognition important, it is a matter of much greater clinical importance to distinguish between typhoid fever and

acute tuberculosis, the latter so closely simulating typhoid as to offer the greatest clinical difficulty. The absence of the Widal reaction, of the characteristic eruption and of the comparatively slow pulse in miliary tuberculosis, are to be especially noted. [A.G.E.]

Heredity to the Disposition for Tuberculosis.—To determine the relative influence of hereditary disposition and postnatal infection in cases of tuberculosis, M. Burkhard⁴ has carefully investigated 250 histories of nontuberculous and the same number of histories of tuberculous patients; all of them were dispensary patients and in dubious cases physical examinations were made to determine exact physical conditions. In 66% of the tuberculous patients he found one or more of the family having been afflicted with the same disease, while among the nontuberculous only 42% could be found to have tuberculosis among their relatives. The relatives investigated were sisters, brothers, parents, uncles, aunts, grandparents, husband, wife and children. One fallacy exists, namely, it is easier to find tuberculous relatives among tuberculous patients because their attention is directed to the disease while that of the nontuberculous is not. Almost as great a frequency among one as among the others is seen and the theory of hereditary predisposition is made still more improbable by their careful statistics. If such investigations are made without prejudice they will be found to be more in favor of family infection than family heredity. [E.L.]

The Primary Seat of Infection in 500 Fatal Cases of Pulmonary Tuberculosis.—Syme and Fisher² give statistics in this series of cases. In 112 cases of tuberculosis under the age of 12 years, 11.7% were apparently definitely abdominal in origin; 55.8% definitely thoracic; 2.35% doubtful whether abdominal or thoracic, while exceedingly few were due to tuberculosis of bones or joints, skin and tonsils. In the post-mortem room they frequently noted the presence of calcareous nodules in the lower lobe of a lung, and this was frequently limited to such a lobe. It appears more commonly than is generally thought that the tubercle bacillus can acquire a temporary lodgment in some part or parts of a lower lobe, but they almost invariably cease to be able to materially advance and consequently basal pulmonary tuberculosis is extremely rare. To sum up, their statistics tend to show that during the first 12 years of life, tuberculous infection of the air passages is four times as common as by the alimentary canal. They also seem to show that the comparative frequency of infection through the alimentary canal during the second 12 years is equally common. Death in hospitals before the age of 12 years can hardly be taken to represent the average causation of death from varieties of tuberculosis for the whole population before that age, because cases of tuberculosis of the lungs are more chronic then at an early period of life, and are not usually admitted to ordinary hospitals. The proportion of abdominal to thoracic tuberculosis in the institutions from which the reports were taken were very small after the age of 24. [A.B.C.]

Different Radial Pulse in Heart Lesions.—The diagnosis of complex valvular heart diseases offers many difficulties, often insuperable. Hence the value of a new and reliable sign, first found by Popoff. It consists in a difference in the radial pulses, the left being considerably weaker than the right. This weakness is due to a number of causes, which need not occupy us here. The sign itself is found in stenosis of the left venous ostium, *i. e.*, in "mitral" stenosis. N. E. Kusheir³ has been enabled in two cases to make a correct diagnosis, confirmed by autopsy, of mitral stenosis, relying partly on Popoff's sign, which was marked during the stage of broken compensation, and appreciated by the palpating finger as well as demonstrated by the sphygmograph. According to Popoff, his sign is chiefly met with in young people, especially women, it being a wellknown fact that the latter are prone to develop mitral stenosis more frequently than men. [L.J.]

Imperforate Duodenum of Congenital Origin.—M. Voron⁴ reports the case of a newly-born infant, which invariably vomited several minutes after beginning to nurse. The

¹ *Zeitschrift für Tuberculose*, 1904, v. 297.

² *British Medical Journal*, April 16, 1904.

³ *Medizinske Obosrenje*, lxi, No. 5.

⁴ *Lyon Médical*, April 10, 1904.

³ *American Journal of the Medical Sciences*, May, 1904.

vomit consisted of the milk ingested, in a noncoagulated condition, and without any admixture of bile. The child died of inanition five days after birth. The stomach was found practically normal. The first part of the duodenum was somewhat dilated, and terminated in a blind pouch, which was fused with the head of the pancreas. The distal portion of the intestinal tract also terminated at the pancreas by a similar nonperforated pouch, which received the biliary and pancreatic ducts. Duodenal occlusion may possibly be diagnosed from occlusion further down by the promptness with which ingested food is vomited, and the absence of bile from the vomit. In esophageal occlusions there occur attacks of suffocation immediately after the administration of food. If the diagnosis can be made, experience has shown that a gastrointestinal anastomosis may possibly save the infant's life. [B.K.]

Chronic Brass Poisoning.—H. N. Moyer and J. M. Lavin¹ review the literature on this subject and report a case that occurred in a brass-polisher of 31. Because of conflicting opinions they state that dogmatic opinions regarding the disease should not be reached. That there is a definite form of poisoning among brass-workers is almost certain and that it is probably due to the copper in the alloy is equally sure. It is really copper poisoning. The general symptoms are those of a chronic metallic intoxication but differ from that of most metals in the development of chills which are strikingly like but lack the periodicity of malaria. These attacks are probably due to excessive ingestion of the metal. A green line on the gums serves to distinguish this from other metallic poisoning, but this sign is not constantly present, especially in those who take good care of the teeth. Organic affections of the nervous system, common in other metallic intoxications, are absent in this form. [A.G.E.]

Epidemic Sore Throat from Suppurative Mammitis in Cows.—Robert French² refers to an article by Pearce and Kenwood having reference to epidemic sore throat in connection with suppurative mammitis in cows. He holds that these epidemics are similar in nature, and, from their wide-spread and pernicious effect, more notice should be taken of their cause and treatment. The disease is ushered in by chilliness, malaise, the symptoms characteristic of follicular sore throat or beginning quinsy, diarrhea and cervical adenitis, high temperature, and neuralgia, particularly in the cranial nerves. French, observing that in a similar epidemic a patient suffering from not only these symptoms, but erysipelas of the face, was induced to try the antistreptococcic serum, after which the symptoms rapidly abated. Following this, he used the treatment in other severe cases of the epidemic. Without exception, the temperature fell to normal within 12 hours and the patient rapidly recovered. This suggested that the epidemic was undoubtedly caused by a streptococcic mammitis bovi and that serum treatment was the proper thing. Cultures taken from discharges were submitted for bacteriologic examination and the report substantiated his views. He therefore believes that the disease is of an erysipelatous affection of the throat, caused by those microorganisms which find their way into the glands of the neck and occasionally spread to the skin, causing a typical erysipelas of the face and head. They eventually find their way into the blood, causing the general septic infection, making their appearance in colonies under the skin and affecting the synovial membranes of the joints, also beginning the neuromalacia of nerves, which accounts for the acute pains in various parts. [A.B.C.]

Appendicitis and Pinworms.—A. P. Morkovitch³ reports an instance of this etiology of appendicitis. The patient was a young laborer, who presented the usual symptoms of the disease. Inside the removed appendix a large number of pinworms of all sizes and stages of development was found, besides many ova. Evidently the appendix often serves these parasites as a protected place of refuge, where they deposit their ova and breed their young. Our routine remedies against them are unable to reach this hiding place. In view of these facts, the accepted theory that pinworms leave the rectum in order to lay their eggs must be abandoned. [L.J.]

GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

REVIEW OF LITERATURE

Postoperative Pneumonia, with Experiments upon Its Pathogeny.—W. Louis Chapman¹ gives a brief account of a few experiments upon the irritative effects of ether: (1) As applied to the frog's web; (2) upon the lung; (3) effects of ether anesthesia; (4) etherized rabbits plus pneumonia culture. From all of which he deems the following conclusions justifiable: 1. Prophylaxis. Care in ether giving lessened shock and respiratory irritation, which reach their maximum when an unnecessarily large amount of ether is given. 2. The disinfection of the mouth and oropharynx by peroxid before operation is a rational precaution. 3. Adequate air space is of even greater importance in surgical wards than in medical. 4. A careful auscultation and percussion of the chest should precede every operation, and if there be signs of disease, operations of election should be postponed until the chest condition is more favorable. 5. A complete clinical record of all cases of postoperative pneumonia, together with a record of the previous state of the patient, is most desirable and provide data of reference for the future. [A.B.C.]

Surgical Importance of Visceral Crises in the Erythema Group of Skin Diseases.—William Osler² says that the possibility of mistaking these crises for appendicitis or intussusception or obstruction of the bowel and referring the patient to the surgeon for operation is by no means remote. One of his cases previously reported was diagnosed as renal colic, another as appendicitis. A girl of 17, at present in his wards, presents intestinal crises, arthritis and renal features that make the diagnosis unmistakable. Three cases in which laparotomy was performed by English surgeons are cited. The conclusions drawn from these three cases are: "1. In children with colic the greatest care should be taken to get a full history, which may bring out the fact of previous attacks, either of skin lesions, of arthritis, or of intestinal crises. 2. Make the most careful inspection of the skin for angioneurotic edema, purpura, or erythema. It is also to be borne in mind that recurring colic may be for years the sole feature of this remarkable disease, in which the obscurity is not cleared up until after the final appearance of skin lesions." [A.G.E.]

External Esophagotomy for Foreign Bodies.—P. A. Baratsky³ pleads for early operation in foreign bodies lodged in the esophagus. External esophagotomy is an operation which every physician ought to be able to perform in emergencies. The comparatively high mortality attending this operation is due to the complications produced by the foreign body, and must fall when early relief will be offered. [L.J.]

Perineal Prostatectomy.—M. Rafin⁴ gives a report on a series of 25 perineal prostatectomies. The rectum was accidentally perforated in 3 cases, but without permanent result. The most frequent postoperative complication was orchitis, occurring in 9 cases. There were 2 deaths following operation; a very good record, considering the age of the patients and the bad condition of the bladder in many cases. In most cases there was a general improvement following the operation, this improvement not only continuing, but even increasing as the time passed. In 9 cases the residual urine entirely disappeared, and in all but one it was more or less diminished in amount. Micturition was rendered easier, but the frequency was very little diminished; nocturnal urination did not completely disappear in any case. Retention of urine did not recur in any of the patients. Operation was refused in patients considerably affected by age, also in those exhibiting simple dysuria without retention, and in those with a slight, aseptic residue of urine. Preparatory treatment is very important in those with infected bladders, and in those whose bladders are unduly distended. The line of treatment here consists of regular catheterism, with disinfection of the bladder if necessary. [B.K.]

Intestinal Anastomosis.—J. G. Clark and J. W. Luther¹ contribute a critical review of the various methods of intestinal anastomosis with special reference to the Connell suture which they have employed in five cases, three for carcinoma of the colon, one for carcinomatous perforation of the stomach, and one for a wound of the sigmoid during a pelvic operation. The principles of this method are commended; the technic is slightly modified by the use of silk sutures and the closure of the final point by a Halsted quadrangular quilt suture. The Halsted suture should not be discarded, but for nearly all cases of intestinal resection the suture of F. G. Connell, the only successful suture with the knot within the lumen, should be employed. The writers reach the following conclusions: 1. The Connell intestinal suture is, without doubt, the most rapid and most perfect method of suture yet devised for end-to-end or lateral anastomoses. 2. For the closure of simple perforations or lacerations, or for exploratory incision into the hollow viscera, Halsted's rectangular quilt suture is easy of execution and quite safe, and is of decided preference. 3. All mechanical devices for intestinal anastomosis should be discarded in favor of the Connell suture. 4. Neither the suture within the bowel, as represented by the Wiggan-Connell method, nor the Lembert suture and its modifications should have the exclusive preference in intestinal surgery, for both are of the greatest value in special fields, and each should be at the command of the surgeon, to be used as his judgment dictates. [A.G.E.]

Pulsating Exophthalmos Due to Traumatic Aneurysm of the Internal Carotid Artery.—H. L. Barnard and Hugh Rugby² report that a man of 42 attempted suicide by discharging a revolver within his mouth; the ball passed upward and backward through the deeper side of the superior maxillary bone to the base of the skull, which was perforated and comminuted in the region of the left petrous bone. A whole series of resulting symptoms are enumerated, among which was a protruding pulsating left eyeball, over which a bruit could be heard. The left common carotid was ligated in two places and severed between the ligatures. The latter, the authors now believe, was a mistake. The bullet was located by skiagraph and removed two months after the wound was received. About the ball was an abscess; the patient died soon after. Autopsy revealed a large abscess in the temporosphenoidal lobe, which did not communicate with the abscess about the bullet. There was found a double sacculated aneurysmal dilation in the intracranial part of the internal carotid artery; there was no arterial communication with any sinus, and there was no noticeable dilation of the sinus or the ophthalmic vein. Their conclusions are: (1) That a traumatic sacculated aneurysm of the internal carotid in the cavernous sinus can give rise to the typical symptoms of pulsating exophthalmos; (2) that this lesion can follow a head injury without being caused by basal fracture; (3) that there is no evidence to prove that this condition does not always occur at first and a communication with the veins is a later and secondary consequence; (4) that the signs of pulsating exophthalmos are not necessarily due to the presence of arterial blood in the ophthalmic veins and need not be dependent on excessive dilation of these veins; (5) in young subjects and in traumatic cases seen early, ligation of the common carotid is the best treatment. [A.B.C.]

Extraction of Projectiles from the Brain under Röntgen Ray Illumination.—G. Holzknacht and P. Dömény³ describe a method devised by them, to remove projectiles from the brain under röntgen ray illumination, while maintaining the strictest antisepsis. Their experiments were first tried on the dead body, and then on living animals. The method consists of placing one röntgen ray tube beneath the head, as it rests on the operating table, and another tube to one side of the head. A trephine opening is made in a convenient situation, and the head is moved so that the shadow of the projectile is brought to the center of the shadow cast by the edges of the opening, the lower tube being used for purposes of illumination. A specially devised forceps is introduced in the axis passing through the opening and the projectile. The lower tube is then

extinguished and the side tube set in action. While observing the shadows cast by the projectile and the forceps, the latter can be manipulated until it reaches and grasps the former, when extraction becomes easy. [B.K.]

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

REVIEW OF LITERATURE

Treatment of Myoma Uteri.—J. Pfannenstiel¹ gives the following special indications of myoma operation: 1. The absolute size of the tumor without the presence of any pain; a size above a man's head may be the chief indication for operation, and much smaller in younger persons, especially if the tumor be nodular, as operation will be necessary sooner or later, and may be required at a time when the chances are far less favorable. 2. Tumors which evoke severe pain. 3. Submucous myoma with bleeding. 4. Deep-seated excentric growing myoma, especially subvesical, causing compression of the urethra and later threatening grave injury to veins, etc. 5. Pedunculated subserous tumors inclining to torsion of pedicle. 6. All rapidly growing tumors, on account of the possibility of becoming sarcomatous. 7. And complicated cases, insofar as the complication is conditioned upon the myoma. The best time for operation is the premenstrual period. Conservative myotomy may be employed for submucous myoma or polyps of the cervix. Large interstitial myoma, also multiple tumors and diffuse adenomyoma should be completely exterminated without reference to the functions of the uterus, as in such cases we must choose the method which best protects the patient. In regard to mortality, there seems to be no essential difference in favor of the vaginal over the abdominal total extirpation. [W.K.]

Technic of Abdominal Section.—F. Barrington² tabulates 100 cases of abdominal section for pelvic and abdominal lesions and emphasizes several points gained from this experience. He considers the tier suture to be the only scientific method of closing the abdominal wall. His rule is to avoid drainage as far as possible; if drainage be necessary it is done through the posterior vaginal fornix, drainage through the parietal wound having been entirely abandoned. Conservative surgery of the ovary is considered of much more importance than that of the tubes. Considerable space is given to the discussion of the treatment of the appendix in cases of pelvic disease. That organ should be removed whenever diseased or adherent to pelvic viscera; the appendix should always be investigated in recurrent attacks of right-sided pain; in operating for relapsing appendicitis in patients who have suffered from dysmenorrhea, the incision should be made internal to the right semilunar line in order to allow examination of the ovary and tube; in every case of appendicitis in the female a pelvic examination should be made before operation is begun. The only point raised in the postoperative treatment is the ensuring of early intestinal peristalsis. To secure this, Barrington now gives five grains of calomel one and a half hours before operation and in addition, if the case be septic, two drams of magnesium sulfate in lemon juice immediately before the patient is taken to the operating-room. [A.G.E.]

Postoperative Cystitis.—K. Baisch³ refers to the fact that after Wertheim's operation for uterine carcinoma, many patients died of cystitis. Investigation led to the conviction that the cystitis was due to the daily catheterization which necessarily followed the operation. Believing that the germs of infection were unavoidably carried into the bladder in the process of catheterization, a disinfecting irrigation of the bladder was used immediately after the catheterization in order to remove or destroy any infectious germs. This prophylactic treatment was employed in 30 cases after the Wertheim operation, with the result that the 5 which died within 8 days showed no symptoms of cystitis; that 22 catheterized for 18 days, under the irrigation treatment remained completely

free from any cystitis; 1 had cystitis before the operation; and only the remaining 2 showed slight traces of irritation of the bladder with clouded urine in which bacteria coli were found. These diminished in a few days, and the patients recovered without any cystitis. Baisch commends this treatment. [W.K.]

Preservation of the Periureteral Arterial Plexus.—J. A. Sampson¹ describes at length the blood supply of the ureter, which he has investigated in numerous human and animal subjects. The main trunks of the plexus run in a longitudinal direction from the kidney to the bladder in the outer loose perimuscular fibrous coats of the ureter; from these arise smaller branches, forming the mesh-work of the plexus. It is possible to inject the entire plexus from the renal or internal iliac artery, and also probably from any vessel that furnishes a ureteral artery. The practical point deduced from this study is, that the ureter may be dissected free for considerable portions of its length without danger of necrosis if the plexus be allowed to remain intact. Sampson discusses this point with special reference to carcinoma of the cervix. If, when hysterectomy is performed the parametrium be removed mesial to the ureter, necrosis of the latter structure is slight, but cancer may be left; if the ureter be dissected free and the surrounding tissues removed, danger of necrosis is greater, but that of recurrence of the growth is less. In either case the periureteral plexus, and also the ureteral sheath, should be preserved. This is best done by resecting the lower portion of the ureters and implanting the renal ends into the bladder; this is the only operation justifiable when the ureteral sheath is involved. [A.G.E.]

Bladder Irritation in Girls.—W. D. Spanton² in examining, under the microscope, a fluffy mass passed by a child of three years, in whom micturition was painful from a tender urethral orifice, found it to contain woolen fibers entangled in mucus. Several similar cases presented themselves later. In all of these the trouble originated in the woolen combination suits, rather rough at the edges, which the little girls wore, some of the fibers from which had wormed their way along the urethra into the bladder by means of their barbed edges. Linen fibers being smooth, this accident cannot occur. With a change in garments and a diuretic for a few days all trouble disappeared. [H.M.]

Treatment of Puerperal Eclampsia by Combined Method.—J. Lithgow³ reports a case of eclampsia in which the patient survived after having had 69 severe convulsions, the fits appearing before labor, and continuing during labor and after delivery. As a primary step in accouchement forcé, he applied or introduced through the os a piece of lint saturated with cocaine solution. The time necessary thus to dilate the os was about the same as required by metal dilators, and all danger of laceration was avoided. The patient was put under chloroform and delivered with forceps, but as the convulsions continued, the rational treatment seemed to be to get rid of the poisonous material by venesection, the bleeding being allowed to cease of its own accord. This loss of blood was replaced by the injection into the cellular tissue below the breast of a pint of normal salt solution. The fits gradually subsided, and although she remained unconscious two days, the patient ultimately made a good recovery. A test of the liquor sanguinis gave 2½ gr. of urea to the ounce. [W.K.]

Central Pregnant Paralysis of the Mother.—R. v. Hosslin,⁴ in the term pregnancy paralysis, includes paralysis which develops during pregnancy, labor, or the puerperium. This may occur without any pathologic lesion as the result of hysteria or myasthenia gravis. He discusses the real apoplexy of pregnancy. The pregnant condition seems to have some causal relation to this as it appears usually in the later months or during labor. Hypertrophy of the heart accompanying pregnancy, greater pressure in the bloodvessels and changes in the vessels through toxic influences may each have its influence. An interruption of pregnancy is indicated, if there exists danger to the life of the mother and eventually cesarean section may be necessary. As the causal relation between the two con-

ditions of apoplexy and pregnancy is often doubtful so it is in cases of paralysis in pregnancy with albuminuria; and the paralysis is more likely to follow eclamptic attacks. Pregnancy exerts an unfavorable influence upon all serious diseases of the cord which develop in connection with it. Clinical experiences prove that brain and spinal diseases do not prevent conception, and in cerebral trouble pregnancy takes its usual course. In spinal affection, if severe, interruption of pregnancy is more likely to occur. Labor is seldom influenced by central paralysis, neither the activity of labor pains nor the sensibility to pain being changed. In spinal paralysis the labor is mostly normal, though frequently without much sensibility to pain. [W.K.]

Incarcerated Volvulus Obstructing the Birth Canal.—J. Saks¹ made a diagnosis of ovarian cyst twisted on its pedicle in the case of a woman who had been in labor for some hours, and in whom a vaginal examination was impossible on account of an obstruction. He believed the labor pains had pressed it downward and it had pressed the uterus upward. Instead of this, the laparotomy revealed as the birth impediment, a much distended loop of large intestine, twisted upon itself and incarcerated in Douglas' pouch. The infant delivered by cesarean section was dead; the patient died shortly after. [E.L.]

Treatment of Fresh Perineal Tears.—J. Eversmann² believes thoroughly in the immediate repair of perineal tears. They may heal, it is true, without any stitch; but since the firmness of the perineum depends upon a perfect union of the muscles, and it is the nature of muscle when severed to retract, unless this tendency is overcome by suture, there will not be a close and firm union, but rather a more or less wide separation of the edges of the wound. Of 132 cases of sutured fresh perineal tears, only two or 1.5% failed to heal properly. In no case was there much pain, and in only 45% a slight rise in temperature. Such experience speaks most eloquently of the suitableness of the suturing of fresh tears. Therefore he recommends this method most warmly. [W.K.]

Chorionepithelioma of the Bladder.—W. S. Devitski³ reports a unique case—chorionepithelioma of the bladder in a virgin, whereas such cases have hitherto been brought into etiologic relation to pregnancy. The patient was 75 and complained of hemorrhages from the vagina, painful micturition, cough with bloody expectoration and dyspnea. A fibromyoma uteri was diagnosed and curetage performed, after cutting the hymen. The patient died soon after and the neoplasm was found in the bladder at the autopsy, beside fibromyomas of the uterus. Metastases were present in lungs, liver and spleen. The author indulges in some speculation as to the origin of this mysterious neoplasm in a virgin. [L.J.]

Treatment of Retroversion of the Gravid Uterus.—G. Ernest Herman⁴ asserts that retroversion of the gravid uterus needs treatment because it produces retention of urine from the effects of which the patient will very likely die, the common mode of death being from extension of inflammation of the bladder up the ureters to the kidneys, causing what is known as "surgical kidney." Prolonged retention of urine may cause exfoliated cystitis, which, instead of tending to recovery after the retention has been relieved, continues until the dead mucous membrane is expelled or removed from the bladder. His experience of many years in London hospitals has convinced him that there is no foundation for the statement that retroversion of the gravid uterus tends to abortion; but that when abortion occurs it is due to uremia following retention of urine. The only dangers of retroversion of the gravid uterus are those which directly or indirectly spring from retention of the urine—cystitis, peritonitis, rupture of the bladder, pyelitis, uremia. The only necessary treatment is the catheter. This, if used in time, will relieve symptoms and prevent danger. Keep the bladder empty and the patient recumbent, and in over 90% of the cases the uterus will right itself. If it does not, pregnancy will still go on. Yet in many of these cases, reposition, though unnecessary, is desirable, as it avoids the long use

of the catheter, and it will usually be found easy after the bladder is emptied to push the uterus up with the fingers in the vagina or rectum. In 20 years, in the two largest hospitals of London, not a case was met with in which the catheter could not be passed. Herman thinks the danger in abdominal section is greater than that of a week's frequent use of the catheter, and greater than that of letting pregnancy go to term with part of the uterus in the hollow of the sacrum. Neither does he advise induction of abortion. [W.K.]

Situation of the Corpus Luteum in Four Cases of Ectopic Gestation.—R. Worrall¹ reports four cases of tubal gestation in which positive or negative evidence showed that the ovum came from the ovary of the opposite side. In two of them a recent corpus luteum was found in the opposite ovary and none was present in the ovary on the side in which gestation occurred. In the other two the ovary of the affected side contained no corpus luteum which must have been on the opposite side, though that ovary was not examined. The inference drawn is that the ovum in all four cases must have reached the opposite tube by migration across the uterine cavity or by external migration across the pelvis. In one case the fimbriated extremity of the fallopian tube corresponding to the location of the corpus luteum was occluded, which leads Worrall to conclude that migration must in this case have been external. [A.G.E.]

Bossi's Dilator.—W. B. Armstrong² having used Bossi's dilator for some time, recommends it to the medical profession for the ease, safety, and rapidity with which the cervix can be dilated. He adopts the following method: Chloroform is administered to its full surgical extent, and the patient placed in the left lateral position. If the os be only slightly dilated, the cervix is carefully pulled downward with volsellum forceps, and the dilator, with the sheaths removed from its points, is introduced with a gentle screwing motion. Dilation is begun and gradually maintained until the os is the size of half a crown. The dilator is withdrawn and reintroduced with the sheaths adjusted to its points. Dilation is very gradually continued; the blades are frequently relaxed and their position changed circularly, so that all parts are uniformly pressed upon. When the os is fairly well dilated, the finger is used to assist. It is well to remember that the index of the instrument gives only very approximately the amount of the dilation. When dilation is complete the membranes are ruptured and the child delivered in whatever manner is indicated. [W.K.]

The Question of the Site of Impregnation.—H. Cripps and Williamson³ report a case of tubal gestation after the complete removal of the ovary on the same side, and consider this as a case of the external migration of the ovum from the left ovary to the right tube with impregnation somewhere in its course, possibly in the abdominal cavity with subsequent tubal gestation, the development of the trophoblast having reached such a stage that the ovum was able to bore its way into the tubal mucosa and gain an implantation before it reached the uterine cavity. In the second case pregnancy occurred after the ligation of both fallopian tubes, the lumen of one tube being completely obliterated, and considerably narrowed in the other, and yet the pregnancy was uterine. [W.K.]

Myomectomy on the Gravid Uterus.—If through a combination of pregnancy and fibromyoma it becomes necessary to operate, Condamin⁴ chooses, if the size and position of the tumor permit it, a myomectomy. In four cases of this kind reported by him he succeeded in not disturbing pregnancy twice, and twice the patients aborted, but in one case at least this was due to external conditions, which could have been prevented. Myomectomy during pregnancy may be performed if the following conditions are present: 1. If the condition is very painful. 2. If the position of the fibroma is bound to prevent normal delivery; in such a case the operation must be performed relatively early, to prevent the dangers of a probable abortion due to the tumor, as well as the complications possible during the confinement. 3. If the presence of the fibroid has already produced one or more abortions the operation certainly is justified. 4. Should the woman not be preg-

nant her wish to give her the chance to become pregnant as long as she is younger than 40, should be sufficient to choose myomectomy.

TREATMENT

SOLOMON SOLIS COHEN

E. LINDAUER

REVIEW OF LITERATURE

Gelatin in Hemorrhage.—H. C. Wood, Jr.,¹ reviews the action and use of gelatin in the control of hemorrhage. It has been found of value in the treatment of hemoptysis, purpura hemorrhagica, various manifestations of hemophilia, especially epistaxis, and various uterine hemorrhages. Its value in hematuria is disputed, a number of authors believing it irritant to the kidneys and therefore counterindicated, while others have found the hemorrhage lessened by its use. Recent literature tends to show that gelatin is more likely to prove beneficial than harmful in hemorrhage from the kidney. In the treatment of aneurysm, gelatin is losing its popularity. Sargo points out that it is useful only in sacculated aneurysms, and if used in quantities large enough to have any powerful effect in causing intravascular clotting, there is grave danger of embolism. The most serious drawback to the use of gelatin is the difficulty in perfectly sterilizing it. This has been overcome by various manufacturers placing upon the market a 10% solution of gelatin, under the name of *gelatina sterilisata*, which is guaranteed to be sterile. The danger of infection and the difficulty in sterilization may be avoided by giving the remedy by the mouth. In menorrhagia and hemoptysis of the milder grades, the use of gelatin by the mouth shows as good results as can be achieved by its hypodermic injection. The use of gelatin tampons in metrorrhagia, and packing the nares with cotton saturated with a solution of gelatin in epistaxis, have also given good results. For hypodermic use it should be dissolved in warm normal salt solution in the strength of from 2% to 5% of which from 100 cc. to 200 cc. may be given as a dose. [L.F.A.]

Abdominal Massage.—J. K. Mitchell² finds that the chief difficulties encountered in applying abdominal massage are fat abdominal walls and irritable or strongly contracting abdominal muscles. The former obstacle can be overcome by deeper and stronger manipulation, using large hand-grasps, and for tapotement by stretching the skin and muscle tightly with one hand while the other performs the vibration. The latter obstacle can be influenced by persistence; the tendency to involuntary contraction lessening as the patient grows accustomed to the operation. When it is not thus lessened, changes of position may be tried. Instead of the usual supine position, with the shoulders a little raised and the knees bent, let the subject lie upon the right side, with the knees bent and the thighs drawn up to right angles with the trunk. Not only do the abdominal muscles lose their point of application of force to a certain extent in this posture, but the small intestines lapse toward the right and leave the rest of the abdominal organs more accessible to the touch. When persistent irritability of the abdominal rectus muscles continues in spite of these devices, it is worth while to try to rub the belly with the patient seated and leaning forward. A narrow chair with a high back should be chosen. The subject is seated astraddle of the chair, the arms are crossed on the top of the chair-back, and the head leaned forward upon them. The position makes contraction of the recti difficult, and although, owing to the narrowing of the accessible abdominal area brought about by the lowered rib margins, massage of the abdomen cannot be so thoroughly done, vibration and general up-and-down shaking of the abdominal contents may be readily accomplished by an operator kneeling behind the patient. Two to three months of massage will cure a great majority of cases of habitual constipation. Even a shorter course may serve, if suitable exercises be combined with massage and the patient will consent to reasonable modifications in diet and will forego drugs. [L.F.A.]

Diet in Hepatic Diseases.—Albert Robin¹ gives a review of the clinical signs of practical value in aiding the selection of a proper diet in hepatic disorders. Among these is mentioned urobilinuria. Urobilin in the urine indicates excessive destruction of the blood-corpuscles, and the complete transformation of the hemoglobin by the liver into biliary pigments is not effected. This, then, is not a true insufficiency, but only an indication that the liver is incapable of accomplishing a task which surpasses its normal capacity. Urobilinuria, then, is the result of hyperactivity of the phenomena of metabolism, rather than a functional insufficiency of the liver. Alimentary glycosuria gives contradictory results as regards hyperactivity or insufficiency of the liver, but it is an index to the functional sensibility of this organ. Finally, certain drugs act as stimulants or depressants to hepatic activity to such an extent that they may be used as a guide to functional disturbances of the organ. Milk is prohibited by Robin in simple jaundice, biliary lithiasis, and in atrophic cirrhosis, because it diminishes hepatic activity, which is already depressed in these conditions. In cases of diminished activity of the liver, he orders a milk-vegetable diet, the vegetables acting as stimulants to hepatic activity. In atrophic cirrhosis, the milk diet should be avoided, because the active elements of the liver need stimulation. The mixed diet should be used until forced to abandon it. In the early stages certain fish and white meats are allowed. [L.F.A.]

Surgical Tuberculosis Treated by Marmorek's Serum.—Alexander Marmorek² employed his serum in a series of cases of surgical tuberculosis, his reasons being that these forms are exceptionally favorable for the continuous observation of the effects of the serum, and that the lesions are relatively similar, so far as the effect on the entire system is concerned, to the initial manifestations of pulmonary and laryngeal tuberculosis. He effected a complete cure in several cases of Pott's disease complicated either by fistula, abscess, intestinal perforation, or by palsy of the lower limbs. He has caused diminution of glandular mass in the neck, groins, and the true pelvis, as well as secured the closing of fistulas which had long been open. When fistulas failed to close it was generally found that a sequestrum caused their persistence. In several instances he observed that the abscess at the seat of caseation was reabsorbed without surgical treatment; multiple granulomas of the skin refractory to treatment for years rapidly dried up and closed. The highest number of injections administered to any one patient was 52; the lowest seven. Marmorek states that in about 2,000 injections he observed a local abscess only three times. The serum does not ordinarily give rise to pyrexia or to any disturbance, local or general. [A.B.C.]

Blake's Antiseptic Soap.—Edward Blake (*Colitis, Appendicitis and Their Allies*, London, Glashier, 1904) calls attention to the conveyance of disease by the use of enema syringes. He advocates the abolition of the bulb syringe entirely and the use of a glass nozzle with the bag syringe. For cleansing these nozzles and other instruments, and also one's fingernails and hands he has devised a soap which is pleasant to use, leaving the skin soft and pliant. It does not stain. It consists of

Formalin	3 cc. (5 m.)
Strong ammonia water	3.75 cc. (1 fl. dr.)
Hebra's soap (spiritus saponis kalinus) 30	cc. (1 fl. oz.)

[S.S.C.]

A Clinical Study of Adonidin.—Reynold Webb Wilcox³ shows by sphygmographic tracings the value of adonidin in several cases of cardiac disease. Bearing in mind that the condition of the myocardium, the arteries and the valves, determine the value of any remedy, the conditions for which adonidin may be administered are mitral and aortic insufficiency, dilation, arrhythmia, precordial pain, and the symptom-complex known as tobacco heart. In fatty degeneration, pericarditis, simple and compensatory hypertrophy, and in certain atheromatous conditions it may safely be administered, when digitalis, if given at all, must be used with great caution. The pulse-rate is slowed, the cardiac energy increased, arrhythmia lessened, and the amount of urine increased under the influence

of adonidin. Wilcox concludes that the remedy seems to have a field of usefulness not entirely filled by digitalis; this is apparently in promptitude of action, and the possibility of long continued use without danger of cumulative effects or liability that the patient will become accustomed to the drug. The objection is that the irritation it causes may sometimes prevent long continued use. [A.G.E.]

Inoculation with Haffkine's Plague Prophylactic.—Chas. E. P. Forsyth¹ gives his results in 30,609 inoculations. He holds that this prophylactic treatment, while not meeting the success anticipated in India and elsewhere, nevertheless has been sufficiently encouraging to warrant its continuance, if done under proper regulations. Among the 30,609 patients inoculated, 329 were attacked by the plague; there were 50 deaths, showing a mortality of 15.1%. Forsyth says this reduction in a disease in which the case mortality may reach 70%, 80% or 90%, and which is usually about 50%, is worthy of note. In 50 villages having an aggregate population of 44,760, the uninoculated numbered 31,874 and the inoculated numbered 12,886, both classes living approximately under the same conditions. Among the uninoculated 4.5% were attacked by the plague, with a case mortality of 45.2%, while among the inoculated 1.3% were attacked, with a case mortality of 16.9%. This, Forsyth holds is proof of the usefulness of the treatment, and as to its freedom from ill-effects, it is stated that in the whole of 30,609 inoculations no serious consequences came to light. It is very important that the people of India be educated not only to accept inoculation, but also to be dissatisfied with it, unless it produces a pronounced reaction. If this could be attained and the system of prophylactic treatment be carried out systematically it is the belief of Forsyth that the plague ravages in India would end. [A.B.C.]

Treatment of Facial Paralysis by Nerve Transplantation.—Hackenbach² reports the case of a girl 8 years old, who suffered from facial paralysis for over seven years. Treatment consisted in implanting two-thirds of the spinal accessory nerve into a split in the facial. There was improvement after four and a half months; at the end of nine months the child could voluntarily draw the right angle of the mouth outward. Encouraged by this result, Hackenbach, in a case of infantile spinal paralysis, implanted a third of the tibial nerve into a longitudinal split in the peroneal nerve, which was totally paralyzed. Three months later there was still some weakness, especially as regards equinus. [L.F.A.]

Treatment of Gastric Ulcer.—M. Wagner³ writes concerning the views of Lenhart, who disagrees with the multitude of clinicians in giving his gastric ulcer patients an albuminous diet from the beginning, having achieved good results with this treatment for years. He has found that in individuals presenting symptoms of hyperacidity, such as nervous patients of all kinds, and chlorotics, all these symptoms disappear quickly if a diet rich in albuminous substances is given. The hyperacidity diminishes and the general condition improves much quicker than by milk diet. Because of these good results and because hyperchlorhydria, and anemia and chlorosis are usually the most important etiologic and concomitant factors of gastric ulcer, he advises the same treatment in this condition; if this treatment is begun early enough the ulcers will usually heal before the stage of hemorrhage is reached, but even should this have taken place he gives albuminous diet as only with it can the patient gain strength quickly and the ulcer be thus healed. He has never observed dangerous complications from this, and the pain always disappears quickly and completely. Occasionally a renewed hemorrhage would be seen, but no oftener than with other treatments. The following is his method of procedure: The patients must be put to bed and kept as quiet as possible; they must use the bedpan and must be encouraged to rest mentally as well as physically. An icebag over the stomach prevents distention, favors contraction, and relieves pain. On the first day after the hemorrhage the patients are given iced milk in

¹ The Lancet, December 12, 1903.² Annals of Surgery, December, 1903.³ Therapeutic Review, Vol. 1, No. 4, 1904.⁴ Münchener medizinische Wochenschrift, 1904, II, Nos. 1 and 2, January 5 and 12.¹ Bulletin Général de Thérapeutique, Vol. cxvii, No. 12, 1904, p. 447.² The Lancet, December 12, 1903.³ International Clinics, Vol. 1, fourteenth series, 1904.

spoonfuls up to 200 cc. and 300 cc. in the 24 hours, also several fresh eggs beaten up. He also gives bismuth subnitrate in $\frac{1}{2}$ dr. (2 gm.) doses with a little water three times daily, during the first 10 days. During the first week this ration is increased daily by 100 gm. (3 oz.) of milk and 1 egg, so that at the end of the week the patient is getting about 800 cc. of milk and 6 to 8 eggs. He never gives more than 1 liter of milk daily, because of possible gastric distention and to preserve cardiac strength, which is already at a low point. After the sixth day the patient also gets 35 gm. of finely cut, raw beef, mixed in with some of the eggs; this is increased in amount after a few days. After several weeks, if the patient does well, he is given cooked rice, farina, zwieback, cooked meat, etc., and after four weeks a mixed diet in gradually increasing quantities. Besides bismuth, Wagner prescribes Bland's pills and arsenic. Of 60 patients thus treated only one died; of the 59 patients only one had a recurrent hemorrhage after the treatment was begun. [E.L.]

Methylene-blue in Sciatica.—Baccelli¹ notes Klemperer's use of the above, which was effectual in 19 out of 27 cases so treated. The writer uses hypodermics of phenol with excellent results (just in what manner is not given). [T.H.E.]

Theocin as a Diuretic.—A. O. Dwiejilny² has studied clinically the action of theocin, and pronounces the drug to be a powerful diuretic, stronger than diuretin and agurin. The diuretic effect is seen inside the first 24 hours, and continues for two to three days, gradually abating after that time, though still noticeable for about one week. Repeated use results in much weaker action. The diuretic effect appears to be due to the action on the renal epithelium, as pulse and blood-pressure remain unchanged. The remedy is borne better in small doses, as 0.15 gm. (3 gr.). Gastric distress is unfortunately a frequent by-effect. [L.J.]

Marmorek's Antituberculous Serum.—Arthur Latham,³ of St. George Hospital, London, reports his experience in the treatment of 30 severe cases of tuberculosis, the treatment extending over a period of three months. He asserts that the short length of time during which the treatment was used and the relatively few cases make his conclusions only suggestive. As to the technic of administration, he states that so soon as the skin is prepared, as for a surgical operation, an injection of the serum is made and the area then covered with cyanid gauze, and subsequent injections are given by simply lifting the dressing and swabbing the skin with an antiseptic solution before inserting the needle. That this procedure is efficient is proved by the fact, that in 450 injections no sepsis has followed. A certain proportion of individuals is unable to support the serum, just as others are unable to support antistreptococci or plague serum. In such cases there may be rise of temperature, malaise, enlargement and tenderness of glands near the seat on injection, rashes, and joint affections. He states that it is quite clear that the use of the serum has its limitations; we cannot expect to obtain permanent relief in cases in which there is extensive disease of long standing or in which there are marked excavations and secondary infection, though some such cases under his observation have made steady progress under the Marmorek treatment. In the majority of instances improvement takes place. In three of the six cases of surgical tuberculosis treated, the pain and tenderness disappeared after a few injections. In the majority of cases of pulmonary tuberculosis, the first injections led to an increase in the weight of expectoration and to an increase of the number of moist rales; in a certain number this increase has been followed by a diminution in the weight of the sputum which has been progressive, together with a diminution in the number of rales. Latham states that it is too early to give a useful summary of the effects of the serum on the various symptoms, especially as the patients are still under treatment. A series of cases with reports appended are recited. [A.B.C.]

The Action of Poisons on Renal Bloodvessels.—W. W. Sakussow⁴ experimented with numerous strong poisons in regard to their action on the vessels of isolated kidneys. The

method is very ingenious, but we are concerned chiefly with the results. He found that: 1. Digitalin produces contraction of the vessels in dilutions of 1 to 1,000,000. 2. Strophanthin acts in a similar manner. 3. The vasoconstrictory action of convallamarin is very feeble. 4. Nicotin is a vasoconstrictor in strong solutions, while diluted to 1 to 100,000 it is inactive. 5. Atropin constricts the vessels at 1 to 10,000 and upward. No dilatatory effect has been observed, even from strong concentrations. 6. Cocain 1 to 10,000 was inactive. 7. Caffein caused considerable dilation in 1 to 1,000 strength, and very mild dilation at 1 to 10,000. 8. Chloral hydrate dilated the vessels at 1 to 100 to 1 to 10,000. 9. Physostigmin gave marked constriction at 1 to 20,000. 10. Adrenalin is a powerful vasoconstrictor, active in extreme dilutions, such as 1 to 1,000,000. [L.J.]

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended May 27, 1904:

SMALLPOX—UNITED STATES.		Cases	Deaths
California:	San Francisco..... May 8-15.....	1	
Dist. of Columbia:	Washington..... May 15-21.....	6	
Florida:	Jacksonville..... May 15-21.....	1	
Georgia:	Macon..... May 15-21.....	4	
Illinois:	Danville..... May 15-21.....	2

Changes in the Medical Corps of the U. S. Army for the week ended May 28, 1904:

KUHN, CHARLES F., contract surgeon, is granted leave for two months, with permission to visit the United States.

HALL, First Lieutenant JAMES F., assistant surgeon, is relieved from duty in command of the casual detachment, Hospital Corps, Luneta Barracks, Manila, and will report on transport Seward for duty as transport surgeon, relieving First Lieutenant Perry L. Boyer, assistant surgeon, who will assume command of the casual detachment, Hospital Corps, Luneta Barracks, Manila.

AYER, IRA, contract surgeon, is granted leave for two months, with permission to visit the United States.

PHALEN, First Lieutenant JAMES M., assistant surgeon, is granted leave for one month, with permission to visit China and Japan, to take effect about April 15.

HALL, W. E., contract surgeon, is relieved from further duty at Camp Jossman, Guimaras, P. I., and will proceed to Camp Harbshorne, Laguan, Samar, P. I., for duty as surgeon at that station, relieving Contract Surgeon M. F. Marvin who will proceed to Manila, P. I., and report to the adjutant-general, Philippines Division, for further instructions.

The following named medical officers will proceed to stations set after their respective names for duty: Captain Weston P. Chamberlin, assistant surgeon, to Camp Gregg, Pangasinan; Contract Surgeon John L. Burkart, to Camp Morrison, Ilocos Sur; Contract Surgeon Leonard K. Graves, to Nasugbu, Batangas, relieving Contract Surgeon W. O. Cutcliffe, who will proceed to Bulan, Sorsogon, and relieve First Lieutenant George H. Scott, assistant surgeon, who will proceed to Camp McGrath, Batangas, for duty; Contract Surgeon Frederick H. Mills, to Camp Stotsenburg, Pampanga; Contract Surgeon Ralph W. Newton, to Legaspi, Albay; Contract Surgeon Edwin W. Patterson, to San Mateo, Rizal; Contract Surgeon Samuel A. Springwater, to Fort William McKinley, Rizal.

EBERLE, HARRY A., contract surgeon, is granted leave for two months, with permission to visit Japan, to take effect about April 15. At the expiration of leave he will be relieved from duty in this division and will report at Nagasaki, Japan, on the transport scheduled to leave for the United States June 15, for duty thereon en route to San Francisco, Cal.

MCALISTER, JOHN A., contract dental surgeon, is granted leave for one month, with permission to visit China and Japan, to take effect about April 15.

RIETZ, HUGO C., contract dental surgeon, is granted leave for two months, with permission to visit China and Japan.

KREBS, First Lieutenant L. LE ROY, assistant surgeon, is granted leave for two months, with permission to visit the United States.

PARKMAN, WALLACE E., contract surgeon, now on duty at Fort Worden, on being relieved by First Lieutenant Samuel M. Waterhouse, assistant surgeon, will proceed to Fort Assiniboine for duty.

HENDERSON, First Lieutenant ALBERT B., assistant surgeon will report on or before June 15 to Colonel Wm. M. Wallace, Fifteenth Cavalry, president of the Army Retiring Board at the War Department, for examination by the Board.

PECK, LUKE B., contract surgeon, now at Jersey City, N. J., will proceed to Fort Andrews for duty.

VAUGHAN, MILTON, contract surgeon, is granted leave for two months.

WILLIAMSON, Captain LLEWELLYN P., assistant surgeon, in addition to his present duties pertaining to the Louisiana Purchase Exposition, will report to the commanding general, Northern Division, for duty as attending surgeon at the headquarters of that division.

TRUBY, Captain WILLARD F., assistant surgeon, is granted leave for one month from about June 1.

STEER, Captain SAMUEL L., assistant surgeon, is granted leave for eighteen days, from about June 1.

BARBER, ERNEST C. A., sergeant first class, Fort McDowell, will report to the commanding officer, Company of Instruction No. 2, Hospital Corps, at that post, for duty.

MANSEAU, OSCAR A., sergeant first class, now at Louisville, Ky., upon expiration of furlough granted him from the Philippines Division, will report at the general hospital, Fort Bayard, to relieve Sergeant First Class Willard M. Barton, who will proceed to Fort McDowell, reporting to the commanding officer, company of instruction No. 2, hospital corps, who will send him to Manila, P. I.

ALBRIGHT, CHARLES W., sergeant first class, now at Camden, N. J., upon expiration of furlough granted him from the Philippines Division, will report at the general hospital, Fort Bayard, for duty.

BAHR, WILLIAM, sergeant first class, now at Shawnee, O. T., upon expiration of furlough authorized February 6, will report at Fort Sill to relieve Sergeant First Class Frederick Schumacher who will proceed to Fort McDowell, reporting to the commanding officer, company of instruction No. 2, hospital corps, who will send him to Manila, P. I., on the government transport sailing from San Francisco about July 1.

BUCK, First Lieutenant CARROLL D., assistant surgeon, in addition to his present duties with the battalion of Philippine scouts at the Louisiana Purchase Exposition, will attend the sick of the 119th Co., C. A.

GWINN, ARTHUR C., sergeant first class, Fort Sheridan, will proceed to Fort Myer for duty.

WOODBURY, First Lieutenant FRANK T., assistant surgeon, is granted leave for twenty days.

RAND, Captain IRVING W., assistant surgeon, Ord Barracks, Monterey, Cal., will proceed to the Presidio, reporting at the infantry cantonment, for temporary duty.

STEARNS, CHARLES H., contract surgeon, is granted leave for fifteen days from about June 19.

TITUS, FRANK H., contract surgeon, is relieved from duty in the infantry cantonment, Presidio, and will report for temporary duty at the depot of recruits and casuals, Angel Island.

CHENAY, ARTHUR, sergeant first class, is assigned to duty in the office of the medical superintendent, Army transport service, San Francisco, Cal.

EISENMAN, FRANCIS J., sergeant first class, will report to the commanding officer, company of instruction, hospital corps, No. 2, Fort McDowell, who will grant him a furlough for two months.

So much of orders of October 12, W. D., as direct Major Guy L. Edie, surgeon (now on duty in Washington, D. C.), to report to the commanding general, department of California, for transportation to the Philippine Islands, is revoked, and Major Edie will report to the surgeon-general of the Army for duty in his office.

KUHN, CHARLES F., contract surgeon, is assigned to temporary duty on the transport Kilpatrick until June 1, and is authorized to take advantage on that day of the leave for two months granted him by orders, Philippines Division, March 25.

WILSON, First Lieutenant COMPTON, assistant surgeon, is granted leave for one month.

SLATER, ERNEST F., contract surgeon, will proceed to Fort Howard for temporary duty, during the absence on leave of First Lieutenant Compton Wilson, assistant surgeon, and upon return of the latter from leave, will rejoin his station—Fort Hancock.

VOSA, First Lieutenant WILLIAM E., assistant surgeon, is granted leave for two months and twenty-three days, to take effect when relieved by another medical officer.

Changes in the Medical Corps of the U. S. Navy for the week ended May 28, 1904:

THOMPSON, E., surgeon, commissioned surgeon with the rank of lieutenant commander, from March 3, 1903—May 21.

LANGHORNE, C. D., passed assistant surgeon, detached from the Monongahela and ordered to the Denver—May 21.

BROWN, H. L., assistant surgeon, detached from the Lancaster and ordered to the Naval Station, Guantanamo, Cuba, with additional duty on the Monongahela—May 21.

IDEN, J. H., assistant surgeon, ordered to the Naval Hospital, Philadelphia, Pa.—May 21.

FLINT, J., assistant surgeon, ordered to the Naval Hospital, Chelsea, Mass.—May 21.

MAY, H. A., assistant surgeon, ordered to the Franklin—May 21.

HIBBETT, C. T., surgeon, detached from the Franklin June 1 and ordered to duty in charge of the Naval Hospital, Cavite, P. I., sailing from San Francisco, Cal., June 11—May 24.

WENTWORTH, A. R., surgeon, ordered to the Franklin, June 1—May 24.

LOVERING, P. A., surgeon, detached from duty in charge of the Naval Hospital, Cavite, P. I., and ordered home to wait orders—May 24.

FURLONG, F. M., passed assistant surgeon, ordered to the Naval Museum of Hygiene and Medical School, Washington, D. C., for temporary duty—May 24.

MCDONNOLD, P. E., assistant surgeon, ordered to the Naval Museum of Hygiene and Medical School, Washington, D. C., for temporary duty—May 24.

BELKNAP, J. L., assistant surgeon, ordered to the Naval Hospital, New York—May 24.

WHEELER, L. H., assistant surgeon, ordered to the Naval Hospital, Chelsea, Mass.—May 24.

EAGLING, E., pharmacist, having been examined by a Retiring Board and found incapacitated for active service, on account of disability incident thereto, is retired from active service, May 19, 1904, under the provisions of section 1453, revised statutes—May 21.

Changes in the Public Health and Marine-Hospital Service for the week ended May 26, 1904:

CARTER, H. R., surgeon, two days' leave of absence from May 26, 1904, under paragraph 189 of the regulations.

NYDEGGER, T. A., passed assistant surgeon, granted leave of absence for fifteen days from May 6, 1904, on account of sickness—May 20, 1904.

CLARK, TALIAFERRO, passed assistant surgeon, to proceed to Duluth, Minn., for special temporary duty—May 20, 1904.

ANDERSON, J. F., passed assistant surgeon, to proceed to Hartford, Conn., for special temporary duty—May 20, 1904.

DUFFY, FRANCIS, acting assistant surgeon, granted leave of absence for two days from May 25—May 23, 1904.

HOUGH, J. S., acting assistant surgeon, granted leave of absence for thirty days—May 23, 1904.

HUNTER, W. R., acting assistant surgeon, granted leave of absence for seven days from May 22—May 21, 1904.

WETMORE, W. O., acting assistant surgeon, granted leave of absence for seven days from May 17, 1904, under paragraph 191 of the regulations.

HALL, L. P., pharmacist, to report to the chairman of the Examining Board at Norfolk, Va., May 31, 1904, for examination to determine his fitness for promotion to the grade of pharmacist of the second class—May 23, 1904.

Boards Convened.

Board convened to meet at Washington, D. C., May 26, 1904, for the physical examination of candidates for admission into the Revenue Cutter Service. Detail for the Board: Assistant Surgeon-General L. L. Williams, chairman; Assistant Surgeon-General W. J. Pettus, recorder.

Board convened to meet at Norfolk, Va., May 31, 1904, for the examination of pharmacist L. P. Hall, to determine his fitness for promotion to the grade of pharmacist of the second class. Detail for the Board: Surgeon J. B. Stoner, chairman; Assistant Surgeon J. S. Boggess, recorder.

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 24.

JUNE 11, 1904.

\$5.00 YEARLY.

The 1904 meeting of the American Medical Association showed the great impetus given by the new plan of organization. The registration was unusually large during the early days of the session, and the proceedings of the deliberative body, standing clear as they do from the mass of detail which hampered under the old regime, were worthy in accomplishment. Particularly to be commended was the character of the work done in the sections and the large attendance in the scientific meetings despite the many distractions. The convocation possessed a unity of spirit, a compactness, a force unusual in the history of the Association, and which reflects honor upon the men whose devoted work is making it literally as well as theoretically the representative national body. The place of meeting was ideal, and there seems to be a growing sentiment that the convention should return at least every third year to Atlantic City, which lacks only a convention hall to be unique in its qualifications for such gatherings.

Memorial to Dr. Walter Reed.—The proposal to erect in the city of Washington a suitable memorial to the memory of Walter Reed, Surgeon, U. S. Army, should appeal strongly to the medical profession, and indeed to every philanthropic citizen of the United States. Concerning the great work planned and carried out by Reed and his associates, physicians have no need of details. "His," as we have previously said, "—was the master mind and he was the guiding spirit in an investigation whereby multitudes of lives have been saved, a pestilential malady robbed of its mysteries and terrors, and an annual expenditure of millions of money shown to be in large part, if not entirely, needless." The Walter Reed Memorial Association has been formed. The American Medical Association and the Association for the Advancement of Science have appointed committees which will no doubt cooperate, and subscriptions to the fund may be handed to any member of these committees or they may be sent to Mr. Charles J. Bell, president of the American Security and Trust Company, Washington, D. C., who has consented to act as treasurer. It is thought that at least \$25,000 should be raised, and it is probable that the exact character of the memorial will not be determined until a considerable portion of this amount is in the hands of the treasurer. While the nonmedical public should

contribute a considerable portion of the amount required, dependence is mainly upon physicians to arouse interest in the project by pointing out the important results of Major Reed's yellow fever investigations. The benefits conferred upon humanity by physicians are less often commemorated by monuments than those of other great men, and it is important that members of the medical profession, who by their training are best qualified to judge of the value of medical and sanitary achievements, should take the lead in movements to honor and perpetuate the memory of them.

The Execution of Criminals.—It has been and is still a much debated question whether people convicted of murder in the first degree should suffer the death penalty or not, but the medical profession is only interested in this discussion insofar as it involves the question whether a murderer *eo ipso* is or is not of unsound mind. The rest belongs to the domains of sociology and criminology. But the subject of the present remarks is neither one nor the other; it rather starts with the assumption that, in accordance with the present state of the law, the death penalty has to be paid, and raises the question as to the ethically least objectionable manner of carrying the sentence into effect. We do not think the death penalty is either good sociology, good economy, or good penology, but that is not the question. There is no doubt that the prevailing feeling among civilized nations culminates in the desire to take the life of the culprit as painlessly as possible. The development of kindlier thoughts in this respect has been gradual. Civilization has advanced from torturing to hanging and strangling, from hanging to the "drop," breaking the spine and causing instantaneous death; from the use of the sword or axe, with its attendant gruesome uncertainties, sprang the guillotine, and finally came the electric chair. That the latter device is by no means an ideal of perfection is admitted on all hands, and even if it were, there is still the harrowing time of preparing and pinioning the victim for execution which to him is worse than death itself. As long, then, as legal killing must be done, why not resort to anesthetics? The dose can be administered while the subject is asleep, it would induce absolute unconsciousness, there would be no pain whatever, while the actual transition from life to death would be left to scientific methods in a manner best

calculated to let medical science at least profit by the loss of a human life.

Accidental Deaths of Railway Employees.—

Since its establishment 17 years ago, the Royal Arcanum has lost 617 of its members who were railway employes, by accidents in their work. Of these there were 102 engineers, 39 conductors, 31 brakemen, 17 firemen, 10 yardmasters, 7 baggagemen, 5 switchmen, 4 mail agents, 5 car inspectors, 4 railroad agents, 4 flagmen, 3 superintendents, and 17 in sundry similar occupations. Of these 248 whose special duties were noted, the average age at death was 43 years, and the average duration of membership was 10 years. The natural hazard of the victim's occupation is thus highly exceptional in this kind of work. Such facts emphasize again the responsibility of our American railway officers and owners. In no other country is there such a disregard of the employes' lives. As insurance companies must more and more refuse these risks, it behooves the companies to undertake the duty themselves. If this were demanded by the law it would doubtless serve in an effective way to increase the safeguards which, now neglected, result in the deaths of so many brave and useful men. In general, during the last three months of 1903, on the railways of the United States, the casualties to passengers alone were more than 2,000, 175 being killed, while the casualties to employes numbered more than 12,000, no less than 1,000 being killed outright. Of the 175 passengers killed, 147 died in train wrecks due to either derailments or mistakes in operation.

Ill-health as a Cause of Suicide.—The Chief Medical Examiner of that excellent organization, the Royal Arcanum, reports that 103 members committed suicide during 1903. The causes, during four years, are given as follows:

	1903	1902	1901	1900
Domestic trouble supposed cause	16	9	12	7
Financial trouble supposed cause	26	30	16	21
Intemperance combined with financial or domestic trouble	2	2	3	3
Temperate and out of employment	10	7	12	5
Intemperate and out of employment . . .	9	6	2	1
Intemperance principal cause	12	5	4	7
In previous ill-health	31	23	25	19
Known to have shown signs of insanity	2	2	4	3
Supposed to have formerly shown signs of insanity	9	7	8	10
Supposed to have been temporarily insane	5	6	12	6
Illness from overwork	4	3	2	6
No cause, etc.	5	7	6	

The last five items may be combined, for to the physician insanity is in a medical sense ill-health. We thus find:

	1903	1902	1901	1900
Domestic troubles	16	9	12	6
Financial troubles	26	30	16	21
Intemperance	12	5	4	7
Out of employment	19	13	14	6
Ill-health	51	41	51	44

By this rearrangement of the table it comes out that disease is responsible for 187 suicides, and all other causes or unknown causes combined, for 232. It is also noteworthy that *previous* ill-health, not existing illness, is assigned in so large a proportion of cases. One clings to life more tenaciously, therefore, while sick than when

looking back upon sickness or facing the world with the fear of it before one. How much in any case depends upon medical science and preventive medicine!

The Morbidity and Mortality of Pneumonia.—

That pneumonia is increasing in both frequency and fatality is believed by many physicians. Statistical studies in support of this view are not lacking, one of the most recent being that of Dr. J. Hall Pleasants,¹ who discusses the situation in Baltimore. In that city the deaths from pneumonia, per 100,000 population, have increased from 35.5 in 1850 to 206.9 in 1903, with a maximum in 1900 of 253. Pleasants states that the Baltimore pneumonia curve fairly represents the general condition throughout the country, and directs attention to the fact, that the increase was gradual and steady from 1850 to 1890, a period during which influenza could not be assigned as a contributing cause. As factors to be considered in accounting for the increasing mortality, he enumerates increased density of population, general prolongation of life, climatic changes, large influx of immigration, the negro element in the population, more accurate diagnosis and more exact terminology in vital statistics, decreased deathrate from pulmonary tuberculosis, increased virulence of the pneumococcus, and influenza. If these do not entirely explain the increase, a part must be attributed to a cause as yet unknown. Pleasants rightly believes that physicians should be brought to realize the gravity of the situation, although he cannot see that it looks hopeful from the standpoint of general prophylaxis. In connection with these statements, we wish to call attention to a very suggestive discussion of the subject from the standpoint of prevention and treatment by Dr. N. S. Davis;² as the result of ripe experience his opinions are entitled to the most serious consideration, even though they cannot be construed as complimentary to modern therapeutic ideas. After stating that there can be no reasonable doubt that a part of the increased mortality from pneumonia is due to lessened resistance induced by the habitual use of alcohol and other narcotic drugs, Dr. Davis adds: "And yet, having carefully observed the actual results of the successive changes in the methods of treatment of pneumonia from the middle of the second quarter of the nineteenth century until the present time, I am fully satisfied that a part of the increased mortality is caused by the injudicious selection and use of remedies." He briefly outlines the now much-abused antiphlogistic and bloodletting treatment of pneumonia as practised by himself and other physicians during the second and third quarters of the nineteenth century with a lower mortality than has been secured by any other method of treatment, before or since. This consisted in the first stage of prompt venesection, followed by sedatives and alteratives; in the second, of slightly anodyne expectorants; and in the third, of more food, bitter tonics, and the maintenance of regular evacuations. Then came the decade of antipyretics, and finally, the adoption of the present theory, that "heart failure" is the chief danger in febrile and inflammatory affections, and the consequent

¹ Maryland Medical Journal, May, 1904.

² International Clinics, Vol. I, Fourteenth Series, 1904.

necessity of the early use of special cardiac and vasomotor tonics. Alcohol and strychnin are often combined and frequently lead to disastrous results. The employment, in conjunction with strychnin, of digitalis and ammonium carbonate instead of alcohol would save many patients. In closing, Dr. Davis states, that "from a long and ample clinical experience, in both hospital and private practice, I am certain that if the administration of alcoholic and other anesthetic drugs were omitted entirely from the treatment of pneumonia and the disease left to the judicious use of such other remedies as have been mentioned above, the present ratio of its mortality would be diminished one-half." These additions to the literature of pneumonia are instructive, and should stimulate investigation of a disease which, in its entirety, needs to be thoroughly studied; its ravages in recent years do not form a satisfactory chapter in modern medicine. To determine its true incidence, and, if possible, check its spread, the disease should be made notifiable.

The D.D., M.D., and Q. D. Businesses Combined.—This is a day of combinations and consolidations, but one of the oddest of the examples we have seen is that by the promoter, the Reverend T. C. Reynolds, D.D., M.D., said to be of Chicago. The gentleman's "sermon on epilepsy" is before us, published by "The American Humane and Scientific Association," which should if truthful put an *un-* or *in-* before each of the three adjectives. It is not said where this sermon was delivered but according to internal evidence, the preacher has been admitted to most of the secrets of God, and there is no doubt of his knowledge of the secrets of a certain manufacturing firm whose nostrum is a sure cure for epilepsy. Any doctor who says the disease cannot be cured is either ignorant, jealous, or does not wish to cure it. A number of famous physicians and of unfamed ones are approved but the — Medicine Co., is far superior to any or all of them. Laws should be enacted for "compelling the cure of every epileptic in the land," and the "law should take their earnings from them and pay them out for medical treatment until they are cured." Here is a new sort of governmental socialism or tyranny, at least a new method of combining into one, three businesses which have heretofore not been united so openly. The enterprising manufacturing company of cure-alls must henceforth have an advertising manager who is a doctor of divinity, of medicine, and of quackery, all rolled into one.

A Hygienic Suggestion as to Hygiene.—From a private letter we quote:

Recently the physician of the Board of Health came here to vaccinate the children. Usually that means rows galore with reluctant pupils and indignant parents, but this time I invented a new trick—I let the doctor vaccinate me. That was enough, 2,500 more docile youngsters you never saw. Those who needed no treatment mourned, for were they not out of the mode? Children are funny things—so very human.

But it is evident that to have such an influence over children the teacher must first get their respect and love.

AMERICAN NEWS AND NOTES

GENERAL.

Requests to Charity.—**Philadelphia:** Bequests aggregating \$50,500 are made to charity in the will of Mary J. Miller, of this city. Among other bequests are: Home for Incurables, for a free bed in cancer annex, \$5,000; Episcopal Hospital, free bed for children, to be called "Rose of Sharon," \$5,000; Hahnemann Hospital, free bed to be called "Faith," \$5,000.—**Chicago:** By the will of the late Thomas Brenan, St. Joseph's Hospital, St. Elizabeth's Hospital, Mercy Hospital, and Alexian Brothers Hospital, will each receive \$1,000.—**Rockland, Me.:** The Knox County General Hospital has received a gift of \$1,000, from Messrs. Francis and George W. Smith.

Miscellaneous.—**Philadelphia:** The surgical staff of the Wills Hospital has invited the delegates and members of the American Medical Association to attend a series of special clinics, to be held at the hospital June 13 and 14.—**New York:** Columbia University has received a gift of \$60,000 from Mr. Horace W. Charpentier for the chair of pediatrics. The Manhattan Eye, Ear, and Throat Hospital has received \$40,000 from Mr. E. R. Thomas, which makes available a conditional gift amounting to \$125,000. Dr. A. C. Kerr has been appointed professor of anatomy at Cornell University, and has been made secretary of the Ithaca Division of the Medical College.—**Maryland:** Dr. Frederick H. Howard has been appointed assistant professor in the department of anatomy and physiology in Williams College.—**Washington, D. C.:** A civil service examination will be held June 16 to fill the position of laboratory aid in physiology and pathology in the Department of Agriculture.—**Missouri:** Miss Eugenia Metzger, assistant in physiology at the University of Missouri, has been appointed to the woman's table at the Zoological Station at Naples for the summer months.—**Brookline, Mass.:** The new private hospital at Brookline, Mass., is now opened for the reception of patients. There are accommodations for 34 beds.

Reorganization of the Red Cross.—At a meeting of the trustees of the American National Red Cross in Washington, D.C., May 26, the way was paved for the early adoption of the recommendations of Senator Proctor's committee, which will prove entirely satisfactory to the remonstrants. On adjournment it was announced that another meeting of the trustees had been called for June 16, at which the election of such officers and trustees as may be necessary to fill vacancies which may exist on that date will occur. No information was vouchsafed as to the number of vacancies on the board of trustees which will exist on June 16, but it is learned that the trustees have given Senator Proctor to understand that there will be sufficient to insure the transfer of the control of the society from those now in power, which is all that the investigating committee or the remonstrants have insisted on. It was further determined to apply to Congress for the new charter drafted by ex-Secretary Foster, as soon as practicable, and to change that charter so as to delegate to the President the appointment of 12 of the 18 trustees who are to act for the first year after the new charter is granted. Afterward the President will have the appointment of 6 trustees, the organization will elect 6, and State organizations which it is proposed to form will elect 6, thus providing for the full board of 18 trustees, according to the terms of the new charter.

EASTERN STATES.

Boston Mortality Report.—The number of deaths reported to the Board of Health for the week ended June 4, is 206 as against 168 the corresponding week last year, showing an increase of 38 deaths, and making the deathrate for the week 17.80. The number of children who died under one year was 30; under five years, 50; persons over 60, 42; deaths in public institutions, 66.

NEW YORK.

Tuberculosis and Milk.—Extraordinary precautions are being taken by the Health Department to prevent the communication of tuberculosis through milk from diseased cows. Extra inspectors have been appointed and a strict examination will be made of the many herds producing the bulk of the city's milk supply. New rules are being formulated for the regulation of the traffic and the meat supply will be closely watched. Some physicians are quoted to the effect that many children are now suffering from tuberculosis contracted through milk from infected cows, but the Health Department officials declare no unusual number of cases has been found.

PHILADELPHIA, PENNSYLVANIA, ETC.

New Home for Nurses.—The cornerstone of the Home for Women Nurses at the Norristown Hospital for the Insane, for which the State appropriated \$55,000, was laid June 3. The home will be fitted up with sleeping rooms, recreation rooms, study hall, reading room, and gymnasium. The stonework and concrete work, the foundations being of the latter, will be done by male patients.

WESTERN STATES.

Chicago's Low Mortality.—According to the bulletin of the Health Department the month of May, 1904, had the lowest May mortality on record. During the 28 days that had elapsed when the count was made there was a total of 1,990 deaths—furnishing an annual deathrate of 13.44 per 1,000 population. The average rate of the previous decade was 15.63 per 1,000, so that the closing month's record will be about 14% lower than the average and nearly 2% lower than the previous lowest—that of 1901, when it was 13.70 per 1,000.

FOREIGN NEWS AND NOTES

GENERAL.

Cattle Plague in Egypt.—According to the London *Times* Dr. Koch has concluded his investigations into the question of the cattle plague in Egypt. His report, which was laid before the ministry on May 13, is disappointing to those who anticipated prompt and effectual measures for the eradication of the disease. The learned bacteriologist considers the plague an extremely mild form of rinderpest, and one more nearly allied to Texas and Transcaucasian fever; the germ conveying the infection bears also some analogy to the parasite found in coast fever in West Africa. His suggestions are confined to advising the government to pursue the measures already adopted, such as the application of injections and the isolation of infected animals.

Miscellaneous.—Foreign: The Naples Table Association, which has for its object the promotion of scientific research by women, has announced the offer of a prize of \$1,000, to be awarded in April, 1907, for the best thesis submitted by a woman on the scientific subject involving laboratory research. This is the third such prize offered by the Association.—Dr. George Oliver has presented to the Royal College of Physicians, London, the sum of \$10,000, to be held in trust for the endowment of a lectureship or prize to be called the Oliver Sharkey Lectureship or Prize, in memory of the late W. Sharkey, professor of physiology in the University College, London.—The University of Leipzig has received from the estate of the late Herr Puschmann 500,000 marks (\$119,000), for the study of the history of medicine.

Human and Bovine Tuberculosis Identical.—The Royal Commission appointed in August, 1901, to inquire into the relation between human and animal tuberculosis has found that human and bovine tuberculosis are practically identical. The commission reports that experiments proved that the disease produced in animals by tuberculous material, whether of human or bovine origin, was identical, both in its broad general features and in the finer histologic details. The report in effect refutes Professor Koch's much discussed theory, that tuberculosis cannot be communicated by animals to human beings, and is regarded by a majority of English medical men as of the highest importance as bearing out the possibility of infection through milk. It is believed that the investigations may lead to a strengthening of the regulations governing the sale of meat and milk.

OBITUARIES.

Ralph N. Isham, for nearly half a century one of the leading physicians of Chicago, at Lake Forest, Ill., May 23, aged 73. He was graduated from the Bellevue Hospital Medical College, New York City, in 1854. In 1859 he assisted in the organization of the Medical Department of Lind University, afterward the Chicago Medical College, now the Northwestern University Medical School. In this institution he occupied the chair of surgical anatomy, operative surgery, and surgery for many years. During the Civil war he served as a member of the United States Sanitary Commission and was for a time surgeon in charge of the Marine Hospital, Chicago. He was surgeon of the Jewish Hospital and trustee of the North Star Dispensary; chief surgeon of the Chicago and Northwestern Railway Company, consulting surgeon to Cook County and Presbyterian Hospitals, and delegate to the International Medical Congress in London, in 1881. He was a member of the American Medical Association, Chicago Medical Society and honorary member of the New York Medical Society.

F. C. Schaeffer, a wellknown physician of Chicago, suddenly, June 4. He was graduated from the Chicago Medical College in 1876; was professor of surgery in the Postgraduate Medical School and Hospital; surgeon-in-chief of St. Hedwig's Hospital, gynecologist to St. Elizabeth's Hospital; surgeon to the Charity, Chicago and Post-Graduate Hospitals; consulting surgeon to Mary Thompson Hospital; consulting general surgeon to the Illinois State Eye, Ear and Throat Hospital. He was a member of the American Medical Association, the Illinois State Medical Society, Chicago Medical Society, Medico-Legal and Pathological Societies.

Matthew Leeper, at Glen Cove, L. I., June 2, aged 50. When the Spanish war broke out Dr. Leeper enlisted as a volunteer surgeon and

he remained in the army until the close of the war in the Philippines. For the last year and a half he has been president of the Board of Health in the Island of Mandanao.

Anna E. Park, said to have been the first woman admitted to medical practice in New York City, May 31, aged 74. She was graduated from the Eclectic Medical College of Pennsylvania, Philadelphia, in 1860, and from the United States Medical College, New York City, in 1881.

Edward Gumpert, the oldest physician in Wilkesbarre, Pa., June 3. He was graduated from the University of Wurzburg, Germany, in 1853. He served as surgeon in the French army for many years and was with the Union army all through the Civil war.

Frederick C. Leber, in Louisville, Ky., May 18, aged 70. He was graduated from the University of Louisville in 1864; served as surgeon during the Civil war and was professor of theory and practice of medicine in the Kentucky School of Medicine.

Harry Hakes, at his home in Wilkesbarre, Pa., April 20, aged 79; he was graduated from the Castleton Medical College, Vermont, 1846. He was a member of the State Legislature in 1864 and then followed the profession of law.

George W. Weems, at his home in Huntsville, Mo., May 13. He was graduated from the University of Maryland, School of Medicine, Baltimore, in 1854.

John F. James, in Ionia, Mich., May 15, aged 38. He was graduated from the Western University, medical department, London, Ont., in 1895.

Theodore C. West, of Troy, Idaho, at Spokane, Wash., May 15. He was graduated from the College of Physicians and Surgeons of Chicago, in 1900.

Bushnell A. Wright, in Los Angeles, Cal., May 17, aged 81. He served as superintendent of the Toledo (Ohio) State Hospital for nine years.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended June 3, 1904:

Changes in the Medical Corps of the U. S. Army for the week ended June 4, 1904:

SNODDY, First Lieutenant CARY A., assistant surgeon, is relieved from duty as surgeon on the transport Sherman, to take effect upon the next arrival of that transport at Manila, P. I., and will then report in person to the commanding general Philippines Division, for assignment to duty.

BROWN, W. E., contract surgeon, is relieved from duty at Fort Casey, and will proceed to Fort Walla Walla for duty.

MUHLBERG, Lieutenant-Colonel JOHN C., is granted leave for one month from about June 10, with permission to apply for an extension of one month.

GORGAS, Colonel WILLIAM C., assistant surgeon-general, is relieved from duty as chief surgeon, Department of the East, and will report to the president of the Isthmian Canal Commission for duty with the commission until further orders.

DEWITT, First Lieutenant WALLACE, assistant surgeon, is relieved from duty as assistant to Major Richard W. Johnson, surgeon, in charge of the medical department exhibit at the Louisiana Purchase Exposition, St. Louis, Mo., and will proceed to Fort Washakie for duty, relieving Harry H. Van Kirk, who will proceed to Fort Sill for duty.

DEWEY, FREDERICK S., contract surgeon, now at Oklahoma City, O. T., will report to the commanding general, Southwestern Division, for assignment to duty as attending surgeon and examiner of recruits at Oklahoma City.

MILLER, ALBERT L., contract surgeon, now at San Francisco, Cal., will report for duty on the transport Sheridan, en route to Manila, P. I., where he will report to the commanding general, Philippines Division, for assignment to duty.

ARNOLD, GEORGE H., sergeant first class, Fort Flagler, will be sent to Fort McDowell to arrive not later than June 25, reporting for transportation on the Buford, to relieve Sergeant First Class Frederick S. Simmons, who will be sent on the Buford to Seattle, Wash., thence to Fort Flagler for duty.

DARNALL, Captain CARL R., assistant surgeon, now on duty in Washington, D. C., is detailed as a member of the board of medical officers appointed for the purpose of making recommendations looking to the revision of the manual for the medical department.

FELTS, ROBERT L., contract surgeon, extension of leave granted May 7 is further extended one month.

COOKE, ROBERT P., contract surgeon, is granted leave for one month.

JONES, JOHN F., contract surgeon, will proceed to Fort Wood for temporary duty during the absence on leave of Contract Surgeon Robert P. Cooke, and upon the return of the latter, will rejoin his station, Fort Totten.

The following named assistant surgeons, recently appointed, will proceed from the places designated to the posts specified, and report as indicated: First Lieutenant Leartus J. Owen from Baltimore, Md., to Fort Myer for duty; First Lieutenant Stanley G. Zinke from Cincinnati, O., to Fort Riley for duty; First Lieutenant Robert M. Culler from Reading, Pa., to Fort Jay for duty; First Lieutenant Frank W. Weed, now at Fort McHenry, will report at that post for duty; First Lieutenant William A. Wickline from New York City to Fort Ethan Allen for duty; Contract Surgeon James H. McCall will be relieved from duty at Columbia Arsenal, and will proceed to Fort Moultrie for duty; Sergeant First Class Forest E. White will be sent from Columbia Arsenal, Tenn., to Fort Desota for duty. Contract Surgeon John T. Jones, now on temporary duty at Fort Wood, will report to the commanding officer, Fort Jay, for temporary duty.

Changes in the Medical Corps of the U. S. Navy for the week ended June 4, 1904:

KITE, I. W., surgeon, detached from the Maine and ordered to the Naval Hospital, Pensacola, Fla., for treatment—May 27.

FAUNTLEROY, A. M., assistant surgeon, detached from the Scorpion, and ordered home and to await orders—May 27.

RICHARDSON, R. R., assistant surgeon, detached from the Naval Hospital, Pensacola, Fla., and ordered home and to await orders—May 27.

TAYLOR, J. L., acting assistant surgeon, detached from duty with naval recruiting party, No. 6, May 28, and ordered to duty at the Naval Hospital, Pensacola, Fla.—May 27.

RICHARDSON, F. A., acting assistant surgeon, detached from the Naval Hospital, Newport, R. I., and ordered to the Scorpion, June 2—May 27.

MURPHY, J. F., assistant surgeon, detached from the Isla de Cuba, and ordered home and to await orders—May 31.

OWENS, W. D., assistant surgeon, ordered to the Naval Hospital, Newport, R. I.—May 31.

SOCIETY REPORTS

AMERICAN MEDICAL ASSOCIATION.

Fifty-fifth Annual Meeting, Held at Atlantic City, N. J., June 7 to 10, 1904.

[Specially reported for *American Medicine*.]

House of Delegates.

The House of Delegates, American Medical Association, convened at 10 a.m., June 6. The report of Committee on Credentials and Registration was largely that of progress, since at the opening of the meeting only a fair proportion of the delegates had registered.

The retiring president, Frank Billings, of Chicago, made the opening address, outlining the progress made during the past year, and detailing the advantages already perceptible in the operation of the new system of organization. His remarks were largely congratulatory in character, but related also to the further advantages to be gained as the plan became more compact and more easy in its working. The chief of the reforms advocated by Billings was probably that of the substitution of reference committees to do the work formerly assigned to the business committee, and which had proved exceedingly burdensome in its scope. The plan was adopted, and these additional committees appointed: Rules and Order of Business, Medical Education, Legislation, Hygiene and Public Health, Constitution and By-Laws, Report of Officers, Credentials, Sections and Section Work, Miscellaneous Business. Prompt adoption was also made of a suggestion of Billings, that the president-elect should have control of the scientific work for ensuing meetings of the Association.

The report of George H. Simmons, of Chicago, the secretary, showed that the American Medical Association has 15,039 members. In May, 1903, there were 13,545. Since then 2,413 names have been added and 919 dropped. The State medical associations have 44,362 members.

On motion, the report of the Board of Trustees was deferred until the meeting to be held on Tuesday at 2 o'clock.

The Report of the Business Committee.—EDWIN WALKER, chairman, detailed a most satisfactory condition, and outlined increasingly brilliant prospects for the future.

The Committee on Medical Legislation.—C. A. L. REED (Cincinnati, Ohio), chairman, made a detailed report, embracing the work done by the committee during the past year in stimulating and arousing interest on the part of the profession in the necessity for representation in the national deliberative and legislative bodies. Reed called particular attention to the fact that although medicine was a profession most directly and intimately related to the welfare of the nation, yet there was not a single member of Congress who could be counted upon as representing its interests and those interests of the people directly bound up with the profession. The committee organized a National Auxiliary Committee consisting of representatives, as far as possible, in every county in the United States, the appointments having been made through the State medical associations. By a referendum system these auxiliary members gave opinions and used their influence in connection with bills in Congress. Some of the measures they considered provided for the representation of the Medical Corps on the general staff of the United States army, a project for the appointment of a physician on the Panama Canal Commission, and referring to the Government Medical Staff the adulteration or misbranding of drugs. The report suggested the appointment of a committee of three from the Association to act as an advisory board. Reed stated that all of the States were interested in the matters under the general advocacy of the committee with the exception of Massachusetts and Alabama, and that through private correspondence, matters were in train in these two States. The ends striven for, it must be understood, were not selfish in that they had the general interest of the nation and of every individual citizen at heart, as well as the uplifting and dignifying of the profession of medicine.

In the absence of the chairman of the Commission on the Rush Monument Fund, the treasurer, H. D. Holton, of Brattleboro, made a brief report of the financial condition of the fund, showing an available balance of \$969.01, after the payment of all the expenses to date upon the monument.

The report of the Committee on Medical Education was then made by ARTHUR D. BEVAN, (Chicago) outlining in detail the work in hand for elevating the standards in the various colleges, to make educational requirements uniform in the different States, and to raise the standards of the profession, encouraging liberal education in connection with the special scientific training necessary in the equipment of the physician. Bevan said that the government assistance in this direction was improbable, and that it was a very large and important question. The committee suggested that the by-laws of the Association be amended so that a permanent council of five members be created to deal with the question. On motion, the report of the committee was referred to the Reference Committee on Medical Education.

L. S. McMURTRY then made a report on behalf of the **Committee on Association Medal**. He stated that the medal was founded in the hope of stimulating scientific research, but that the development of interest was less than had been anticipated. The last prize awarded was four years ago, and since that time, in the opinion of the committee, no essay had been submitted worthy of receiving the award. The demands for the medal were moderate, it not being desired that the essay should have too great a technical bearing, although the standard could not be set too low. The conditions, in the opinion of the committee, were not difficult to meet; still but one essay had been submitted during the past year, and that did not attain the standard of excellence set. The plan for offering the prize should be abandoned, since competition, although well advertised, did not seem to have achieved its desired object.

The report of the Committee on Transportation and Place of Session was deferred.

The report of the Committee on Revision of the Constitution and By-Laws was deferred, as not quite complete for presentation.

H. O. WALKER (Detroit), on behalf of a Michigan delegation, offered the following resolution:

"Clearing House for Medical Supplies of Unknown Composition."—WHEREAS, An exact knowledge of the composition and properties of substances used in the management of disease, is essential to a physician's best success; WHEREAS, Commercial push, by advertisement and drummers, persuades many physicians (often the very elect) to use and commend drugs, mineral waters, artificial foods, etc., of unknown composition and effects; WHEREAS, As it is impossible for the individual physician to verify the statements of sales agents, to separate fact from fancy, he often uses substances quite unlike those indicated, to the discredit of himself and his art; WHEREAS, The American Medical Association was organized to promote the exact knowledge and intelligent practice of its members; *Resolved*, That the Board of Trustees, American Medical Association, is hereby requested to provide for the analysis of medicinal substances of unknown composition and undetermined effects, and to publish promptly the results in the Association journal; *Resolved*, That the Board of Trustees be requested to appoint a "Journal Clearing House Commission," three in number, to serve without salary, with authority to have analyses made in reliable laboratories, by experts of recognized ability, or to equip a suitable laboratory and employ one or more competent experts, at a yearly expense not to exceed \$5,000. This preamble and resolutions were unanimously adopted by the Michigan State Medical Society at its meeting in Grand Rapids, May 25, 1904, and its delegates were instructed to present the same to the American Medical Association at Atlantic City, and urge their adoption.

HAROLD MOYER offered a resolution that the consideration of the resolution be deferred, and that it be referred to the Reference Committee, together with other matters germane to the subject.

ELIOT HARRIS (New York) stated that the resolution trenched upon the work of the **Provisional Committee on the establishment of a National Bureau of Medicines and Foods**, and in his opinion the consideration should be deferred until after the report of the committee and its recommendations had been read. The report of this committee followed. It recommended that a National Bureau for the standardization of medicines and foods should be established, to be composed of ten experts, physicians and pharmacists, whose duty it should be to examine all medicines and compounds submitted to them, and certify as to their quality, ingredients, and strength. It would probably be well to base such certification upon the openness of the product; in other words, since the action of this bureau could not be condemnatory, the privilege of examination and certification should only be extended to such products as would be submitted with a full formula. The committee was of the opinion that it was not practicable to put this labor in the hands of any existing department of the United States Government, at least not until further provision would be made by the Hepburn Pure Food Bill. It was, therefore, recommended that five directors be named by the Association, to act in conjunction with five appointed by the American Pharmaceutical Association, to consider the feasibility of the plan, and report at a future meeting. Good results might be obtained by including one member from the allied sections of the American Association, and it would be well, also, to have the plan receive further consideration before the end of the present meeting.

On motion, the report of the Provisional Committee and the resolution offered by the Michigan delegation were referred to the Reference Committee on Medical Legislation.

The first business before the afternoon meeting was the consideration of the report on **revision of the constitution and by-laws**. This report made a number of changes, looking toward the end of simplification and easy working. Its provisions received careful consideration at the hands of the Reference Committee on Constitution and By-Laws, and a detailed consideration will be given later.

The Committee on Miscellaneous Business, to whom the report on the **Association prize medal** had been referred, reported that they concurred with the suggestion that the prize be withdrawn. There was some opposition to the measure, but the resolution was finally carried.

The Senn competition for prize essay was continued. No essays had been submitted during the past year.

Report of the Committee on Sections and Section Work.—L. S. McMURTRY said: At the meeting held in Saratoga in 1902, Osler of Baltimore and Vaughan of Michigan and

myself were appointed on this committee which we mapped out at that meeting. We found that the section work of the Association, the importance of which could not be exaggerated, was very much in need of reconstruction. The committee undertook to bring the section work up to the standard of special organizations in the country which were engaged in similar work, and among the first things the committee realized was the importance in the selection of chairmen and secretaries of the sections, to get men who were familiar with the work, and especially to have the secretaries somewhat permanent. This in great part had been done. Many of the sections overlapped, many papers being presented in one section which properly belonged in another section, and there was no rule or regulation by which the officers of the sections cooperated to separate and classify papers so as to make the work effective. At the meeting in New Orleans the committee recommended that there should be a meeting annually, in the interim between sessions of the Association of the officers of the various sections together with the general officers of the Association. Such a meeting was held last October in Chicago. Nearly all the officers of the sections were present at this meeting, together with the general officers of the Association, and the work was gone over and arrangements made by which the officers of the sections could cooperate, one with the other, and increase the efficiency of the sections, elevate the standard of requirements for papers, and exercise some discretion in securing papers. Arrangements were made for the classification of papers of kindred subjects, together for discussions, and to arrange the work of the sections after the manner of the special organizations so that every section could of itself be a complete society, addressing itself to scientific research.

The **Committee on National Incorporation** made a report suggesting work to obtain the passage of an act of Congress enabling the granting of a charter to the Association, thus freeing it from the necessity of incorporation under the laws of any one particular State, with the necessary subjecting to corporation laws of that State. The report was made after a lengthy conference with Judge Ray, of New York, who decided that the plan was both legal and feasible. There was a strong recommendation that the charter be obtained from Congress at the earliest possible moment.

The **Committee on Public Health**, in its report, suggested the obtaining of an act of Congress making systems for the registration of vital statistics uniform in the Southern States. There was also a recommendation that a committee be appointed to secure uniform laws from various State Legislatures. The form which was embodied in the report was obtained through consultation with government officials. The committee reported that circulars advocating the movement had been sent out, reporting that measures had already been made in California and Iowa. The appointment of a second committee of five members to formulate plans for the establishment of the National Institute of Hygiene was also advocated, which should have for its object the distribution of information, and the planning of systems to make the study of hygiene more popular.

Committee on Organization.—J. N. McCORMACK said the prompt and cheerful acceptance of the plan of organization by States and counties in every section of the country, and the uniformly gratifying reports of the results secured under its operation, are gratifying. A member of the committee has attended the annual meetings in a majority of the States, and in a number of them before and after their reorganization. Since the New Orleans meeting the standard Constitution and By-Laws, with such modifications as were necessary to adapt them to local conditions, have been adopted in North Carolina, Indiana, New Jersey, New York, Rhode Island, South Carolina, Maryland, Oklahoma and Delaware, in the order named. In addition, Minnesota, West Virginia and Kansas, which had partially reorganized in 1902, have also adopted the standard plan. As Alabama and Massachusetts have long had most of the important features of the Association plan, Pennsylvania, Virginia and Georgia are the only great States still operating under the old methods. Michigan led the procession of States in this work last year, increasing the membership from 452 to about 2,100. Texas easily takes the banner this year, with an increase from 382 to about 2,510, although several States have quadrupled their membership. What is probably still more significant, as indicating the rapid growth of the movement, over 1,600 of the 2,880 counties in the United States are more or less completely organized. While these results are almost phenomenal when compared with the past, they seem small in the light of what remains to be done before our organization is really complete. Few States except Alabama have over 50% or 60% of the eligible physicians even enrolled as members. The work will cover every phase of professional work and interest, scientific, social, material and legislative, and in the very nature of things will never be completed. Instead, the assumption and proper discharge of these functions will constantly open up or develop new avenues of activity or usefulness. The real test of the plan of organization will come in each State when the first outburst of enthusiasm has passed, and county societies, the foundation for everything, are likely to disappear as rapidly as they have been formed unless their usefulness to the rank and file of the profession can be demonstrated in a very broad way.

[To be concluded.]

Section on Practice of Medicine.

FIRST SESSION.

Adaptation of Pure Science to Medicine.—ALEXANDER LAMBERT (New York), in his address as chairman of the section, spoke of the relation between the practising physician and the laboratory worker, these being the two classes into which the graduates of today may be roughly grouped. Many problems in medicine can be worked out only by the intelligent cooperation of the two. In outlining several of these, their present status was briefly sketched. The antitoxins are instances of laboratory discoveries; along this line are the bactericidal serums, some of which are yielding valuable practical results. Those for plague and cholera give more promise than do those of typhoid fever, pneumonia, and kindred diseases; in the former group 50% are protected by inoculation, and among those attacked the mortality is reduced to half. The Widal reaction is positive in about 95% of typhoid cases; late investigations indicate that it may serve as an index of the resistance of the individual or of the severity of the infection. In blood diseases the laboratory finding is the final arbiter in many instances. The study of the feces has not only cleared up many obscure conditions, but has added to the list of parasites infesting man. Numerous conditions formerly grouped under the term indigestion have been differentiated. Uremia and eclampsia are still to be explained. The former may develop when least expected, with or without the presence of anuria. Clinical and pathologic investigations are needed to determine the action of the kidneys in these cases. Eclampsia is even more puzzling. Is it primarily renal, or is a hepatic or other lesion the exciting cause? The ordinary methods of urinalysis are useless in solving this problem. In closing, Lambert emphasized the unfairness of sending a specimen to the laboratory without accompanying data. The full clinical history should in all cases be furnished, as it may be essential for rendering a correct diagnosis. The duration, rapidity, and manner of growth, and other points may help decide as to whether a tumor is a carcinoma or sarcoma or even a malignant growth.

Pernicious Anemia and Its Relation to Gastric Digestion.—CHARLES G. STOCKTON (Buffalo) based his paper on a study of 24 cases; these represented half of the cases seen during the last 10 years, the data in the other half not being complete. The cases were discussed from three standpoints: (1) General condition; (2) gastric digestion; (3) the blood. Among the more constant symptoms were dyspnea, weakness, digestive disturbance referred to the stomach or intestines, pallor or lemon-yellow color, little loss of weight, pale tongue with loss of epithelium. In the majority there was complete achylia gastrica. That this condition is not an etiologic factor in pernicious anemia is asserted by Stockton for three reasons: 1. When the blood improves the general condition of the patient becomes better; this does not occur when only the stomach condition improves. 2. In not a single case of achylia gastrica alone have there been any blood changes characteristic of pernicious anemia. 3. In a few cases of marked pernicious anemia there was not complete achylia gastrica. Pernicious anemia is therefore considered to be the cause of achylia gastrica. Diarrhea was occasionally troublesome, but less often than in cases of achylia gastrica without pernicious anemia. There was surprisingly little evidence of marked cardiac disease. No constant changes were observed in the liver, spleen, or lymph-nodes. Symptoms of spinal cord disease were observed in six of the nine cases studied after articles calling attention to this feature were published. Most cases gave no history of previous serious illness. Ages ranged from 32 to 70; 20 were males, 4 females; 11 had indoor occupation. The duration varied from five months to six years. Other data were given, but the point most emphasized was that digestive troubles are secondary to the disease and not a causal factor in the production of pernicious anemia.

Discussion.—R. C. CABOT (Boston) stated that his results from a study of 151 cases were entirely in accord with those of Stockton. Five-sixths of the patients had no HCl, and yet digested their food perfectly well. The striking thing about this is that HCl appears to be a luxury instead of a necessity. Another noteworthy point is the lack of serious cardiac symptoms, even when the heart is known to be markedly fatty. MAX EINHORN (New York) coincides with the view that there is no intimate relation between achylia gastrica or atrophy of the stomach and pernicious anemia. In many cases atrophy of the stomach is a sequel of the anemia. In most cases of achylia gastrica the blood is in good condition. WILLIAM OSLER agreed with the other speakers, that in many cases of pernicious anemia the digestive organs are in good condition. In certain cases, however, the stomach symptoms are so dominant as to indicate that probably in a few instances the stomach condition is essential and the pernicious anemia exists because of it. A case previously reported by him, in which the stomach was entirely sclerotic, bears out this belief. After all has been said, we are still at sea as to the precise and exact etiology of pernicious anemia. The profession should not be so much at sea regarding the diagnosis. It is not at all creditable that in many cases the diagnosis is first made by the consultant. J. N. HALL (Colorado) mentioned a case in which marked improvement followed the administration of HCl. This is possibly a neglected method of treatment in many cases. A point in diag-

nosis is, that the absence of eosinophilia should point to pernicious anemia instead of the presence of parasites. Arsenic in this disease possibly does good by its antiseptic action upon the mouth and intestinal tract. In one case under observation Fowler's solution produced no beneficial results; when the patient was put at entire rest in bed and given sodium cacodylate hypodermically he improved rapidly and is now as well as ever and is practising medicine. GEORGE DOCK (Ann Arbor) agreed with the previous speakers as to the condition of the stomach. As to the treatment with HCl, he has seen a number of patients improve as much under its use, with fresh air and proper diet, as under the use of Fowler's solution. The action of HCl may be entirely apart from the condition of the stomach. He gives from 45 m. to 60 m. of the diluted acid, or as much as the patient will tolerate, after meals. It may assist in intestinal digestion; for this reason it is very important to examine the stools to determine the extent of the intestinal changes. The point to remember is, that HCl is a very useful adjuvant and may act quite apart from any improvement in the stomach itself. STOCKTON, in closing, said that he was not prepared to accept the dictum that HCl is a luxury. Einhorn's statement that atrophy of the stomach is found as a sequel in some cases of pernicious anemia suggests an explanation of the class of cases referred to by Osler. With the marked degeneration of tissues everywhere in the body in pernicious anemia one would expect to find just such cases as Osler has reported without attributing to the stomach condition a causal relation. There is some doubt as to whether therapeutics adds very much to improvement in cases of pernicious anemia. He believes that it is proper to give HCl if the patient can stand that drug. But little knowledge of the condition of the patient was obtained from the examination of the stools in a series of cases.

Diagnosis and Treatment of Perforation in Typhoid Fever.—MORRIS MANGES (New York) reported a series of 19 cases, in 16 of which operation was done. The 19 cases occurred among 268 patients within 2 years; this fact suggests a seasonal incidence or a special virulence of certain typhoid bacilli. The diagnosis was verified by operation or autopsy in all but one case. The age of the patients varied from 6 to 42 years and the perforation was on the ninth to the fifty-eighth day of the disease. Pain is the most important symptom of perforation; it occurred in 17 of the cases, the other 2 being delirious, and was the first symptom in 14. Rigidity was present in 16. In order to make variations in liver dullness of value in diagnosis the condition should be noted every day during the disease; the time now spent in examining the spleen could be more profitably used in outlining the liver. Of the cases in which observations could be made, the temperature fell in 3, rose in 9, was unchanged in 4. The pulse rose in 12, was unchanged in 4, fell in none. The leukocytes rose in 7, fell in 3, were unchanged in 6. Blood-pressure is not an important diagnostic aid. Operation was performed from 5 to 72 hours after perforation though in some instances the time of perforation is problematic. The possibility of spontaneous cure of perforation is raised by the one case reported as such; Manges believes this to be possible if the opening is small and is at once shut off by adhesions. But in all the cases reported as such the recovery is only 5% and this leaves no doubt as to the proper course to pursue, this being operation in all cases. General anesthesia is to be preferred to local. Special attention should be given to the diagnostic significance of pain, which is variable in degree, situation and character.

Discussion.—WILLIAM OSLER said he was present when in 1886 J. C. Wilson read his paper advocating operative interference in typhoid perforation; then he felt very conservative regarding the proposition but his views have since changed. Two things are needed to lower the mortality from this complication: 1. Intelligent watchfulness on the part of the physician of the progress of the disease. In general hospitals the chief should put down in writing what the house physician should especially look for in the typhoid cases; if they appear, help should be summoned within a few minutes. 2. The prompt cooperation of the surgeon. It is better in many cases that the house surgeon should operate as the time spent in summoning the chief may be too long. The record at Johns Hopkins Hospital is now 19 cases with seven recoveries. J. C. WILSON (Philadelphia) said in reference to the management of cases in hospitals he insisted on hospital residents examining the abdominal wall of typhoid patients at every visit to note if rigidity be present; the merest appearance of rigidity must be reported to the visiting physician by telephone. If abdominal pain be present the surgeon is at once called and the operating-room prepared, as a matter of precaution, while he is coming. Yet there are cases where abdominal pain, sudden and severe, accompanied by rigidity comes on and in a few hours has passed away and no perforation has occurred. Wilson is at a loss to explain how the symptoms of perforation can occur without the presence of that complication. Regarding the relation between intestinal hemorrhage and perforation, he believes that they rarely occur at the same time; hemorrhage is very often a precursor of perforation and for this reason vigilance, if possible, is to be increased in cases of hemorrhage. It is time for the profession to consider seriously the advisability of opening the abdomen in cases of profuse hemorrhage that threatens the life of the patient. This will permit the arrest of hemorrhage, it is believed, in certain cases. An instance was cited in which

a child died from hemorrhage that operation would probably have saved. MANGES, in closing, said that the trouble with too many physicians is that they wait too much before making the diagnosis of perforation in typhoid fever; they must have all the symptoms before they are willing to risk the diagnosis of perforation and then the proper moment has gone by. He hopes that Wilson will succeed in doing as much for hemorrhage in typhoid as he has done for perforation.

Typhoid Fever with an Unusual Complication.—W. E. DARNALL (Atlantic City) reported a case of typhoid fever in a single woman of 30, during which severe hemorrhage from the uterus was a complication. The fever was mild; the case being what is known as a walking typhoid. The hemorrhage occurred during the third week of the disease, menstruation having taken place two weeks before. At autopsy the lesions of typhoid fever were found, but there was absolutely no lesion of the uterus to explain the hemorrhage. He finds no mention in the literature of uterine hemorrhage during typhoid fever.

Mortality and Management of Pneumonia.—E. F. WELLS (Chicago) spoke of the increase in prevalence and mortality of pneumonia and mentioned factors that may be considered as causes. The increase in virulence of the pneumococcus is probably largely at fault in the increase as this change can be demonstrated to take place. This organism is present in many individuals supposedly healthy, it being found in the respiratory passages of 45 out of 135 persons. In some instances it was found in all the members of a family and in these was usually obtained the history of pneumonia in one or more members. This fact points to a reasonable hope of a successful prophylaxis against pneumonia. The organism is disseminated by coughing, sneezing, and expectoration, of the people who harbor it. It is taken into the body by inspiration and possibly by the blood from the upper respiratory passages. Wells distributed tables that have been made from statistics collected during several years to show the increase of mortality from pneumonia. In all 465,020 cases are included with 93,110 deaths, a rate of over 20%. Death in the vast majority of cases is due to toxemia. As regards treatment, he believes that the people are well enough instructed to cooperate with physicians in an effective prophylaxis. All sputum from pneumonia patients should be destroyed before it becomes dry, and it would even be well to destroy all sputum. Rooms of pneumonia patients should be afterward disinfected the same as in the case of diphtheria. Active treatment consists in putting the patient in the best environment, surrounding by hot water bottles, giving a single small dose of morphin and saline enemas. To reduce arterial tension during the first few hours veratrum viride is given; later digitalis is administered. For pyrexia the icecap and guaiacol are used. Venesection followed by salt solution may be indicated. Fluids should be given freely. Antipneumococcus serum may be of service. Oxygen inhalations are begun early. For pulmonary edema, strychnin, adrenalin, and morphin are employed. The suddenness of changes is the important feature in pneumonia; this means that the most careful watching of the patient is essential.

Study of a Series of Cases of Pneumonia, with Special Reference to Diagnosis and Complications.—JOSEPH SAILER (Philadelphia) read a paper giving in detail the characters of 65 cases of croupous pneumonia. The cases were from the Philadelphia Hospital with all the unfavorable conditions there existing. Forty percent were over 60 years and there were 35 deaths. While the average leukocyte count was slightly higher in the cases that recovered, Sailer does not believe that any positive conclusion regarding treatment or prognosis can be based thereon. A careful study of the chlorids in the pneumonia cases and also in healthy persons leads to the conclusion that their diminution or absence is of diagnostic but not of positive prognostic value. In one case this test made the diagnosis (confirmed by autopsy) when the physical signs were absent. A careful study was made of bronchial breathing; faint breathing of this type was heard not only in the early stage but also in the later periods in some cases. Herpes appeared only 4 times, icterus 3 times. Ten cases were treated with antipneumococcus serum. Of these, 7 recovered and 3 died. Large doses were used and in the majority of cases it produced an antipyretic effect. In one patient, 7 days after the temperature had been normal, urticaria and severe joint pains, lasting 7 days, appeared. On the whole the results from the serum were encouraging.

Discussion.—R. C. CABOT (Boston) said he did not consider the tables of Wells, referring to the Boston hospitals, as proving his point. Only since 1884 were they accurately kept, and since then there was no rise in mortality. JENKINS (Iowa) considers influenza and crowding of people in cities as the two most important factors in increasing the mortality from pneumonia. ROBERTS (Buffalo) took issue with the treatment of symptoms as symptoms. The cause of the symptoms (toxemia) should be treated. He would bleed early and late in the disease. BABCOCK (Chicago) believes that pulmonary edema is not due to failure of the heart, but to the action upon the pulmonary alveoli of the pneumococcus. The blood-pressure is low at the onset, and he would not give cardiac depressants. Digitalis is the better drug. S. S. COHEN (Philadelphia) firmly believes that venesection may be of value in the beginning to reduce the toxemia and later when the right heart is overloaded. The need of the individual is the determining factor in the employment of this measure, individualization being more important in

this disease than in any other infection. He looks upon cases with high temperature as being more favorable. He has seen veratrum viride do good in cases where its physiologic action would not seem to be indicated. The use of drugs is still largely empiric, and the results of clinical experience must be taken as of value along with experimental data. Hence, the drug in question does good in some cases, though the reason cannot be given. WELLS, in closing, did not agree that high temperatures were favorable. He again emphasized the value of morphin early and later in the disease. SAILER, in closing, stated that low blood-pressure in the beginning is considered unfavorable. He would employ antipneumococcus serum intravenously in a second series of cases.

Appendicitis from the Standpoint of a Physician.—S. G. BONNEY (Denver) believes that the responsibility of the physician in cases of appendicitis is much greater than that of the surgeon. Early diagnosis is of extreme importance. In cases seen late the early manifestations should be carefully reviewed. A careful examination of the abdomen should be made in all cases of even the slightest abdominal pain. Leukocytosis is of comparatively little importance. Cases were detailed to show that symptoms of appendicitis are present occasionally when the appendix is normal and also that grave disease of the appendix may give no local signs, the general condition of the patient being the important point. The writer emphasized the need of a much greater definiteness among physicians as to what should be done in the various stages of the disease.

Suicide: Some Instructive Cases.—J. L. DAVIS (Cincinnati) spoke of the increase of suicides in recent years and of the various factors that may be of causal importance. The crime is greater among insured persons. The paper was devoted largely to a discussion of how suicidal tendencies may be lessened. First is to diminish the strenuous life of today, especially among Americans. This no doubt has much to do with the destruction of physical and mental poise. The fundamental mistake here is in the conception of life, the material side being too largely exalted. The relation of religion to suicide is that of lessening it. This is illustrated partly by the fact that men are three times as apt to commit suicide as are women. The daily press, with its revolting details of suicides and other crimes, is largely responsible for the increase of suicides. Papers should be allowed to print only the dry facts regarding trials, etc. They claim that they give the people what they want, but they should be compelled to give them better than they want.

[To be continued.]

Section on Surgery and Anatomy.

FIRST SESSION.

Chairman's Address.—CHARLES A. POWERS (Denver). The Chairman mentioned a number of the eminent surgeons of America who had previously occupied the chair of the Surgical Section since its organization in 1860, soon after the organization of the Association and expressed his appreciation of the honor of succeeding these men. He briefly referred to the history of surgery in America, stating that while in 1873, probably not a medical man practised surgery exclusively, a large number of the members of the section at present, devoted their time entirely to surgery. A recent writer called attention to the fact that while in earlier times the best minds took up the study of theology, and in more recent times the profession of law at present, many of the best men are going to medicine. In addition to liberal education and thorough professional training, the surgeon needs the intellectual qualifications of the naturalist, a judicial mind, the highest character and most delicate feeling. In our choice of operation or no operation, we should, as Billroth suggested, ask the question, whether we would be willing to undergo the operation ourselves. In the early career the surgeon is inclined to look at the ready results of operation, while in later years, he is more careful in his selection of cases, and in a third period of his career, is likely to limit himself to certain special conditions in which he has gained special skill. The responsibility of surgery is not equalled by any other calling, and men of the highest character are needed.

The Danger of Allowing Moles and Warts to Remain, lest They Become Malignant.—W. W. KEEN (Philadelphia) prefaced his remarks by stating that his paper referred to the clinical aspects of warts, moles, and other similar growths, not their pathologic character. Many of these growths do not undergo malignant change, but we can never tell when such changes will occur. These small growths are subject to irritation and injury and are very likely to be stimulated by scratching. When they increase in size they are generally malignant. The patient does not usually fear them, because they have existed so long without giving trouble. Warts, he believes, generally degenerate into epitheliomas, while moles are more likely to undergo sarcomatous degeneration. The textbooks on diseases of the skin often give radically wrong teaching with regard to these growths, advising that they be treated by constriction or shaving the growth away, which seldom entirely removes the tumor. Few regions of the body are exempt from these growths. The operation is generally so small that it can readily be done by the family physician if taken early. Twenty-

five cases were reported, in which these apparently small growths had undergone degeneration. Twelve of these were from Keen's own practice. Among other cases he mentioned, that of a birthmark in the region of the scapula and axilla, which, when he first saw it, had become so extensive that a removal of the entire upper extremity was necessary. In another case, amputation of the leg for a growth arising in a small wart over the external malleolus was followed by a recurrence of the growth in the glands of the groin, from which the patient died. In a large proportion of the other cases reported the results were equally unfortunate.

Discussion.—RODMAN (Philadelphia) stated that he had seen more warts undergo epitheliomatous degeneration than moles sarcomatous. He recalled three distinct cases of the first kind, one an epithelioma arising from a wart beneath the patient's hatband, which resulted fatally. FUTTERER (Chicago) exhibited specimens showing epithelial metaplasia resulting from friction. He believes, however, that there are other causes than mechanical ones that give rise to such malignant degeneration. WEIR (New York) believes that the same rule might well be applied in dealing with these small defects that applies in dealing with all tumors. They do no good, and are better removed than left. In the early stages of such growths, when patients are unwilling to submit to operation, he has had good results from the use of glacial acetic acid. LAPLACE (Philadelphia). While many people are not destined to have malignant growths, others are subject to them, and such growths are much more apt to occur in some spot of lessened resistance, such as these moles and other defects offer. BEVAN (Chicago) mentioned the danger of infection of wounds from growths which are being removed, and believes that when their surface is moist, it is well to cauterize with the actual cautery before removal. Moles are too common for us to remove all. He believes that probably half of the members of the section are affected, and some have numerous growths of this kind.

Starvation: Operation for Malignancy in the External Carotid Area, Its Failures and Successes.—ROBERT H. M. DAWBARN (New York City). This method is still generally untried in the hands of most surgeons, but from considerable experience, Dawbarn considers it worthy a trial. He has had more favorable results in operations for sarcoma than for carcinoma. In special cases permanent shrinkage has followed the operation, which has continued for three years after operation, and in one case of small-celled sarcoma of the lower jaw, which Butlin considers hopeless whether removed or not, the patient is apparently cured. In growths of the lower jaw, he advises control of the inferior dental artery, and removal of the nerve as well as excision of the carotid. In operating, it is best to excise the external carotid of the sound side first, for if the diseased side is tied first, the growth will shrink and the patient, being encouraged by this, will refuse to have the other side operated upon, and in a short time, when the circulation is reestablished, the growth will return as bad as ever. Though the chances of cure are slight, it is the only chance offered these unfortunate patients, and even in desperate cases it usually prolongs life.

Discussion.—BRISTOW (New York) has operated in 11 cases. In one case of sarcoma the patient died shortly after; all of the others recovered, and were relieved of pain. The tumor always shrinks in size, and the discharge is lessened or ceases. In none of his patients, however, was life prolonged over one year. He believes that the danger of the operation is out of all proportion to its extent. During the operation, when the stump of the artery is passed beneath the hypoglossal nerve, there is decided inhibition of respiration, which is probably from the tugging on the superior laryngeal nerve. DAWBARN, in closing, mentioned the benefit which prolongation of life, even for a few weeks, may have for a business man who wishes to arrange his affairs. In certain cases the shrinkage permits a radical operation to be performed later. The mortality in 60 uncompleted cases he believes is less than 5%.

Surgical Treatment of Presumably Benign Tumors of the Breast.—J. CLARK STEWART (Minneapolis), in dealing with small, hard tumors of the breast, growing in women over 40, believes that we should be decidedly suspicious. We are in need of some better means of exploration to determine the character of such growths. That such growths may be grafted by the use of an aspirating needle has been abundantly proved. Experience at the Johns Hopkins Hospital, in Baltimore, has shown that small cysts make up less than 50% of all cystic growths. Several authorities were mentioned in referring to the malignant degeneration of apparently benign cysts. All tumors of the breast should be considered as malignant until they are proved to be benign.

Discussion.—JEPSON (Iowa). Malignancy is becoming progressively more frequent in recent years until at the present time it has been estimated that nearly 50% of women past 45 years of age die of malignant growths. Jepson doubts if it is necessary to make a diagnosis in many of these cases, for only a small proportion of breast tumors are benign, less than 10% probably. WHARTON (Philadelphia), in several doubtful cases which he left for observation has later found the growths to be malignant. BLOODGOOD (Baltimore). The hope for improvement in the results of operations for tumors depend upon earlier removal. The number of benign tumors coming to hospitals for operation is increasing, because patients are coming to recognize the danger of such growths, and come to the

hospital early for examination. In the case of a young woman under 30, multiple tumors are generally intracanalicular fibromas, and benign. Single tumors occurring at any age should be looked upon with suspicion, and after 45, immediate operation should be advised. In doubtful cases it is desirable to cut into the tumor before excising, and in this way it is usually possible to make the diagnosis. A large proportion of cysts undergo malignant degeneration. Every woman whose case gives the clinical picture of cyst, has 10% of chances of cancer. ROBERT MORRIS (New York), said if we delay operation in the case of tumors of this kind, patients usually drift into the hands of quacks. When patients are unwilling to have an operation it is well to tell them of the dangers of delay, and suggest excision of a small area and making frozen sections for microscopic examination under ether, when, if the growth is found malignant, the complete operation can be done. STEWART, in closing, expressed the opinion that generally a macroscopic examination was sufficient for diagnosis, and that it was not necessary to use the microscope.

Painful Affections of the Knee-joint.—HOFFA (Berlin, Germany). Practically the same points were covered in this paper as in a paper quoted recently in the surgical editorial columns of *American Medicine*. We refer those interested to this editorial, which was based on Hoffa's publication in the *Deutsche medizinische Wochenschrift*.

Surgical Lesions of the Axillary Plexus.—JOHN A. WYETH (New York City) reported a case of large fusiform neuromas of the brachial and axillary plexus. On exploring the region of the growth, removal without paralysis of the entire extremity was seen to be impossible; hence, the clavicle was divided and bent upward, so as to relieve the pressure on the growth. This was followed by entire relief from the symptoms, and the patient is still living and well, 13 years after the operation, with complete control of all muscles. In another case, incision and removal of a thickened sheath was done for a neuroma of the inner cord of the axillary plexus. A case of complete paralysis of the upper extremity by stretching of the axillary plexus, by raising the arm during the removal of tuberculous glands of the axilla, was also mentioned. Six weeks later sensations began to return, and at the present time, five months later, sensation and motion are almost entirely restored.

Discussion.—MURPHY (Chicago) believes that it is quite common to get paralysis of the arm from holding it above the head during the operation. This position should be avoided as far as possible. Experience in operations for trifacial neuralgia seems to show that nerves regenerate readily after division, but usually degenerate by pressure and stretching. HOLMES (Philadelphia) suggests obviating pressure on the nerves of the axillary plexus by flexing the forearm and supinating the hand when the arms are elevated above the head during operation. SUMMERS (Omaha) called attention to danger of paralysis from the crutch arrangement that is commonly used to separate the legs and hold them in the lithotomy position during perineal operations.

Matas' Operation for Popliteal Aneurysm.—J. F. BINNIE (Kansas City, Mo.). The case of a patient is reported who had had syphilis, rheumatism, gonorrhea, and who had been addicted to alcohol. On examination, a pulsating tumor of the region of the calf of the leg, 6 inches by 3 inches, was found. At the operation the aneurysmal sac was found to be filled with clot. The Matas operation was performed, with complete recovery of the patient, and restoration of circulation of the leg.

Discussion.—MATAS (New Orleans). The value of reports of such relatively untried operations is great. In the case reported it was shown that infection need not interfere with satisfactory recovery. Since the publishing of his first paper, Matas has had one additional case. In performing the operation, he emphasized the necessity for free exposure of the sac, control of all vascular orifices, and reduction of the size of the sac by several tiers of sutures. In all these cases where operations have been performed, every one who has tried the operation agrees as to its simplicity. MURPHY (Chicago) mentioned a case in which he modified the technic of the original operation by excising a part of the sac and overlapping the walls. At first the vessel bled freely, through the stitch holes when the tourniquet was removed. This soon ceased, but seven days later infection occurred, necessitating first ligation of the artery, and later, amputation, which was followed by death. PONDZER (Indianapolis) reported a case in which he performed this operation only 12 days previous to the session's meeting. There had been slight rupture of the sac wall previous to operation, but as the vessels elsewhere were good, operation was thought to be justifiable. Up to the time of the report, patient was doing well. Ligation in such cases, where the circulation of the limb is faulty, is sure to be followed by gangrene.

[To be continued.]

Section on Obstetrics and Diseases of Women.

FIRST SESSION.

Chairman's Address.—L. H. DUNNING reviewed briefly the progress in gynecology during the past year. He stated that the year's work had consisted of a large amount of good gynecologic work, but not much that was new and of signal

importance had been accomplished. He then discussed at length senile endometritis. The affection is more common than is generally supposed, constituting about 3% of all the pelvic troubles among women. There are two forms—acute and chronic. The former may be due to gonorrheal infection, but other germs may be the etiologic factor. It not infrequently results in abscess in the adnexa. Thorough drainage, dilating the cervical canal if necessary, is the main thing in treatment. No curetment should be done until acute symptoms subside. The application of carbolic acid and other medicaments to the interior of the uterus may be helpful. The chronic form is often a mere continuation of the acute. This is sometimes so severe and persistent as to require hysterectomy. The histologic findings in both forms were dwelt upon, several illustrative cases were reported, and illustrations were exhibited.

Invasion of Carcinoma Cervicis Uteri into the Surrounding Tissue.—J. A. SAMPSON (Baltimore) held that the high percentage of recurrence following the operative treatment of carcinoma of the cervix shows that the growth has invaded the surrounding tissues at the time of the operation, and that hysterectomy alone cures the disease in but a small percentage of cases. A study of the anatomic relation between the cervix and the neighboring parts shows that this relation is varied by the position of the uterus in the pelvis and that the growth does not have to extend far anteriorly in order to involve the bladder or laterally to reach or extend beyond the ureters. A study of the specimens obtained from the more radical operations demonstrates how the above takes place, and emphasizes the importance of wide excision of the primary growth, and that the only hope of bettering our results lies in early diagnosis and radical operation. The position of the ureters makes accidental injury to them frequent in operations for malignant disease of the cervix. In the Johns Hopkins Hospital there were 19 such injuries in 156 hysterectomies for carcinoma of the cervix, while there were but 11 similar injuries in 4,518 other major gynecologic operations. A study of removed specimens showed malignant extension into the parametrium in 7 out of 15 cases of operable cancer at the cervix, and metastases, especially in the parametrial lymph-nodes, in 4 out of the 15 cases, and in 3 of these 4 cases these lymph-nodes were involved without there being a direct extension of the growth into the parametrium. Thus the ureters pass through tissue which should be removed. It should be remembered that rough handling or stripping of the ureter at its lower extremity is apt to result in necrosis of its walls. The thorough radical operation with removal of pelvic lymph glands, and the proper disposition of the ureters should be attempted only by one conversant with the anatomy of the pelvic contents and with the gravity of the disease.

Primary Chorioepithelioma Malignum Outside of Placental Site.—P. FINDLEY (Chicago) discussed at some length a number of reported cases, and reported one in his own experience. The subject has been one of some investigation and of much more speculation. The uterus is by no means the primary seat of the disease in all cases; it may arise primarily in the vagina, lung, liver, spleen, etc. Metastatic growths are common in various organs, and these may cease to grow and disappear, especially on removal of the primary growth. The tumor, even when in the uterus, may cease to grow and subside. The theories as to etiology have been discussed, but none has entirely explained the situation. Not only may the growth follow a normal delivery, but it may also develop after the expulsion of a hydatidiform mole, or it may follow an abortion. Scrapings from the uterus examined by the microscope will not make a diagnosis. The prognosis is grave, even when the uterus is removed, because metastases may occur even later.

Electrothermic Clamps in the Treatment of Cancer of the Uterus.—CHARLES P. NOBLE in 1902 had reported 4 instances in which he used the electrothermic cautery in performing hysterectomy for cancer of the uterus. In the present paper he reports 10 additional ones—all of the patients being unfavorable subjects for operation. His experience convinces him that the results are better after using the cautery. Its main disadvantage however is the increased danger of forming a fistula by injuring the ureters or bladder. This happened in several of his cases, but all but one of these has healed spontaneously. By even the best methods recurrence takes place in about 20% of the patients operated upon for malignant disease of the uterus. Early diagnosis and early operation are the hope for the future.

Discussion.—WILLIAM WALTHER has long held that radical operation yields no better results than the less radical, and the primary mortality is increased. He holds that attempted removal of the pelvic glands is impractical. CLARK favored radical and extensive operations if done by a competent man. The best results are poor enough, however; therefore, we should encourage the work of investigation now being done by certain men. MASSEY held to the parasitic nature of cancer, condemned cutting and cureting operations for malignant disease of the uterus, and favored the use of the cautery. LAWRENCE believes that high amputation of the cervix, followed by the use of the cautery, in cancer of the cervix, will give as good, or better, results than the more radical procedures. HUMISTON believes long duration of the anesthetic for radical operation is bad, and he therefore employs hypodermoclysis during such operations. GOLDSPOHN insisted that more of the

upper part of the vagina should be removed in hysterectomy for cervical cancer. CORDIER has abandoned the cutting operation for the cautery, and uses calcium carbide for cleansing and disinfecting the diseased area, following this with irrigations of potassium permanganate. CARSON held that the mere removal of a diseased uterus and the pelvic glands is practically useless when the disease has passed beyond the uterus. It has been shown in fatal cases that in only 13% of the cases were the pelvic glands involved, while in 87% glands in other parts of the body were diseased.

The Technic of Wounds Incident to Laparotomy.—H. O. MARCY (Boston) gave a historic review of the advent and the general employment of sutures and ligatures in surgery. Coming to more recent times he gave a review of the evolution of abdominal surgery as related to ovariectomy. He recounted various experiments he had made, many of them years ago, in regard to the asepsis of sutures and ligatures, and the proper closure of abdominal wounds. He was the first, in 1881, to close the peritoneum over the stump after abdominal hysterectomy, and he early insisted on covering all raw surfaces, within the abdominal cavity, with peritoneum. We should drain only in infected cases. He described in detail the proper closure of an abdominal wound, the main point being that similar structures should be approximated layer by layer. The skin is closed with a deep subcuticular suture and the wound healed by iodoform collodion. No bandage is employed unless the wound be very long or the patient vomiting.

Discussion.—GOLDSPOHN insisted that we are not sufficiently careful to reunite the fascia anterior to the rectus muscles. This is the one essential thing in reestablishing the strength of the abdominal wall. DORSEY insisted that no animal suture or ligature material can be certainly sterilized except it be of small size. He therefore uses fine catgut in all abdominal cases.

Appendiculoovarian Ligament.—D. H. CRAIG (Boston) said this structure had been much misunderstood. Its anatomy was dwelt upon at length. It is a band extending from the outer end of the broad ligament to the iliac region. Yet Clado and Durand described it as extending from the appendix or the mesoappendix to the upper part of the broad ligament. It is absent in a third of all female subjects, is somewhat inconstant in form, and has been much more discussed by the German and French than by Americans. It is in reality a fold or plica formed by the ovary in its descent from near the kidney, the upper part being obliterated by the descent of the cecum and colon. It should be called the extrapelvic portion of the suspensory ligament. If diseased it gives rise to chronic pain extending from McBurney's point into the pelvis. Several cases are reported illustrative of the author's explanations and deductions.

[To be continued.]

Section on Diseases of Children.

FIRST SESSION.

Address of the Chairman: The Demands of the Child by Virtue of Right.—CHARLES GILMORE KERLEY (New York City) emphasized the importance of good nutrition, cleanliness, exercise, and constant supervision in the rearing of children, since only by such methods can the highest type of individual be produced. Malnutrition is not due to lack of food so much as to improper food, and it is the office of the physician to teach the mother the most approved methods of infant feeding. Only 20% of the children over 1 year of age, coming under his observation in New York City, are of normal development. Heredity plays an insignificant part in the development of children. The strongest factor is the errors of nutrition, which greatly increase the susceptibility to disease. He then discussed the effect of this bodily weakness on the child's mentality, its resulting degeneracy leading to all sorts of crimes and misdemeanors, stating that in Great Britain physical degeneracy had become so prevalent that a royal commission had been appointed to look into the matter. Also the increasing use of alcohol by women was often given as a cause for this physical and mental defect. The poor and ignorant mother should be under the direction of the physician who thus becomes the guiding star of future generations, the most important member of the community in which he resides.

Erythema Nodosum in Children.—I. A. AET (Chicago) said that by many authorities it is considered one of the exanthematous fevers because of the high temperature and constitutional disturbance. It is especially liable to attack scrofulous children. There is great tenderness over the tibia and dorsal surface of the foot, rarely, the tongue and face being affected. It requires a week or 10 days for the nodule to complete its cycle, usually ending in necrosis and ulceration. Rheumatism was formerly considered a causative factor, the frequency of endocarditis suggesting its rheumatic nature.

Whoopingcough: A Study of 17 Cases Treated with the Elastic Belt.—THERON W. KILMER (New York) discussed very enthusiastically the application of this elastic abdominal belt and its almost miraculous effect in modifying the paroxysms and reducing the vomiting. He exhibited a number of charts showing the results of its application. He stated that the belt put the stomach and abdomen in a splint, as it were, and could also be used to control vomiting of pregnancy.

Discussion.—KERLEY spoke in high terms of the benefits resulting from the use of the belt. LOUIS FISCHER (New York) had employed the bandage for relief of paroxysms of whoopingcough. GILBERT (Louisville, Ky.) spoke of the induction of hernia by the use of the belt, but the speaker had seen no evidences of hernia from its use.

Some Clinical Observations on Malnutrition and its Relationship to Infantile Tuberculosis.—LOUIS FISCHER (New York) had made a careful study of 5,000 cases in the children of the poorer classes. In the great majority of these cases the many evidences of rickets were manifest. He stated that most of the rachitic manifestations could be attributed to faulty feeding, unsanitary surroundings and lack of sunshine and fresh air. In his study of some 800 nurseries very few of the breast-fed children acquired tuberculosis. He discussed the liability of these children to the acute infections, thus paving the way for tuberculosis. He spoke in detail of the transmission of tuberculosis by ingestion and inhalation and the effect of adenoids as a causative factor in pulmonary disease. Start the baby afloat by giving it breast milk, which may contain an immunizing serum, and plenty of fresh air and sunshine.

Discussion.—ABRAHAM JACOBI (New York) ably discussed the question. He said the danger of a tuberculous mother transmitting the disease to her offspring was not so much due to her milk as to the sputum spread by coughing, and inhaled or ingested by the nursing child. He did not believe in the theory of heredity, but recommended isolation of the child from the tuberculous mother and artificial feeding. He said that the milk from a herd of cows was much better than that of a single animal. The tubercle bacilli would pass through not only diseased, but healthy mucous membrane. Tubercle bacilli enter the nose and mouth and are absorbed, appearing in glands of the neck, from which they pass to the mediastinal glands, especially of the left side. CHARLES BROWNING (California) stated that the transmission of tuberculosis occurred oftentimes between six and eighteen months, when the child was frequently on the floor. When asked about the use of condensed milk, the speaker said it was about the poorest possible foundation for a child to start life upon.

[To be continued.]

Section on Ophthalmology.

FIRST SESSION.

Chairman's Address: Thoughts Suggested by a Study of the Eye Injuries of Independence Day.—ROBERT L. RANDOLPH (Baltimore) cites the mortality following this variety of traumatism as compared with other affections. As a means of preventing these injuries he suggested the passing of a law imposing a higher fine for the sale of explosives of this character. He incidentally referred to his efforts to bring this about in the city of Baltimore.

Treatment of Purulent Ophthalmia.—MYLES STANDISH (Boston) briefly reviewed the several characteristics of this disease, and laid great stress on the importance of bacteriologic examination as an aid to diagnosis. He mentioned the various microorganisms at times responsible for the affection, and then passed on to the consideration of the treatment as carried out by him at the Massachusetts Eye and Ear Infirmary. This consisted in gently but thoroughly cleansing the lids and conjunctivas with boric acid solution and the local application of the less irritating silver salts, especially protargol and argyrol. These he believes to be greatly superior to mercuric chlorid, silver nitrate, and other antiseptics, and quotes statistics of his own to prove these assertions. He believes that protargol is more valuable when there is corneal involvement. He sees no indication for the employment of cold in any stage of the disease, and believes it to be harmful, particularly in the stage of swelling.

Discussion.—CASEY A. WOOD (Chicago) said the irritating effects of the silver nitrate were its great drawback and that the tendency at the present period was to employ nonirritating applications in this disease with a view to prevent undue irritation of the cornea. He referred to the crying its application produced in children and said he considered the congestion following crying more than counterbalanced any good effect the drug might produce. He believes the judicious employment of cold of great value. Cleansing of the lids and conjunctivas by ordinary simple means is far superior to the perforated retractors and similar apparatus as the latter are capable of injuring the cornea. He prefers argyrol to protargol and thinks that it is somewhat anesthetic. He also employs hydragrist in collyrium alternating with argyrol. MAITLAND RAMSAY (Glasgow, Scotland) stated that in his experience purulent ophthalmia was a much rarer disease in Scotland than in this country. He considered cold to be of great help in relieving pain but acknowledged that it may also aid in the corneal destruction. A. W. CALHOUN (Atlanta, Ga.) spoke of argyrosis following long-continued use of protargol and stated that this danger was less with argyrol. In acute ulceration of the cornea from various causes he believes either in weak solution is curative. F. C. TODD (Minneapolis) stated that he used protargol and argyrol and preferred them to silver nitrate. He thought that the nursing should be considered in comparing cases of this character. In his experience, in which the same nursing was employed but different forms of local treatment, the argyrol

and protargol forms of treatment were most effective. He used protargol in one eye and argyrol in the other in one case and the eye in which protargol was employed progressed more rapidly toward recovery. He employs 50% solutions in glycerin. J. E. WEEKS (New York City) said that he washed the conjunctiva more thoroughly than Standish, but did not resort to perforated retractors and similar devices. He believed the new silver preparations to be very efficient and uses them in 35% solutions every two hours. Cold he believes to be useful in reducing temperature and inhibiting growth of microorganisms and when employed carefully is not harmful to the cornea, and usually makes the patient more comfortable. H. WOODS (Baltimore) urged ordinary cleanliness, avoiding instrumental means. Considering the comfort of the patient, he believes cold to be of value. He spoke favorably of argyrol, and noted 10 cases in children in which recovery occurred on an average of eight and a half days after beginning treatment. He uses it twice daily, and has noted no staining or irritation following its use. SEABROOK (New York City) uses cold for the swelling after cornea is involved, and questioned how cold could affect the corneal structure when it was unable to affect the bacteria in the lids, as shown by Standish. J. L. THOMPSON (Indianapolis) urged the use of the nonirritating forms of treatment, and referred briefly to an early case reported by Loring, in which the eye was lost from purulent ophthalmia. RITCHIE (Washington) said he prefers silver nitrate to other silver preparations, and believes it brings about constructive metamorphosis. PARK (Harrisburg) stated that he employed thorough washing of the eye every 30 minutes, and dusted nosophen after each irrigation. He prefers it to silver preparations, the best of which he thought to be silver nitrate. N. M. BLACK (Milwaukee) said he used protargol and argyrol in cod-liver-oil, and instilled them after irrigation. M. STEPHENSON (Akron, Ohio) called attention to the use of alphasol in ophthalmia neonatorum, 1 to 5,000, and 1 to 2,000. He never uses instruments to wash the eye, but instead employs cotton. L. CONNOR (Detroit) stated that he experimented with protargol and argyrol, and found argyrol the most effective. He also uses heat. He insists on thorough cleansing every five minutes. E. E. HOLT (Portland, Me.) believes cleanliness to be of greatest importance. He employs a Davidson syringe, and begins the irrigation at the external canthus. In closing the discussion, STANDISH stated he had never observed argyrosis following these preparations. As regards the use of cold, he believed the chemosis it induced injured the cornea. In response to the statement regarding the number of patients that get well without treatment, he said this was not borne out by the numerous patients he had seen in previous years with perforation and scarred corneas.

Postoperative Infection of the Eye.—J. A. WHITE (Richmond, Va.) discussed the causes of postoperative infection before and since the antiseptic period, and briefly mentioned the gradual decrease in frequency of this complication during recent years and the apparent reasons for this favorable reduction. From a study of the replies to a circular letter sent to various ophthalmic surgeons with a view of determining the percentage of infection after operation, he places the average percentage from 1% to 2%. He believes that the cause of infection is local and not systemic and reviews the various methods of ante and postoperative treatment. When infection has occurred he thinks the most rational treatment is to reopen the wound, fill the anterior chamber with 50% argyrol solution, and to cauterize the edges of the wound, employing the open method with irrigation of the culdesac. In preparing his patients for operation and also after operation he uses locally, mercuric chlorid in vaselin. He believes that by this procedure he obtains constant sterilization of the conjunctivas without irritation. He alternates it at times with aqueous solutions before operation, but prefers the unctuous medium. He then quoted statistics to support the use of mercuric chlorid in salve form.

Discussion.—S. D. RISLEY (Philadelphia) stated that the effect of the drug was of longer duration in unctuous medium, and thought that injury done to the eye by antiseptics was responsible for postoperative infection in large part, and therefore he avoids the use of mercuric chlorid preceding the operation. He uses either boric acid or normal salt solution in preference, taking great care to scrub carefully the edges of the lids with the solution. In a suspicious case of lacrimal or conjunctival disease he uses the alkaline solution, and dilates and irrigates the lacrimal canal and nasal duct. When infection occurs, he uses boric acid solution, normal salt solution, or even mercuric chlorid. He scrubs the lids and conjunctivas with cotton and the solution and applies a weak silver solution to the wound. He has not used modern silver salts, but employs silver nitrate, following it with normal salt solution. Frequently the infection results from unsuspected sources, such as the infecting particles in the expired air of the surgeon or bystanders and dust in the atmosphere of the room, set in motion by various causes. H. KNAPP (New York City) related cases of apparent infection following operation occurring in syphilitic, gonorrheal and traumatic cases in which the conjunctiva is swollen and a fibrinoid exudation is in the anterior chamber and vitreous, but there is no swelling of the lid. When there is actual infection from lacrimal disease he advises extirpation of the sac after the operation. If the disease is present and operation is contemplated the canaliculi should be ligated. He briefly referred to

a case of this character. ARD (Plainfield, N. J.) briefly referred to the condition of spongy iritis with spongy exudate in the vitreous following cataract extraction already discussed by Knapp. J. A. LIPPINCOTT (Pittsburg) cited cases of infection occurring in his early practice. He routinely used to cleanse the nose thoroughly before operation to prevent infection but has recently become an advocate of White's method with which he has had great success. He believed it to be the best method of disinfecting the conjunctiva and that the salve became dissolved in part and found its way into the lacrimal canals and nasal duct. E. E. HOLT (Portland, Me.) spoke favorably of White's method and uses it routinely with success. C. R. HOLMES (Cincinnati) stated that he refuses to operate for cataract in the presence of lacrimal disease unless he has extirpated the tear sac; he rejects attempts at cleansing of the conjunctiva in the absence of active inflammation. For irrigating purposes when necessary he employs boric acid solution and sterile water. V. T. CHURCHMAN (Charleston, S. C.) spoke very favorably of White's method and said he had used it with success. L. BORSCH (Philadelphia) laid great stress on cleansing of the eyelashes as well as the conjunctivas. He rejects strong antiseptic solutions and referred to De Wecker's treatment in using mercuric cyanid. F. PARKE LEWIS (Buffalo) remarked that he uses a weak protargol solution (3%) prior to the operation. He also made a plea for uniformity in the pronunciation of the word argyrol. In closing the discussion WHITE said the treatment after infection was extremely various. Some used 50% protargol under such circumstances every time the bandage was removed. He expressed great regret that the subject of how to treat the infection after it has occurred had not been more fully discussed. He believed that in all cases the eyelashes as well as the lids should be carefully scrubbed and the salve applied to them likewise.

[To be continued.]

Section on Nervous and Mental Diseases.

FIRST SESSION.

HOWELL T. PERSHING took the chair in place of F. SAVARY PEARCE, deceased. A committee was appointed to draw up resolutions expressing regret at the news of the death of the chairman of the section.

The report of committee on the Collection of Information regarding Public School Methods and their Effects on Mental and Physical Health of School Children, was given by W. J. HERDMAN (Ann Arbor, Mich.)

Symposium of Choreiform and Other Spasmodic Movements.

Symptomatology, Pathology, and Treatment of Choreiform Movements.—WM. G. SPILLER (Philadelphia) discussed these phases of Sydenham's chorea, Huntington's chorea, posthemiplegic chorea, and postapoplectic hemihypertonia. He also spoke of athetosis, chorea of pregnancy, the relation of chorea to Graves' disease, as well as the pathology of chorea, of which very little is known. Apropos of this, he referred to the chorea bodies (chorea-körperchen), a case of Rhein's, in which capillary hemorrhage into the cortex was observed, and distention of the perivascular spaces in the cortex in other cases.

Convulsive Tic.—HUGH T. PATRICK (Chicago) discussed under this heading the various muscular spasms, and especially torticollis. He emphasized the psychic element in cases of simple tic and torticollis. He believes that hypnotism plays an important part in the treatment of these cases, though the results often are indifferent.

Hysteric Movements.—HOWELL T. PERSHING (Denver) believes that the cause of these conditions can be found in some morbid process in the higher cortical center, and often some psychic origin can be traced. Chorea is frequently imitated by hysterics, as is also Jacksonian epilepsy.

Discussion was opened by MILLS, and continued by STERN, SINKLER, RHEIN, and others, and closed by SPILLER and PATRICK.

Tuberculosis of the Nervous System.—D. J. MCCARTHY based his conclusions upon a study of a large number of clinical cases and 68 autopsies. Meningitis, encephalitis, chronic infiltration tuberculosis, localized encapsulated tuberculosis (tyroma), tuberculosis of choroid plexus, and hydrocephalus, internal and external, were present. The spine, spinal cord and its meninges may be involved; there may be a myelomelalacia of vascular origin. He found atrophic degeneration, muscular dystrophy and myositis. The peripheral nerves may be diseased, due probably to a toxin, and beside there may be infiltration tuberculosis of the nerves. There were present in some of the cases cerebral asthenia, psychic manifestations resembling paresis, to which he gives the name paretic type of tuberculous insanity. Cephalalgia may be present from eye-strain or meningitis. In some cases the sympathetic system is involved; for example, transient symptoms of Graves' disease may be present. Then there may be hysteria, neurasthenia and various other forms of insanity. The paper was discussed by MILLS, SPILLER and DERGUM.

The Nature of Traumatic Sclerosis.—ARTHUR CONKLIN BRUSH (Brooklyn) reported the pathologic findings of five cases, showing numerous hemorrhages in the spine, edema,

infiltration of the bloodvessels, with secondary areas of sclerosis. The weight of evidence, in his opinion, is in the nature of a distinct organic entity. His conclusions support the contentions of Strümpell, that traumatic sclerosis and multiple sclerosis differ. He studied clinically 15 cases and discussed the literature.

The Present Campaign against Insanity.—W. J. HERDMAN (Ann Arbor, Mich.) referred to the advance which is being made in Europe and this country in the study of the various phases of insanity and their prospect of cure. In various institutions, work is being done along these lines in medical, chemic, pathologic, physiologic, and other laboratories. He looks upon psychotherapy as a very important agent, by which good results have been obtained.

The Dividing Line between Neuroses and Psychosis, and the Position of Neurasthenia.—RICHARD DEWEY (Wauwatosa, Wis.) believes no clear line exists, and approves of applying the word psychosis to conditions usually termed insanity, neurasthenia, and hysteria.

The Treatment of Aphasia by Training, with Some Remarks on the Reeducation of the Adult Brain.—CHAS. K. MILLS (Philadelphia) exhibited two cases, one of motor aphasia, the other sensory aphasia, who under reeducational methods showed great improvement. The method consists of training the patient to repeat small words at first, then to spell, read, and write them. It is important to teach the patient grammar. He exhibited a chart indicating what he termed a "physiologic alphabet." Cases of sensory aphasia are susceptible of more rapid improvement than cases of motor aphasia.

Discussion by BURR, HERDMAN, and SPILLER.

Dementia Præcox.—F. X. DERGUM (Philadelphia) divided these cases into hebephrenia, katatonia and dementia paranoides—in all cases there is first a period of depression, then expansion and finally progressive dementia. In katatonia there is added to these symptoms automatic and other motor symptoms. He thinks only cases that are associated with adolescence should be considered under this heading. The "Insanity of Adolescence" is a preferable name in his estimation.

[To be continued.]

Section on Pathology and Physiology.

FIRST SESSION.

The meetings of the section were opened on Tuesday afternoon at 2 o'clock, in Green's Hotel, by the address of the chairman, JOSEPH MACFARLAND (Philadelphia), on **The Relation of the Section on Pathology and Physiology to the Other Sections of the Association.** The chairman points in his brief address to the distinctively special nature of the section, and to the fact that it was designed for those papers which have less general interest to the profession at large. Its success does not depend upon the number of papers read, but upon the quality, and the best efforts of the members should be devoted to making the section an important and interesting part of the Association. The unusual program offered this year is in great part to be attributed to the efforts of the Secretary, Christian (Boston).

Will the Long-continued Administration of Digitalis Induce Cardiac Hypertrophy?—FRANK B. WYNN (Indianapolis) said that this experimental study was suggested by a case in which the patient had taken with marked benefit 45-m. doses of the tincture of digitalis four times daily over a long period. Failure of compensation came rapidly at last. The necropsy showed an extraordinary specimen of cor bovinum, which was demonstrated. To determine if the digitalis had influenced the hypertrophy, the drug was given to rabbits; doses of as high as 90 m. daily were given. The principal effect was to cause a loss of appetite, and a singular effect was noticed upon the character of the animals, making them cross and of carnivorous tendencies. After 120 days the animals were killed and the hearts compared with those of a parallel series of normal control animals. Wynn concluded from his experiments that a slight degree of cardiac hypertrophy was induced, but that the chief effect was an impairment of general nutrition.

Secondary Manifestations of Hypernephromas.—WALTER L. BIERRING and HENRY ALBERT (Iowa City). Bierring thinks that the Cohnheim theory of implantation is a satisfactory explanation of these growths. Those arising within the kidney are of the most malign type. Two classes of these tumors may be distinguished—those in which the cell type is that of the cortex, and those of medullary character. Five cases are reported, two of the medullary and three of the cortical type. Metastasis may occur through either the blood or the lymphatic circulation, though the bloodvessels form the usual channel. Metastasis might also occur along the urinary canal. Direct growth along the bloodvessels may take place, and also an implantation in the peritoneal cavity. Metastases usually occur in the lungs, liver, and in the bones. The tumors have the characteristics of both sarcomas and carcinomas, but are not to be classed with either group; they form a distinct group.

Discussion.—MACCALLUM (Baltimore) points out that the liver metastases cannot well be considered due to retrograde embolism, but are rather to be explained by assuming that particles of tumors have passed the wider capillaries of the

lungs, to become lodged in the liver. WYNN (Indianapolis) calls attention to the great frequency of supernumerary adrenals in cattle, and to the rather frequent occurrence of adrenal tumors in beef cattle. MACFARLAND (Philadelphia) thinks that his experience in postmortem work would not bear out the idea of Wynn, that supernumerary adrenals are of frequent occurrence. COPLIN (Philadelphia) has found only five cases of adrenal tumors in the 2,600 autopsy records at his command.

The Character of the Chromatophores.—LEO LOER (Philadelphia) has studied the chromatophores in a number of species of animals, bearing in mind the disputed question of the origin of these cells, and their relation to the origin of the nevi and the melanotic tumors. He concludes from his study, especially of the transplanted skin of guineapigs, that the chromatophores arise from ordinary epithelial cells; it is not unlikely that the melanin in these cells is the product of the action of some enzyme upon the cell proteins.

Report on the Metabolism of a Case of Diabetes Mellitus.—GRAHAM LUSK (New York). This patient presented a complete intolerance for carbohydrates, although there was little ammonia or acetone and no betaoxybutyric acid present in the urine. This finding is of no little practical interest, since it proves that the acidosis is not indicative of the condition of the patient, as is taught by many. When the patient was put upon a meat-fat diet the ratio between dextrose and nitrogen in the urine was 3.65 to 1. The ratio was not influenced by the amount of fat fed, and remained constant at different levels of proteid metabolism. The same ratio has been obtained for phloridized dogs; it represents a maximum production of sugar from proteid. It is a serious prognostic sign. The patient died five weeks after this ratio was determined. A lower ratio means that sugar can be burned by the organism. In other words, the question is not one of the amount of sugar in the urine, nor of the acidosis, but of the ratio between the excreted dextrose and nitrogen. The laboratory is the only proper place to determine the treatment of this class of patients.

Discussion.—HALL (Chicago) and VAUGHAN (Ann Arbor) advise the use of alcohol, and LUSK, in closing the discussion, considers alcohol a very valuable aid in the treatment of severe diabetes.

Regenerative Changes in Cirrhosis of the Liver.—W. G. MACCALLUM (Baltimore). The cirrhotic process is primarily a destruction of the liver cells; the growth of the connective tissue is purely secondary. The regeneration in this disease is parallel to that in the cases of acute yellow atrophy, where the subacute character of the case has furnished the opportunity for obtaining material; the regeneration may be one of two types, or probably both occur in the same organ, a regeneration from the intact liver cells, and a regeneration from the bile ducts.

Discussion.—LOER (Philadelphia), MACFARLAND (Philadelphia), ADLER (New York), and LIPMANN (New York), emphasize the importance of the regenerative processes which originate in the bile ducts, and the early stage and rapidity with which this reaction takes place.

The Relation of Chest Contour to Lung Capacity.—F. F. MALONE (Chicago), and **Mathematic Relations of Chest Dimensions.**—W. S. HALL (Chicago), were read by WINFIELD S. HALL (Chicago). These papers are the result of an endeavor to establish simple, yet definite, schemes of measurement, which would enable the physician, especially those interested in life assurance work, to determine the lung capacity, or the "vital balance" of the patient. After considerable experiment with various instruments, specially devised, Hall has decided that the simple pelvimeter, with a tape measure, is all the apparatus needed, and gives results of practical accuracy. The details of the process by which this conclusion was reached, and the exact methods of taking the measurements, must be consulted in the printed paper.

Notes on Vaccine.—CHARLES J. MCCLINTOCK (Detroit). These studies have collected, correlated, and verified, in part, a great portion of the mass of work which has been done on the vaccine bodies, the results of experimental vaccinia, etc. Among the most important conclusions are that guineapigs are the most satisfactory animals for such experiments, and that adults are more susceptible than young animals. Studies on the nature of the specific organism have borne negative results; all the organisms which have been described at various times as the specific cause of vaccinia, can be found, but none of them can be considered specific.

Discussion.—ROSENAU (Washington), BERGEY (Philadelphia), OHLMACHER (Gallipolis, O.), and MCCLINTOCK brought out the fact that all the agents which will sterilize vaccine virus will also attenuate it; all attempts at cultivation, either in the peritoneum or in artificial media, have been negative.

[To be continued.]

Section on Laryngology and Otology.

FIRST SESSION.

The meeting opened at 2 p.m. with an unusually large attendance both of the members who have been prominent in the section from the time of its foundation, and those of more recent affiliation, there being many who registered today

for the first time. Such growth of interest is gratifying and thoroughly in keeping with the timely and encouraging remarks of the chairman John F. Barnhill, in his opening address "The Present Status of Otology; How May We Improve It?"

Reflex Apnea and Cardiac Inhibition in Operations on the Respiratory Tract.—WILLIAM HARMAR GOOD and W. G. B. HARLAND (Philadelphia). Based especially on observations during adenoid operations and during intubation, in which cases of instant death are on record, they conclude that the origin of reflex apnea and cardiac inhibition is through the medulla by irritation of trifacial and sensory branches of the vagus; that inhibition may be caused by irritation of the mucosa of the nose, rhinopharynx, larynx, and lungs; that obstruction to respiration is indicated by cyanosis and full pulse, while reflex inhibition produces pallor and slow, weak pulse. Reflex inhibition differs from syncope in not causing distention of bloodvessels. Carbon dioxide starts respiration, and the consequent inflation of the lungs removes cardiac inhibition. In the prevention of inhibition care must be directed to the proper use of anesthetics, both local and general; atropin may be employed effectually. When the condition occurs, stop operation and use with vigor and persistence the usual methods for resuscitation, particularly tongue traction, lung inflation, and position of patient.

Tonsillectomy by Forceps and Snare, Thorough, Painless and Safe.—E. FLETCHER INGALLS (Chicago) states that the operation here proposed although practised for years and justifying the above title, is not generally familiar to physicians. In addition to an exhibition and description of instruments with a clear demonstration as to the manner of employment, he dealt at some length on the indications and contraindications for tonsillectomy, emphasizing the point that the pathologic condition of the tonsil structure and not its size must be the guide. In most cases the tonsil, not larger than an almond, does not need removal; but even when much smaller, if frequently inflamed, it should be extirpated. Points of advantage claimed for the snare method of removal are: 1. Abnormal distribution of arteries sometimes renders the ordinary tonsillotome dangerous. 2. After freeing adhesions—by an instrument which he devised for that purpose, the clamp forceps holds the tonsil in such position that the snare can be drawn around base, thus insuring complete removal—otherwise the operation would be futile. 3. Bleeding is not so profuse after removal with snare. 4. The snare may be gradually tightened so that the pain is very slight. For children he prefers general anesthesia. 5. The method is especially recommended for buried tonsils. The paper was freely discussed and generally approved for certain selective cases, by Casselberry, Stucky, Richards, Wood, Donnellan, Pyncheon and Freer. FREER exhibited a snare guard he had devised to prevent the wire loop from catching in the forceps.

The Significance of Tuberculous Deposits in the Tonsils.—GEORGE B. WOOD (Philadelphia). In an exhaustive study involving much original research, Wood deduced the following points of interest: Tuberculosis of the tonsils occurs secondarily in almost every case of advanced pulmonary involvement. It occurs as a primary infection in about 5% of all hyperplastic, faucial, and pharyngeal tonsils. Tubercle bacilli can probably pass through the tonsillar tissues into the lymphatics without causing any local disease in the tonsil itself, which goes to show how important may be the tonsillar structures as an etiologic factor in the production of tuberculous adenitis of the neck. While tuberculous adenitis in most cases is not followed by pulmonary tuberculosis, it must be remembered that experimentally the tubercle bacilli, when placed in small doses in any portion of the body, show a predilection for the apices of the lungs. A series of experiments was carried out on pigs, the tonsils of some of which were exhibited.

In the discussion which followed, by SWAIN, MYLES, PYNCHON, MAYER, and others, the author was highly commended for the thorough and painstaking line which he had followed in carrying out this most interesting research.

Operative Treatment of the Faucial Tonsils, with a View to Prevention of Cervical Adenitis and General Infection.—ROBERT C. MYLES (New York) states that while it is generally believed that the faucial tonsils are the usual portals of acute infection of the cervical glands, a point which is either entirely overlooked or at most given scant consideration by the average author, is that there is frequently a hidden chronic septic condition in the bottom of the cysts of the sub-merged or basic tonsils, which often escape what is considered a complete extirpation. He advises not only the removal of all cryptic tonsils, but further states that approximately complete extirpation of these basic lymphoid masses should be performed in all suspicious cases and the earlier in child-life, the better.

Discussion.—STUCKY stated that he believed in the radical operation, but not to the extent of removing every particle of tonsillar tissue, since small remnants will atrophy in many cases after the bulk of the tonsil is removed. PYNCHON emphasizes importance of after-treatment in cases where small points or remnants of tonsil may be reduced and depressions developed by "massage," which may help in the development of a smoothly-healed surface. TIDINGS expressed approval of the plan of tearing loose the adhesions instead of cutting.

Section on *Materia Medica*.

FIRST SESSION.

Chairman's Address: The Scourge of Nostrums and Irregular Practitioners.—OLIVER T. OSBORN (New Haven) believes all senators and representatives should receive copies of all resolutions passed by this body. He advises the election of a vice-chairman, to assist and substitute the chairman. He maintains that the strenuous life of the present day stimulates the use of hypnotics and sedatives, and encourages quackery and pseudopractitioners. The sale of alcohol in the last 20 or 25 years has been doubled. This is due to the growth of nostrums. Many foreign countries regulate and control the sale of patent medicines. He spoke of the amount of alcohol contained in many of the nostrums; for instance, Jamaica ginger contains about 90% of alcohol, and Lydia Pinkham's preparation contains 17%. He spoke of the effects of medical traditions; how they prevented fear and in that way did good. The chairman especially pointed out that individuals whose medical knowledge was very meager often met with great success, owing to their egotism. Their publications, although illiterate, had an extensive circulation. He pointed out many of the absurdities of Christian scientists and osteopaths; for instance, he says, Still, the founder of osteopathy, maintains that a fly-blister will do more good in smallpox than vaccine. Believers in Christian science, by constantly inhibiting this supposed science, deteriorate mentally until they become practically insane. He strongly urges war against eddyism.

Report of Committee on Proprietary Medicines.—Owing to the absence of MOODY (Alabama) the secretary read the report in which the committee recommended that the following medical articles be excluded: Those of secret composition, those of wrong composition, those possessing trade names, mixtures whose chemic composition is not described, those articles in which the quantities of the ingredients are not stated. By motion of COHEN the report was accepted, adopted and sent to the journal for publication.

Federal Supervision of Drugs.—HARVEY W. WILEY (Washington, D. C.) stated that the act for the regulation of the importation of drugs was passed in 1848. According to this act the drugs coming from England, Scotland and France should be judged from the pharmacopoeias of the country from which they came, while those drugs coming from any other country should be judged from the U. S. Pharmacopoeia. The Bureau of Chemistry of the department of agriculture, examines the drugs both domestic and foreign to prevent fraud and adulteration. Attempts are being made to introduce into this country plants of all drugs that will flourish here. After these drugs are introduced and grown in this country their nature is carefully examined, since it has been found that if a plant is taken from its natural habitat and grown in new countries its nature changes, sometimes becomes decidedly inferior in quality. The Postmaster-General cooperates with the Agriculture Department in the effort to suppress fraud and adulteration in drugs by preventing the transmission in the mails of the products of fraudulent and adulterating establishments. If, says Wiley, the postmaster is sustained, these people will be annihilated.

The Eighth Decennial Revision of the Pharmacopoeia of U. S. A.—JOSEPH P. REMINGTON, (Philadelphia) says only such drugs as have been tried clinically will be placed in the pharmacopoeia which is to appear in October next. He believes that the druggists, who make cheapness rather than purity of drugs their object, should be punished. The pharmacopoeia calls for certain tests to be applicable to certain drugs but states specifically that these tests are to be applied to those which are used as medicines only. He spoke of the attempts that have been made to adopt an international pharmacopoeia. Remington believes the failure of adoption is due to the fact that each nation has been accustomed to use drugs with which its members are most familiar so that one is more inclined to put more value upon one drug than is another, consequently disagreement constantly arose and no international pharmacopoeia. The United States is the first nation to endorse the international pharmacopoeia suggested at Brussels. Here many of the official preparations are of inferior strength than of the United States pharmacopoeia, but attention is called to this so that the dose will be necessarily increased correspondingly. Such drugs as "carbolic acid" will receive their proper names but the old ones will be retained as synonyms. Synonyms are discouraged. Average doses are given as they are thought to be of more value than maximum doses. Definite chemic names are used.

The Relation of Physicians to Proprietary Remedies. How May Substitution Be Avoided and the Desired Preparation Obtained without Unduly Advertising the Manufacturers?—WILLIAM J. ROBINSON (New York City) divides physicians into three groups. Those in group A prescribe anything that comes to their knowledge. B comprises a group that is extremely conservative and never uses proprietary medicines. At this point he differentiated between patent medicines and nostrums. Patent medicines are not secrets, they must be fully described and the chemistry of their ingredients be stated so that anyone can make the remedy after the time limit of their patent right expires. Nostrums are of secret composition and are monopolized forever. He believes the time will come when the government will buy all useful inventions and turn them over to the public free. Robinson

also believes that men who have spent their time and energy to work out something new should be protected by a patent as a compensation for their labor. He then described the physicians in group C as being investigators who want to know about new drugs. They give those drugs which are put out by first-class manufacturers a trial. He believes substitution is largely due to the fact that the physician is unfamiliar with preparations, and to a certain extent in not keeping strict watch upon the prescriptions put up and sent to patients. Druggists who know they are being watched do not substitute. If the physician knows of a druggist that is reliable and in whom he has confidence there is, in Robinson's opinion, no objection to encouraging his patients to patronize that particular druggist, and when he cannot trust the druggist the physician is perfectly justified in prescribing in original packages.

Discussion.—H. C. WOOD, JR. (Philadelphia) said that to oust the nostrums the matter must be placed and remain in the hands of the government. The political influence of these manufacturers should be counteracted by the influence of physicians. PORTER (Indianapolis) believes the chief instigator of substitution is the practice of prescribing proprietary medicines. In the Indianapolis County Medical Society proprietary medicines are not mentioned in their meeting, in the papers read, and are also not published in the journal. LOW (Philadelphia) said that in his opinion the students in medical colleges are not thoroughly drilled in prescription writing, therefore when they graduate and practise medicine they prescribe proprietary medicine because they cannot write others. BEATES (Philadelphia) said the proprietary medicine manufacturer thrives because physicians prescribe such medicines, and they do so because they lack knowledge of physiology and morbid physiology. WESCOTT (Atlantic City) suggests that the sale of sulfonal, trional, chlorotone and other hypnotics be controlled by the physician. He is not an advocate of the sale of original packages. KOENIG (Pittsburg) believes there is a defect in the teaching of materia medica. Editors of medical journals should eliminate from their advertisements all proprietary medicines. SCHWEITZER (New York) maintains that large manufacturers and inventors of patent medicines should be protected by patents to compensate the men they have engaged to determine the drug. He thinks there are many proprietary drugs which cannot be substituted by drugs in the pharmacopoeia. The chairman, in answer to Low's criticism of medical colleges, says the students are well trained in prescription making, but owing to hospital formulas they forget. WILLARD (Philadelphia) states if hospitals employed competent druggists, hospital formulas would be dispensed with. In closing the discussion WILEY said many nostrums were composed of sugar and starch and colored with an anilin dye. REMINGTON is greatly opposed to patenting of medicines. ROBINSON principally reasserts what he said in his paper. But he does believe that the physician can not use chemic names in his prescriptions.

[To be continued.]

Section on Cutaneous Medicine and Surgery.

FIRST SESSION.

Developmental Defects of the Skin, and Their Malignant Growths.—H. G. ANTHONY (Chicago) described nevus. The word should be used for clinical convenience. He gave instances of developmental defects and their characteristics. In his opinion developmental defects are results of embryonic displacement of cells; the symptoms are due to amount of cells displaced. Unna found that fibroma molluscum was simply a nevus. Among malignant growths developing with nevus, the most frequent is the so-called nevocarcinoma; melanosis is not always pathognomonic of malignancy. Nervous shock may cause nevi; he cites a case due to shock caused by report of suicide of a relative. Nevocarcinoma has distinct features of its own; it is not so with other malignant growths.

Discussion.—FORDYCE (New York) says that benign cystic epitheliomas are not always multiple, but are found single very frequently. RAVOGLI (Cincinnati) has had several cases of nevocarcinoma, two pigmented and two unpigmented, in his own practice, which proved fatal. He says we should look upon the condition more in the light of a tuberculous malady. CORLETT (Cleveland) says the term should be limited to a looseness of epithelial tissues. HEIDINGSFELD thinks that Anthony is taking a step back when stating that nevi is always of prenatal development. MONTGOMERY (San Francisco) believes that slate-colored nevi are more malignant than the buff-colored ones. The former are more likely to become metastatic. ANTHONY, in closing, thinks that 90% of all persons have nevi of some sort.

Falling of the Hair.—R. A. McDONNELL (New Haven, Conn.) said that premature baldness is becoming more and more frequent. Very little is known of this condition. Seborrhea of the scalp is the greatest cause. Sanitary barber shops would be a great step in diminishing the disease. Exposure (continued) to light is not an infrequent etiologic factor. Hair tonics and too frequent washing of the head are responsible for a great many bald heads. He described a method of treatment of the condition. Heredity plays an important role in causing, as do gastrointestinal derangements and acute infectious diseases. The alopecia of specific disease rarely lasts longer than a few months.

Discussion.—L. WEISS (New York) reported a case of acquired syphilis in a physician who had alopecia areata but recovered in three months. Cox (Harlem) emphasizes the fact that the röntgen ray is a frequent cause of baldness, he warns members of the dangers of the use of röntgen ray in the scalp region.

Report of a Case of Paget's Disease of the Gluteal Region.—JOHN A. FORDYCE (New York City) said that the patient dates the trouble to seven years previous, when she received a wound in the gluteal region. Symptoms did not appear until one year after injury. She was treated with röntgen ray but treatment was abandoned because of suppuration; it was resumed later. The wound was dressed with aristol. He outlined the pathologic histology of the disease, comparing it with Paget's disease of the nipple. In Paget's disease of the nipple there is no epitheliomatous condition.

Discussion.—STELWAGON (Philadelphia) had a case of Paget's disease of the nose and it resembled epithelioma very minutely. PUSEY (Chicago) saw two cases of Paget's disease of the nipple and says a characteristic dermatitis was present. He says that operation is by far better treatment than the röntgen ray.

Radium and Its Therapeutic Possibility.—WM. A. PUSEY (Chicago) said that actual facts regarding radium are quite meager. He described radium minutely, showing the definite actinic properties of the different rays. Radium, he says, gives off gas, heat and electricity. Thus far the gaseous emanation has no therapeutic value. The beta and gamma rays are the only ones which have proved of any note in therapeutics. Radium burns do not differ in any way from those of the röntgen ray. Radium has been found to have a distinct bactericidal effect. The result of treatment of lupus and other skin diseases by radium is analogous to that of the röntgen ray, perhaps the former is slightly more rapid. Pusey believes that radium is most effective in growths situated deeply. No doubt on account of its easy method of handling, radium will become more popular than the röntgen ray. He summarizes some of the cutaneous diseases in which radium will have a large field of usefulness.

Discussion.—SCHAMBERG (Philadelphia) said that radium was employed in the Polyclinic Hospital of Philadelphia in but one case with distinct beneficial result. He believes that the field of usefulness of radium is extremely limited.

Linear Nevi.—M. L. HEIDINGSFELD (Cincinnati) claims it is unfortunate that this condition is not classified as a type of affection having a distinct entity of its own. He reports three cases. Most linear nevi are congenital or develop shortly after birth. Linear nevi are usually unilateral; they dispose to follow nerve distribution. Various authors have seen cases of undoubted linear nevi and have erroneously reported them as lichen planus and like affections. Dermatologists, he says, should strive to obtain a more definite classification of all skin diseases.

A Typical Case of Xanthoma.—J. V. SHOEMAKER (Philadelphia) exhibited this case, giving the clinical history, description, and situation of the lesions. It occurred in a boy of 12, who appears to be 18 years of age. Lesions are found all over the body, even extending to the buccal cavity. The boy is cadaveric in appearance. Shoemaker has little hope of benefiting the patient; he has had all sorts of drugs with little or no effect. Nitrohydrochloric acid in small doses made the best impression, although even this in time became inefficacious.

Discussion.—PUSEY has seen such a case, which was benefited by the administration of arsenic. LIEBERTHAL (Chicago) said that in all cases of infantile xanthoma the affections did not extend to the eyelid. He believes that there is always an underlying internal condition. SMITH (Philadelphia) says that in examining the case the liver and spleen were found very much enlarged.

Treatment of Hyperidrosis, Especially of Hyperidrosis Pedum.—L. WEISS (New York City) said the etiology is not clear in every case. Unhygienic clothing as well as diet are important causes. Palmar hyperidrosis, he says, is least obnoxious. Dietetic treatment should be considered first. The potassium permanganate solution used as a wash has been proved a most effective remedy. Weiss details a mode of foot bath which he employs in these cases. He concludes with saying that the potassium permanganate treatment is a harmless and not an unpleasant one.

Discussion.—HAY (Hot Springs) has used salicylic acid in alcohol in hyperidrosis pedum in a number of cases with very few failures.

[To be continued.]

Section of Hygiene and Sanitary Science.

FIRST SESSION.

The address of the chairman, GARDNER T. SWARTS (Providence) was entitled **The Relation of the Physician to Sanitation**. He described the professional organizations of national scope whose purpose is to consider matters of practical hygiene—the American Public Health Association, the Conference of State and Provincial Boards of Health of North America, and the Annual Conference of Official Hygienists—called under the provisions of federal statute by the Surgeon-General of the U. S. Public Health and Marine-Hospital Service. These pro-

vide for the practical needs of administrative health officers, and of those who are engaged in public health laboratories or upon large sanitary works. The Section of Hygiene and Sanitary Science of the American Medical Association offers the only ground upon which professional relations to matters of public sanitation can be freely and profitably discussed. Swarts commented on the too prevalent ignorance of the medical profession concerning public hygiene, professional knowledge of the subject being in general little if at all superior to that of the intelligent lay public. This ignorance keeps alive many of the popular delusions concerning the propagation of communicable diseases. It is due primarily to faulty training in the medical schools, and after that to the indifference of the medical practitioner toward the whole subject of hygiene. The interests of the average business man in a large sanitary undertaking as a water-supply or a sewage system is often indeed keener and more intelligent than that of the average medical practitioner. The half informed or misinformed physician puts groundless fears into the minds of his patients where no ground for fear exists, and causes them to trust in saucers of chlorinated lime and other absurdities when real danger is present. The selfish or faint-hearted doctor seeks to conceal from Boards of Health information which is essential not alone to public safety, but to the directly helpful relations which Boards of Health seek to establish with infected households. Even in his death certificates he is sometimes a prevaricator or at best a careless recorder, not realizing that he is making the statistics which he may at some time consult to his own confusion. In such matters as food and drink, even their own food and drink, physicians do not often discriminate as they might with the superior knowledge imputed to them. In a matter as important as a milk supply many intelligent laymen are wiser and more practical than the rank and file of medical men. Excluding the pediatricists, the best posted men upon this subject are not physicians, but men of adventure, who derive, perhaps, some amusement, and certainly some profit, from their advantage over the medical man. It is largely due to the indifference of medical men that so very insignificant a portion of the country can at present give a reliable account of its mortality. The registration of births and deaths receives from the medical profession only an inactive support, though vital statistics are a necessary part of the data of medical science.

SECOND SESSION.

Symposium on the Venereal Diseases.

LUDWIG WEISS (New York) read the second annual report of the **Committee on Prophylaxis of Venereal Diseases**, giving the results of the committee's investigations into the present status of the subject in this country and in Europe. The hospital accommodations for venereal patients in this country are found to be very inadequate; the idea of reglementation is not likely to find favor in America, that prostitution is absolutely ignored in the laws and ordinances of American States and cities, and that the only means of inaugurating an active campaign against the venereal diseases is, in the opinion of the committee, a national society for combating the venereal diseases. The committee gave notice that it would undertake the formation of such a society, with the hope of holding at some not distant date a congress similar to the recent international congress at Brussels.

What is the Right Attitude of the Medical Profession toward the Problem of Venereal Diseases?—HOWARD A. KELLY (Baltimore) maintained that a hopeful approach to the solution of this problem could not be made except upon moral grounds. He declared that the state of those countries where the effort to control these evils proceeds upon the prevalent dual standards of sexual morality is in no wise encouraging. On the contrary he said that those countries who have gone farthest upon this treacherous path are nearest the foul pit in which all past civilizations have perished. The double standard, he declared is the device of cowardice. The responsibility is upon every intelligent man, but more heavy upon those who pursue the professions to uphold public morals, to turn from the futile and dying regime of indifference and to undertake "an active crusade inspired by a profound sense of personal responsibility." We cannot afford to be "practical" at the sacrifice of principle, and must stand firm at all cost against the debasement of public standards of right. No matter what cataclysm may overtake our children or our children's children, never must it be said that in this day of enlightenment the public standards of right were debased. This is the difficult path, for instead of shifting the responsibility by asking the passage of a law it places the responsibility where it belongs, on the shoulders of every man and woman in the country.

Syphilis as an Innocent Disease.—L. DUNCAN BULKLEY (New York) emphasized the important relations of syphilis to morbidity and mortality among those who are not sexual transgressors. Bulkley introduced the following resolution, which was passed.

The conjoint meeting under the auspices of the Committee on Prophylaxis of Venereal Diseases of the American Medical Association recommends to the House of Delegates the following preamble and resolution, urging their adoption and wide circulation:

WHEREAS, Syphilis and gonorrhea have been abundantly shown to be the cause of incalculable damage and danger to the health and life of the community, both among the innocent and those guilty of sexual transgression; therefore, be it *Resolved*, That the American Medical Association earnestly call the attention of the profession to the matter, and urge that Boards of Health throughout the country give serious attention to the same, with a view to securing proper protection against these diseases by legal measures.

Syphilis Affecting Infant Mortality.—HENRY ENOS TULEY (Louisville, Ky.) placed syphilis second in the list of causes of premature birth, second only to criminal abortion. The direct mortality of syphilis in infancy is as great as that of any other disease. Unlike gonorrhea, syphilis does not deprive men and women of the power to procreate, but it robs offspring of the ability to become in their turn men and women. The comparative influence of paternal and maternal syphilis upon the children was discussed, closing with the observation of Morrow that syphilis is "not only a factor in depopulation, but a cause of degeneration of the race. It is the quality of expansiveness, this capacity of morbid irradiation through family and social life, that gives to syphilis its superior significance as a social danger."

The Effects of Gonorrhea on the Female Generative Organs.—JOSEPH TABER JOHNSON (Washington, D. C.) placed gonorrhea ahead of all other diseases as a cause, either direct or indirect, of mortality and of mutilation. It sterilizes the whole class of prostitutes; it invades lawful wedlock, and sterilizes chaste women; it is vastly more prevalent than syphilis, and a larger factor in depopulation. It often extinguishes the reproductive power of a woman in one pregnancy, it is but little inferior to syphilis as a cause of abortion, and is coming into prominence as a cause of ectopic gestation. The committee of the American Medical Association appointed in 1901 for the collective investigation of statistics upon the dangers of gonorrhea, found that of the pelvic inflammations necessitating abdominal operations upon women, 40% were due to gonorrhea. This takes no account of the large number of women who drag out an invalid existence without seeking the aid of surgery.

[To be continued.]

AMERICAN ACADEMY OF MEDICINE.

Twenty-ninth Annual Session, Atlantic City, N. J., June 4 and 6, 1904.

[Specially reported for *American Medicine*.]

Report of the Council on the paper of H. Bert Ellis, of Los Angeles, Cal., on "Necessity for a National Bureau of Medicines and Foods." This paper was read at the meeting held at Washington, May 11, 1903, and was referred to the council of the Academy for action at the present meeting. It was published in the Bulletin of December last. The proposition suggests a commission of certification for several diverse classes of products, which may be divided into three groups: 1. Professionally medicinal preparations. 2. Preparations of vague composition. 3. Food products. The council recommends that food products be omitted, on account of the difficulty of limiting the articles to be certified, and also to exclude from such a commission consideration of any and all preparations whose complete formula is not furnished. With these limitations the objections to such a commission are (a) the work necessary to carry out the scheme properly; (b) the work to be effective and above suspicion must be performed by members of the commission and not by subordinates; this would require large salaries to secure capable men; (c) the danger of self-seekers for the appointment if salary is attractive; (d) the difficulty of meeting the expenses of the commission. Funds would have to be derived from those benefited, i. e., the large manufacturers of the various products examined. In conclusion the council reports that notwithstanding its commendation of the abstract proposition embodied in the paper, as at present developed it is fraught with too many difficulties to be employed satisfactorily, beside being open to the dangers of great abuse. Further thought and consideration must be given to the plan with the hope of working it out thoroughly.

On motion of Corss, of Pennsylvania, that the suggestions of the council be adopted, Ellis, of California, seconded the motion, stating that he could not see that the council could have acted otherwise, although something should and must be done in the matter in order to relieve the busy practitioner from an investigation of the great masses of patent medicines, proprietary medicines and incorrectly made drugs or preparations of drugs. Connor, of Michigan suggested that such a commission could be appointed to serve without pay and to use laboratories already existing or established. The object of the commission would be to secure facts and give publicity. If such a plan were carried out he predicted a large increase in the membership from those physicians who are not affiliated with the organization, as it would enable the offering of something as an inducement to nonmembers. Jones, secretary of the joint committee of medicines and foods, A.M.A. and A.Ph.A. stated that this plan had now been under discussion for two years, and the committees appointed from the two associations had brought

forth the plan as suggested in the paper of Ellis. The conclusion was that the work should be done by a private corporation as it is done in England, Mexico, France, and several other countries. This would take the matter entirely out of control of government and politics, without commercial strings or relations. The paper did not attempt to outline the details of the scheme; that would be a future consideration. The joint committee reached the unanimous conclusion that it would not be practicable to condemn by published statements or inference, but to certify to those products which attain the standards that may be established by the bureau and the United States Government departments, which is another fundamental part of the plan. There would be no question of partiality, as all manufacturers who have a proper preparation could have their goods certified. After consulting with a large number of the better manufacturers, the majority were found to be in favor of such a plan and would welcome it, while a few from purely selfish motives are opposed to it on the ground that it would sacrifice vast amounts of money which they have expended in building up a trade in their products. The report of the council was adopted.

The Results of the State Examination for Medical Licensure, 1903.—The secretary, MCINTIRE (Easton, Pa.), said that it is impossible as early as June to give a complete report of the examinations for 1903, as some of the reports are not out until later, and in some States it is almost impossible to obtain reports at all. The report this year covers 26 States, which show a total of 2,478 licenses issued, and 445 refused, making a total of 2,923 applicants. The report then gave in detail the number of applicants, licenses issued, and refusals in each State. GROSVENOR suggested that it would be a good addition to the report to give percentages, in addition to the figures, and moved that McIntire be authorized to publish the report in the bulletin as the proceeding of the Academy, with the percentages. The motion was adopted.

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-ninth Annual Meeting, Held in Boston, Mass., May 24, 25, and 26, 1904.

• [Specially reported for *American Medicine*.]

[Continued from page 885.]

Uniformity in Pelvic and Cranial Measurements.—A. F. A. KING (Washington, D. C.) reached the following conclusions: (1) That at present the measurements of the normal pelvis and fetal head are indefinite and unsettled, and must continue so to be, so long as they are determined by our present methods of mensuration; (2) the chief purpose in obtaining the normal dimensions of these structures being for teaching and learning the normal mechanism of labor, it is proposed to adopt an ideal or hypothetical head and pelvis upon the dimensions of which all authorities may agree; (3) in the adoption of such ideal measures it is unnecessary and undesirable to define any measurements with exact precision—no fraction smaller than a fourth of an inch, or than half a centimeter, in the metric system, being required; (4) race variation forms no real obstacle to the proposed plan, and other apparent difficulties can be overcome. Finally, should the proposition meet with approval, it was suggested by the author that the society take the initiative in bringing the matter in proper form before some forthcoming international medical congress for general adoption. Accordingly, a committee was appointed by the president to consider the matter of uniformity in pelvic and cranial measurements, and report at the next annual meeting.

Symposium of Nonoperative Local Treatment in Gynecology.—WILLIS E. FORD (Utica, N. Y.) in reading the first paper, said that no one would deny that greater good had come from surgical treatment of diseases peculiar to women than was ever dreamed of by the early gynecologists, who did not operate. No comparison of results could be made. He did not think it was true, however, that the specialty ought to become purely surgical. Pathology learned by pelvic and abdominal surgery ought to be clearer and better than was ever discovered postmortem. It was fair to assume that men who did this work had a better idea of the natural history, progress, and dangers of these diseases than those who did not operate, and that the early treatment ought to be in the hands of men who are also doing surgical work. That the nervous habit could not be cured by surgery had been proved by the fact that the removal of diseased ovaries, and such like operations on epileptic women, had not cured the epilepsy or neurasthenia. The argument, therefore, was that in those ailments that tended to disturb the emotions, especially those of the reproductive organs of men or women, the serious thing was not the pain experienced, but the permanent invalidism which was brought about by the protracted local sensations, that in time disturbed the mental equilibrium and brought about the individual habit. These local irritations ought to be treated by skilled gynecologists, and not allowed to develop either the mental or physical ailments which were so common a result.

TUBERCULOUS PERICARDITIS, WITH REPORT OF CASES.*

BY

CHARLES G. STOCKTON, M.D.,
of Buffalo, N. Y.

Tuberculosis has naturally been accepted as a cause of pericarditis and the frequency of its occurrence has been urged by Osler.¹ Beverley Robinson² and others regard it as a comparatively rare affection. This difference in view probably depends upon the fact that the tuberculous lesions are sometimes not easily discovered. The gross appearances of the pathologic specimens are sometimes not unlike that of rheumatic or other forms of the disease, but when submitted to the test of bacterial investigation, a proportion of cases regarded as simple pericarditis, whatever that term may mean, will turn out to have the essential cause in tuberculosis. The cases differ widely in character, not only in clinical manifestations, but in the lesions. It may occur as an acute disease with abrupt and severe invasion, terminating in a few weeks, as illustrated in the first case which I report, or as a chronic process it may continue for many months, as in the third case. It may show itself as a dry plastic pericarditis without fluid effusion, or the effusion may be massive with little plastic element in the exudate, as illustrated in the second case. Frequently the exudate is sanguinolent, as exemplified in two of my cases, and Musser³ reports a case in which there were two liters of nearly pure blood. Rarely the exudate is purulent. Again, there is an obliteration of the pericardial sac as the result of dense adhesions, as in the third case. Sometimes the sac is enormously thickened, partly by plastic exudate, partly by masses of caseous material and, in the words of Merklen,⁴ looks as though covered with a cuirass. Calcareous degeneration is also seen, and the typical hirsute state or "hairy heart" is sometimes found, as shown in the first case. Riesman has lately reported a case of primary tuberculous pericarditis, although, as in my first case, an old pulmonary lesion was discovered. Usually the disease is secondary, although not infrequently the lesions extraneous to the pericardium are inconspicuous. That which is most often found is caseous degeneration of the bronchial lymph-glands and other mediastinal structures; however, tuberculous pleurisy, pulmonary tuberculosis, general tuberculous adenitis, peritonitis, osteitis, or other tuberculous lesions may be the primary focus from which the pericardium becomes invaded. A remarkable fact is the frequency with which the pleural effusion occurs as an accompaniment in the disease, and ancient adhesions indicate antecedent pleuritis. The first case reported might, in a clinical sense, to adopt Riesman's phraseology, be considered an instance of primary tuberculous pericarditis, yet the accompanying laryngitis and the old tuberculous focus in the lung lead to the conclusion that it was, strictly speaking, secondary.

CASE I.—The patient was under the joint care of Dr. Jones and myself.

J. U., aged 71, retired business man, German by birth, five feet eight inches high, well developed. The family history is unimportant, although tuberculosis has not been known to exist in the family. For the past five or six years he had complained of an irritable heart. It was sometimes arrhythmic, and in general presented the manifestations of functional cardiac disturbance in a somewhat neurotic, but very well-preserved man of advanced years. The heart was thought to be slightly dilated, the myocardium moderately degenerated, but on the whole, it was regarded as possessing good strength, considering the age of the patient. The other organs appeared to be in good condition. The patient had always led a hygienic life, took excellent care of himself, and seemed destined to live to an advanced age. Three years ago he had a severe, acute, dry pleurisy of the right side, accompanied by extreme pain,

followed by abundant fibrinous exudate, but there was no evidence of fluid. He made a prompt and complete recovery, save occasional twinges of pain, apparently depending upon adhesions. Two and a half years later, in August, 1903, while rusting in northern Michigan, he had some illness, the nature of which is uncertain, but which appears to have been located in the thorax. Two months subsequently I examined the patient's chest, and found nothing unusual in the physical signs. In the middle of February last, the patient suffered from chilliness and sudden rise in temperature, a feeling of great weakness, with pain in the extremities, and insomnia. It was found that, unknown to his physician, he had for the last four or five years taken 1.3 gm. (20 gr.) of sulfonal each night, without which he found himself unable to sleep. Apparently this large dosage produced no untoward symptoms. He showed slight laryngeal irritation and reported that he had recently been treated for his throat by Dr. W. S. Renner, laryngologist, who found merely an irritable larynx. A careful examination revealed no reason for the present illness. For five or six days the temperature ranged from 102° to 103°; the respirations were not increased in frequency; there were no physical signs to be found in the chest, abdomen or other regions. He was evidently seriously ill. A blood-examination showed 5,200,000 red cells; hemoglobin, 85%; white cells, 5,400; polymorphous cells, 73%.

Showing the pericardium in the first case, acute tuberculous pericarditis.

On the sixth day there were heard for the first time distinct pericardial friction sounds; there was also a dull aching over the precordium and slight tenderness there upon deep pressure. The liver was enlarged, the lower border two or three fingers' breadth below the ribs. The urine was abundant and contained an unusual amount of urea, from 28 gm. to 35 gm. in 24 hours. There was a slight trace of albumin, a few hyaline, and an occasional finely granular cast. The patient took liquid nourishment well; but sleep was disturbed, owing to the withdrawal of sulfonal. This embarrassment, however, was soon overcome. The pericardial friction continued during the second week, and very soon there was an increase of the area of cardiac dullness, particularly in the second and third interspaces. The friction sound then became less evident, and it was assumed that an effusion of pericardial fluid had occurred. At the end of the second week there was diminished breathing in the lower part of the left lung posteriorly, with some increase in the voice sounds, and dullness upon percussion. The respirations were 24, there was no cough, nor other symptoms of pulmonary involvement. In the beginning of the third week there was a distinct onset of pleurisy on the left side, accompanied by a good deal of pain and marked respiratory friction sound. After 48 hours there were the physical signs of fluid, extending upward to the angle of the

* Read before the Wayne County Medical Society, Detroit, Mich., April 28, 1904.

scapula, and yet evidences of pulmonary retraction were more marked than could be accounted for by the fluid, apparently resulting from the pressure of the distended pericardium upon the lung, which latter was believed to be adherent, preventing its retreat upward. Three days later there was a severe right-sided pleurisy, with very loud friction sound, and also extensive perihepatitis. The respirations had increased to 28 a minute, and it was thought well to aspirate the left pleural cavity, from which was withdrawn 900 cc. of straw-colored fluid. Considerable relief was afforded the patient, but two or three days later there was a fresh attack of the pleurisy on the left side, accompanied by increased constitutional symptoms. The pericardial friction sound at times disappeared, but recurred, although never so loud as in the beginning of the illness. At the end of the fourth week precordial dullness extended midway between the sternum and the nipple line on the right side, left of the nipple line on the left side, and was remarkable in the second and third interspaces. Traube's space remained resonant, and apparently the pericardial effusion did not extend downward, but upward. We could find no point along the lower border of the pericardium at which it was deemed safe to introduce an exploratory needle, for the reason that the heart sounds could be heard and the heart movement palpated at a point corresponding with the lower border of precordial dullness. The patient's general condition at the end of the fourth week was very well maintained. There occurred a slight thrombophlebitis of the left femoral, with edema of the left lower extremity, accompanied by the usual local, but no constitutional symptoms. The heart required stimulation by strychnin and strophanthin in small doses. After consultation with Dr. Cary, it was decided to use moderate portions of brandy. At this time the patient was visited by Dr. F. S. Dennis, of New York. We now began to give a certain amount of solid food, because liquids irritated the larynx and led to coughing, and the patient had raised from the larynx a considerable amount of clear mucus. This now became mucopurulent, viscid, and contained a moderate number of streptococci and tubercle bacilli. On the fifth week the left pleural cavity was again aspirated, and 600 cc. of fluid was withdrawn. This process was repeated after three days, and a still smaller amount, 500 cc., withdrawn; each time the patient was relieved by the procedure. A week later it was apparent that there was fluid in the right as well as left pleural cavity, but only 20 cc. or 30 cc. was found in the right side, and about 250 cc. in the left. The evidences of pressure, or as some believed, the consolidation of the left lung, continued. The physical signs were really those of pressure rather than of consolidation. The blood now showed 4,800,000 red cells, 10,400 whites, 78% hemoglobin, 78% of polynuclear neutrophils. The whole process was now regarded as tuberculous, and was so declared. During the fifth and sixth weeks there were evidences of hypostasis, although following the subsidence of the perihepatitis, the liver decreased in size, and at this time was apparently no larger than normal. The digestive apparatus behaved well—the urine continued to be abundant, and still showed the large amount of urea. The edema disappeared from the left leg. The larynx, under the care of Dr. Renner, at this time showed considerable infiltration, which rapidly increased. The secretion from the part now showed tubercle bacilli in increased number. From this time the fluid ceased to accumulate in the pleural cavities, but signs of pressure upon the left lung continued. The patient gradually lost strength, and died after 50 days' illness, from depression of the respiratory center, Cheyne-Stokes' breathing progressively increasing for three days. Intelligence remained perfect until near the end.

Autopsy by Dr. R. N. Russell, eight hours after death. The left pleural cavity contained a small amount of pinkish serum, moderately firm adhesions to diaphragm, pericardium and chest wall. The left lung seemed normal, except for congestion and small solid areas (hypostasis) in dependent parts. The right pleural cavity contained very little fluid, had firm adhesions, particularly at apex, and fresh adhesions at the base and over the diaphragm. The right lung showed a tuberculous area at the apex, about the size of a small egg; it was firm and showed no softening. No other tuberculous processes were discovered in either lung. The bronchial nodes were not enlarged nor soft and showed no bacilli. The pericardium was distended with fluid, about 250 cc. of a clear reddish color. The parietal pericardium was thick and lined with a layer of fibrin about 1 cm. thick, having a shaggy surface. A small area near the base of the heart was caseous and showed a great number of tubercle bacilli. The visceral portion of the pericardium was covered with fibrin, shaggy, similar to the parietal layer. There were numerous fresh adhesions. When separated from the heart the pericardial cavity showed an astonishing appearance owing to the thickening, to the areas of deep red staining, the irregular ragged surface, the numerous adhesions to the heart, which latter seemed very large. There was evidence of very active inflammation. It seems remarkable that the heart was so well sustained during the illness. The heart together with the pericardium after withdrawal of fluid weighed 1,280 gm. The heart muscle was light in color and near the surface had a grayish appearance to a depth of 3 mm. to 1 cm. Free from the pericardium, its weight was 704 gm. This included an organized clot that was not removed from the ventricle. The valves were intact and competent. Cultures from the fibrinous exudate, which was so abundant in the peri-

cardial cavity, contained an extraordinary number of tubercle bacilli. The liver was slightly enlarged, fatty and of a somewhat "nutmeg" appearance. Its surface showed a recent deposition of fibrin as well as inflammatory adhesions to the diaphragm. There was a small amount of fluid in the peritoneal cavity. The kidneys showed a moderate degree of contraction. The larynx showed tuberculous infiltration and ulceration along the left arytenoid and just under the epiglottis. Smears from this as well as from various parts of the pericardial cavity showed tubercle bacilli, and in the latter no other organisms were found. The photograph gives a good idea of the general appearance of the heart and pericardium, but unfortunately the color effects must be left to the imagination.

Among the interesting features of this case are, a severe and abrupt onset; the constitutional symptoms previous to the appearance of physical signs, suggesting typhoid more nearly than anything else, although it was never considered to be typhoid; the severe and repeated pleurisies and the perihepatitis which, with the pericarditis, led us to suspect a case of multiple serositis. There was no evidence of tuberculous lesions in any of the serous sacs, except the pericardium. The tendency to pleurisy has been noted in numerous cases of tuberculous pericarditis. The fact that the source of pericardial infection could not be traced to any area of softening tuberculous tissue is of interest. It is not known in what way infection reached the pericardium. No contiguous tissue was involved, the mediastinal and bronchial lymph-nodes were healthy. The nodule in the apex of the right lung was firm and the process not very active. The laryngeal process seemed in point of time to correspond with that in the pericardium, and it was through the discovery of tubercle bacilli in the former that we were able ultimately to make a correct diagnosis. The pericarditis was truly terrific in character as revealed by autopsy. The marked enlargement of the heart took place subsequent to the attack of pericarditis. The reasons for this have been explained and dwelt upon by Beverley Robinson.⁵ The severity of the constitutional symptoms appearing early in the history of the case would seem to indicate a general infection, and the decline of fever in the later stages remains a source of speculation. The question of pericardial aspiration was repeatedly considered. A large area of precordial dullness invited puncture; but the position of the heart so low in the pericardium, held there doubtless by adhesions, led to its abandonment. The necropsy justified the decision. No good would have followed aspiration in this case, as the amount of fluid was moderate, and the large area of dullness was owing to the increased size of the heart, the thickening of the pericardial walls, and to abundant fibrinous exudate. The transient phlebitis in the left femoral vein with edema of the left leg was probably of tuberculous origin and part of the general infection; it entirely subsided before death. The difficulty of diagnosis in such a case is evident, and taken in connection with pain in the lower extremities, the repeated pleurisies and perihepatitis might not unnaturally have been explained as the expression of multiple serositis. This symptom-complex is frequently of tuberculous origin, and, as accompanied by enlargement and cirrhosis of the liver, was graphically described by Hutinel⁶ ten years ago. Considering the age and excellent nutrition of the patient, tuberculosis would scarcely have been suspected but for the laryngeal complication.

CASE II.—In consultation with Dr. Allen A. Jones. Mrs. B., a middle-aged woman, had in 1894 an enlarged cervical lymphatic gland, some cough, and symptoms of an indefinite nature that were apparently due to neurasthenia. In 1901, she came to the doctor's office suffering from great distress in the chest, short, hacking cough, and marked dyspnea. Her pulse was frequent and feeble, and she was sallow. There were signs of effusion in both pleural cavities, being more marked on the left than on the right side. Subsequently the woman was visited at her home. She steadily grew worse, orthopnea developed, there was ineffective cough with much general distress. About 500 cc. of reddish serum was withdrawn from the left pleural cavity, which afforded her slight relief. A few days subsequently the same amount was withdrawn from the left pleural cavity, and 250 cc. from the right. This also was followed by very slight relief. The orthopnea

continued and dysphagia developed. The dyspnea was probably produced by mediastinal pressure, and there was wide precordial dullness; but at the same time there was flatness that appeared to arise from fluid in the pleural cavities. There was no friction sound at any time. The woman died about ten days after first coming under observation, and massive pericardial effusion was found at the autopsy, the report of which follows:

Autopsy by Dr. H. U. Williams. Considerable fluid in the right pleural cavity; right lung adherent at apex, the upper lobe showing a number of small, yellow uncalcified nodules, old calcified scar at junction of lower and middle lobes; small area of bronchopneumonia in lower lobe. The left pleural cavity contained much fluid; the left lung showed old adhesions at the apex, also an old scar, and below this was in a state of great retraction and airless as the result of pressure from the distended pericardium. There was an area of solidification, probably tuberculous, the size of an egg in the lower lobe, also an area of bronchopneumonia. The bronchial and mediastinal lymph-nodes were large and caseous. The pericardium contained about 1,000 cc. of bloody serum. The surface of the pericardium showed a thick, shaggy, fibrinous exudate. The heart was small, the valves normal. The pericardium showed numerous tubercle bacilli, and sections of the pericardium showed miliary tubercles in abundance along the most superficial layer. Lying over these was abundant fibrinous exudate with polynuclear leukocytes and considerable blood. The bloodvessels of the pericardium were much dilated.

Of interest in this case are the following facts: The old and unsuspected tuberculous lesions in the apices of both lungs, evidences of old pleurisy unsuspected, the insidious onset (a woman walking to the office with evidence of fluid in both pleural cavities, and doubtless with the pericardium already distended). The most important comment is that although the pericardial cavity was believed to be involved, the physical signs pointed particularly to double pleural effusion. Four aspirations for the relief of this were made, and a moderate amount of slightly reddish serum withdrawn without greatly relieving the patient. This shows how easily even a large pericardial effusion may sometimes be masked. In this, unlike the first case, the heart was small. It presented a characteristic picture of small miliary tubercles lying in the superficial layer of the pericardium. The ragged and bloodstained appearance of the pericardium was marked, although not so evident as in the former case. Death doubtless resulted from pericardial pressure.

CASE III.—T. R., male, aged 53, a patient at the Erie County Hospital under the care of my colleague, Dr. DeLancey Rochester, through whose courtesy I am allowed to make this report. The patient entered October, 1900.

The family history showed tuberculosis in the case of a brother, but the patient's personal history is negative save that a year ago he began to cough and feel weak. Three months ago he had a severe cold with chills, fever and edema of the legs which laid him up for several weeks.

On entrance, the man complained of weakness, cough and dyspnea with some edema of the extremities. The blood count showed 8,125 leukocytes. His temperature varied from 98° to 101°; pulse 80 to 90, respirations 24 to 36. There was little variation in this until November when fluid gradually accumulated in the right pleural cavity. He was repeatedly tapped and on December 3, 1,856 cc. of straw-colored serum was withdrawn at one time, resulting in relief of the dyspnea and betterment in the general condition. The temperature curve and the rate of the pulse and respirations showed but little change. He coughed much, raised little, but no tubercle bacilli were found. The pericarditis was masked. The man gradually failed and died on the first of January; the clinical diagnosis being pleurisy with effusion.

Autopsy by Dr. H. U. Williams, January 3, 1901. The left pleural cavity was obliterated by old fibrinous adhesions; the right pleural cavity contained about 1,000 cc. of turbid serum, the costal and pulmonary surfaces were covered with firm, tough layers of fibrin. The lung was much retracted. The lymph-glands at the root of the right lung were much enlarged; both lungs contained round, nodular tuberculous masses and areas of tuberculous pneumonia, more numerous in the left. The pericardial cavity was obliterated by tough, fibrinous adhesions; there was no fluid, the heart was small. On stripping off the fibrin, small miliary tubercles could be seen in the most superficial layers of the pericardium. Tubercle bacilli were numerous in the nodules of the lung and miliary tubercles were found in sections of the pleura and pericardium. No bacilli, however, were discovered in or on the fibrinous exudate.

This case is interesting in showing a slower evolution than the preceding cases. Here there was no pericardial effusion, the pericardial cavity being obliterated and the real condition obscured by the abundant serous

exudate in the right pleural cavity. As in the second case, the real nature of the effusion was not discovered until autopsy.

The following conclusions seem warrantable:

1. Tuberculous pericarditis is not a rare affection.
2. The diagnosis is usually not made except in cases with simultaneously active tuberculous processes in other parts.
3. The concurrence of pleurisy with bloodstained effusion may be regarded as suggestive.
4. The pericarditis may be of a chronic obliterative type, or there may be massive effusion, generally sanguinolent, but rarely purulent.
5. It may be acute, continuing for but a few days, or chronic, existing for many months.
6. It may be a part of a multiple serositis, and the proportion of cases in which at least one or more of the pleural cavities are involved is remarkable.
7. The disease is to be regarded as a secondary affection, although from a clinical point of view, some cases may be looked upon as primary.
8. The point of origin of the infection is often found in the bronchial and mediastinal lymph-nodes, although these may be quite exempt from the disease. The infection may be direct from continuity of tuberculous tissue, or by transmission through lymph vessels or through the circulation.
9. The heart may be greatly enlarged, or normal in size, or even somewhat small.
10. Some observers believe that occasionally the process subsides and that comparative cure results.

SOME ASPECTS OF MEDICAL EDUCATION.¹

BY

JOHN H. MUSSER, M.D.,
of Philadelphia.

It is no trifling occasion that draws together from the uttermost parts of the country a fifth of an organization of a profession that is taxed to its utmost in the prosecution of its duties. It is not with sounding trumpets and tinkling cymbals that from the sorrowing bedside—whether in the hovel of the poor or the palace of the rich—from the excitement of the operating-room, from the stimulus of the hospital ward, or the quiet but inspiring haunts of the laboratory this assembly gathers. That it is possible is a handsome tribute to the noble animus in which are embodied a spirit of inquiry, a thirst for knowledge, a longing for inspiration, a desire to uplift and to be uplifted that pervades the profession. The event is one that should be fraught with the dignity, the inspiration, one might almost say solemnity, befitting a symphonic march. For such animus, fellow members, we have just cause for self-congratulation.

It scarcely need be reiterated here that the spirit which pervades such a meeting is the outcome of that evolution which began with the introduction of precision in medicine. Just as soon as the art of medicine had for its foundation the science of medicine, the possibility of harmonious medical organization arose. When "rule of thumb," or intuition, gave way to precision; idealism to realism; when speculation was displaced by fact; when, in short, inductive methods were employed and honest inquiry became the guiding star of action, then harmony could sit in council.

With medical, as with all organizations made up of human elements, it would be only human if not pervaded by the essence of science—truth. Hence with the latter wanting, jealousies and ambitions, self and selfishness, would prevail to

¹ President's Address at the fifty-fifth annual session of the American Medical Association, at Atlantic City, June 7-10, 1904. Published synchronously with the *Journal of the American Medical Association*, by courtesy of the Editor.

the end that the true object of organization—a fraternal spirit and conscientious seeking for truth—would be as a flickering flame. A little observation will show that that society, whether county, State, or national, that does not have this true reason for its existence, for its guide of action, will be a failure. The reverse is also true, that that organization which may be called unsuccessful and unhappy, of snarling men, and backbiting colleagues, can be labeled at once as without its true vocation, to the discredit of its members.

The great heights to which our organization is rising rapidly preclude the activities of such as have self for their basis of action, so that each day we see more and more a noble rivalry of its members to do the utmost and the best for the organization; a healthful vying with one another for its welfare. Self and selfishness are looked at askance; partisanship and faction, save for a common end—the welfare of the Association—are memories.

But, fellow-members of the Association, at this the fifty-fifth session of our Association we have other causes for congratulation and felicitation. We are on the eve of a union of all the members of the profession in one harmonious organization, each individual of which is willing and proud to consider his fellow a gentleman until he is proved not to be, and not, as of yore, a knave until he is proved to be a saint. We are reaping the rewards of that untiring committee which gave to us this organization with which we now labor. We are prospering beyond measure and gathering a force scarcely to be estimated, in great part as a result of the untiring efforts of the apostle of organization—our McCormack. To say that 34 States have adopted the uniform plan of organization, and that "membership in the reorganized States has increased 400% and enthusiasm," writes our coadjutor, "tenfold more," is enough. We are standing out in our own manliness with the majesty that belongs thereto because of the sentiments expressed when our broadly inspired committee voiced the unanimity of feeling which belonged to the Association, in our principles of ethics. We are letting our light shine through the instrumentality of that genius of medical editors—our Simmons. From 5,000 to 20,000 in less than a decade is a statement of circulation which appals and at the same time arouses a feeling of pride and stimulates to further effort, increased all the more when we reflect that the scientific value of the articles in *The Journal* are surpassed by none of its contemporaries; its tone is emulated by all.

Such causes for congratulation bring to this Association greater responsibilities and weightier problems for solution. It is held to be the bounds of this address to indicate responsibilities, some trite and apparently trifling, others most weighty; to point out duties, many so grave and vast, beyond the powers of your official to justly define.

NECROLOGY.

Before passing to the task let us pause a moment and with due reverence take cognizance of our colleagues who have since our last meeting gone to the great majority. The Silent Reaper has been as rapacious as in the past, and more than 1,500 fell in his swath. He has spared neither the humble nor the great. The less conspicuous but just as potent laborers in the vineyard can say with the others: "I have fought a good fight, I have finished my course, I have kept the faith."

Of those who have been honored by this Association in the past we lost two ex-presidents, the hearty, rugged, yet withal gentle and kindly Donald MacLean, surgeon and teacher, and the urbane James Farquhar Hibbard, a revered general practitioner and teacher; two ex-vice-presidents in John Bates Johnson, one of the founders of the Association, a great practitioner and honored teacher, and Isaac Newton Love, genial and magnetic. From the ranks we lost Edmund Andrews, scientist, pioneer in surgery and medical education in the West; George Julius Engelmann, obstetrician, scientist, litterateur, teacher, honored at home and abroad by membership in great organizations; James McFadden Gaston, pioneer in the surgical treatment of affections of the gallbladder and gall-ducts, an esteemed practitioner; Franklin Staples, Hamilton Atchison West, Orpheus Everts, each obtained prominence and respect by force of character and natural attainments; Emil

A. deSchweinitz, scientist and brilliant investigator, laboring not for his own renown but for that of his profession, passing away at the threshold of a most promising career; Frank Savary Pearce, untiring and enthusiastic, who had been expected to counsel with us this week.

HOUSE OF DELEGATES.

The conduct of business under the new constitution bodes success. The two years of trial have indicated that to the House of Delegates the greatest responsibilities fall. When its members consider the great power the American Medical Association will have for weal or woe in the future, and that the great body gives that power almost unstintingly to the delegates, they should justly realize the honor and confidence bestowed on them. With such realization will come honest purpose and deliberate action. All the county and State organizations must appreciate the vast duties to be undertaken and the breadth of view, deliberation and wisdom essential to their correct performance, and consequently select from their number the best of their possessions. Let us as an organization see to it that honor and homage come to those who labor unceasingly in the House of Delegates.

NATIONAL LIFE.

It can be readily seen that an organization of the magnitude and with the object and the spirit of our Association must in justice to itself and duty to its country take part in its social and political life. In order that we can be in touch with such life it would be well for the Association to devote some time to the discussion of broad general topics. We have provided for discussions at this meeting, the advisability of which may be termed tentative. We feel that they can be productive of great good, and if the experience on this occasion is the least encouraging, we would urge their continuance. We had hoped to have government officials take up matters pertaining to the relation of the medical profession to the executive, legislative, and administrative departments of the government. The exigencies of politics forbade our obtaining the services of those worthy to address this body. All men of political affairs are too busy at this juncture. At other times we may learn with profit from our rulers and law makers. As arranged for this week, so in various parts of the country in which the meetings are held, broad topics of general interest, perhaps with local flavor, could be discussed. From those in the far West we might learn much of climate or how to conquer the plague, or the medical aspect of "the yellow peril." The good judgment of the committee, or the president, can be relied on to select topics suitable to the occasion.

It is needless to refer to the demands that will be made on us by the nation in the future. You will learn through the representatives of the Army, the Navy, and the Marine-Hospital Service what is expected of us. My distinguished predecessors, Reed, Keen, and others, have pointed out our possibilities for good in the legislative halls of county, State, and nation. We must have care never to be partisan or factional toward the weighty matters we will have to decide. We must realize that the power we have may be our undoing. We must realize that we are entering on dangerous ground, and that it would better become us to be bidden rather than to intrude ourselves into such territory. Indeed, one may tremble not a little at the possibilities of our development in the wrong direction. So long, however, as we hold true to the spirit which comes out of devotion to science we need not fear.

THE SECTIONS.

The work in most of the sections the past few years bears favorable comparison with that of coordinated organizations throughout the country. To inflict discussion concerning them on this general meeting is, we realize, somewhat of a hardship. Your indulgence is craved, however, for through your medium alone can the sections be reached, while peradventure the work of these sections is fully as important as that of any branch of our Association work. If you will look into it you will find the rise of the Association came with the development of section work. To enhance the value of such work is, therefore, to uplift the organization. The present methods are worthy of trial for a few years just as we should not make haste in chang-

ing the new constitution. Regarding it, may we suggest thought along these lines?

1. The continuance of the secretary for a term of years.
2. The collaboration of sections so that one topic can be exhaustively considered at the meeting of the Association without repetition in other sections. For this purpose the officers of the sections should meet for consultation six or eight months before the annual meeting. We feel we did good work by having our distinguished chairmen and secretaries come together last October.
3. The division of the Association into two main sections for work in the mornings, that of (A) *medicine*, including pathology, diseases of children, nervous and mental diseases, materia medica, stomatology, cutaneous medicine and sanitary science; (B) *surgery*, including obstetrics, gynecology and the more closely related surgical specialties. The members interested in diseases of the eye or nose or throat could contribute to either section the result of any studies related to the respective section. The afternoons could be occupied by the specialized labor of the 12 sections now in existence.

Perhaps it might be thought better to have one morning, at the direction of the Section on Practice of Medicine, devoted to the discussion of general topics related to medicine, in which the entire Association could take part; another morning, at the direction of its secretary, to surgery; a third to the specialties; a fourth to sanitary science. The object is to secure the views of physician, surgeon, and specialist on general topics. For instance, endarteritis is a subject to call up at once the possibilities for the internist, the surgeon, and the specialist.

4. The sections should take up and organize special international congresses when the time is ripe for such meetings. Thus an International Congress on Dermatology could be managed by the correlated section of this Association. With the patronage of the American Medical Association any congress that could command such special energies and broad general support could not fail.

5. The section should name to the president a list of its members from which he could select, when asked, delegates to important national meetings or international congresses.

SANITARY SCIENCE.

The Section on Hygiene and Sanitary Science should receive greater support from the organization. It is the section which must bring us in closer touch with our national life. Through it and those devoted to it we ought to secure greater respect from the body politic, and hence more wholesome power for the welfare of the community. Through it the profession should learn to take greater interest in the work of sanitary officers throughout the country. The valuable address of Billings on "The Relation of Medical Science to Commerce" and that of Thompson on "The Economic Value of Medical Science" indicate the opportunities and responsibilities of the profession. The time has gone by when sanitary positions should be used for temporary sources of income and obtained by political means. Such offices are growing more and more vital to the public welfare. They have not been attractive because the rewards have not been commensurate with the responsibility and the labor demanded. They should, we will admit, if looked at from the proper viewpoint, grant large compensation and the occupant should be guaranteed tenure of office not subject to party exigencies but dependent on value received. The fault is partly ours that such is not the case. In but few medical schools is there a serious attempt to educate sanitarians; consequently the physicians who engage in sanitary science in an amateurish way do not give a *quid pro quo*. It does not pay a community to hire them. In one of the large cities of this country it has been impossible for the health authorities to get men who were competent to take up health matters, even though the city was prepared to pay fair salaries. Speculation need not run riot in estimating what would occur in a few years if our universities would give sound practical courses of a broad character, including some engineering, some economics and other features which would round out the man. In preliminary and subsequently in the elective studies the student should not be tempted to go into the special lines of practice. He should have opportunity to go in for sanitary

science and perhaps for government service in the Army, the Navy, or other departments. The communities would soon find the worth of men thus educated, and the demand, we would venture to predict, would outrun the supply. In proof of the former, we may cite the fine tribute given to Wende of Buffalo by the citizens, *en masse* and of one accord, for the work of self-sacrifice, of unselfishness and of worth, as official of the health department. Our Association could as a body and in its constituent parts encourage the medical schools to make such training possible; they could educate the community to demand such services and insist that good compensation is to be allotted for it. The Section on Sanitary Science could take up this as one feature of its work.

But for a more grievous reason, the profession's attitude, there is public disrespect. Survival of the old dictum that a patient's woes are confidential, supports too often the attending physician in failing to realize his responsibility to the community while attending to the welfare of his client. For this, as well as too often for personal reasons, he readily connives with the patient to thwart civic authority, thereby endangering a community. Instead of aiding in securing respect for and obedience to the rules of his sanitary colleague he joins in opposing him. Candor must compel us to admit that too often he fears the advent of the health official may mean some disclosure of his own incapacity. It is fair to say the official on his part is often too ready to give advice, to sneer at diagnosis, or rail at treatment. To inspire, therefore, wholesome respect toward these co-workers and establish an *esprit de corps* should be one of the educational prerogatives of this section. Were we to be called to account for duties undone, the sin of not fulfilling our obligation to the community in sanitary matters would doubtless be found the most conspicuous, the one most detrimental to its interests.

Again, if not too insistent, could not this section further educational exhibits in sanitary matters not unlike the superb exhibit last winter in Baltimore, conceived and conducted in the main by our present official of the Sanitary Section? The Association could not do better than issue a grant for the furtherance of this object.

THE SCIENTIFIC EXHIBIT.

It is gratifying to see the interest and success attendant on this new feature of section work. It is another tribute to the belief in the permanent tenure of office of an official when we have the good fortune to get a good one. Attention is particularly called to this exhibit to ask the Association and the other sections to look to the conduct of somewhat similar exhibits. The Section on Ophthalmology showed the possibilities at the time of the Helmholtz anniversaries. When a section takes up a subject let us not have the clinical, pathologic and therapeutic aspects alone discussed, but bibliographic and historic features brought out. Let such features be as national as possible. What a fine exhibition it would be to have in connection with, say typhoid fever, a loan collection of the pictures of authors and investigators, of the various editions of their works and of the material things with which they worked, illustrating the evolution of their knowledge of the subject. Who would not be thrilled by a picture of the wards of the old Pennsylvania Hospital where Gerhard worked, of the instruments or materials he worked with, how he lived and what he did; of the first editions of his works, indeed of the manuscript of them? We must confess to a quiver of delight, mingled with reverence, on being permitted to handle the manuscript on which Stillé inscribed his communication to the Paris Society. This is not the time or place to indulge in a homily on the value of such exhibits, agreeable though it might be. Through them, as of biography and sculpture and painting, we keep in touch with our history. Foster efforts in these directions, gentlemen of the Association, grant liberally to sections their small demands on you, to the end that you will be stimulating the best instincts in our profession.

THE ASSOCIATION OF LIBRARIANS.

We are not far amiss when we call attention to an organization which in a quiet, unobtrusive way is bringing together the members of the profession on a common ground, where tars

do not spring up and thistles do not blossom, but instead there is an atmosphere clear, refreshing, invigorating. Jealousies do not thrive in libraries; books soften ambitions. No stronger, more liberal friendships can develop than those that come to book lovers. We owe a debt of gratitude to the Library Association and to its distinguished president, under whose fostering care the influence and power of the Association are unfolding as the hardy rose, exhaling like it a fragrance which cheers and stimulates. Of the many abundant works we owe him, none, we venture, will be more satisfying to him and more lasting for good than the work of the Association of Librarians. This Association should hold not its hand nor stint its heart in upholding its educational efforts.

THE RUSH MONUMENT.

Before this session adjourns, by proper ceremony, graced by the presence of the President of the United States, with an oration befitting the occasion by our distinguished colleague, Dr. Wilson, the monument erected by the Association to the memory of Benjamin Rush will be dedicated. The Association is to be congratulated on the completion of this tribute in perpetual bronze to one of the most distinguished of our countrymen. Not alone should we rejoice on the fruition of this agreeable task but also because it augurs for the erection in the future of tributes to the memory of others full worthy of our reverence. The invigorating, stimulating influence that comes from having about us our heroes of the past in stone or bronze behooves this Association and its constituent bodies to strain every effort to encourage in this manner hero worship. It is due ourselves to perpetuate the inspirations, the thoughts, the feelings in the counterfeit presentment of our fellows. We are not of those who decry the world because it has not recognized our Jenner, our Pasteur, our innumerable heroes either by reward in their lifetime or by permanent tribute. We do not begrudge the meed of praise and the plenteous bounty which flow to our warriors and statesmen. It is true their glory has been attained often by carnage, lives sacrificed to avenge some insult. It was not life that was at stake. It was principle or thought or feeling or, our misanthrope suggests, greed. What countless lives are sacrificed for aspirations; what thousands of innocents for national gain! So, to the actors who stand for such, unstinted regard is given. The public neither appreciates the loss nor the saving of life. Hence, so long as it does not come close to them, civic murders from bad hygienic conditions do not move them. Even when home is devastated they submit to that which they consider mystifying or providential, and merely go their way. They are callous beyond measure to the presence of epidemics. They do not consider for one moment the power they have to assuage the virulence or even wipe out the existence of pestilence. Every effort for amelioration, as we see in tuberculosis, comes from our profession. With such lack of appreciation of their own welfare we need not expect much appreciation from them of our efforts.

In all honesty, we must admit among ourselves, we may not deserve public appreciation. If we realize the truth we may make amends. Could the public be expected to revere and respect when, as usual in the past, perhaps too common now, the profession was divided against itself, not from principle, but generally because of pocket, of sordid ambition, of devouring jealousy? Look ye to your county societies! Do the brethren dwell together in harmony? Go to the warfaring court rooms! Do we emerge from them respected and respectful of one another? Until such sores are healed, as they happily will be, when science—and hence liberality of mind and largeness of heart—is furthered by associations like ours, it must remain to us a cherished heritage and privilege to worship our heroes alone. When we learn to respect ourselves, then will we be respected.

MEDICAL EDUCATION.

The object of this Association shall be for the purpose of elevating the standard of Medical Education.

This Association has been, should be, and we trust will be, the storm center of legislation for reform in medical education. Since the memorable editorials of Wood in the old *Philadelphia Times*, and the masterly papers and addresses of Pepper and the practical action of the University of Pennsylvania there has

been virile progress. In most respects it seems definitely settled as to the course of education a candidate for the degree of medicine should take. Questions of pedagogy are still debatable, but we take it that that student who wishes the quickest returns, the most lasting remuneration, perennial stimulation of the intellect, and continuous enjoyment in the pursuit of his labors, should take a college education of three or four years, a four years' course in medicine, and, if possible, a hospital internship.

Reference need only be made to the reports to this Association, to the famous report of the majority committee of the Association of American Medical Colleges, to the numbers of *The Journal* comprehensively devoted to education, and to many recent admirable addresses in support of the statements.

There is talk about maximum and minimum requirements, about laboratory and hospital courses, the merits of didactic and clinical teaching—a mass of material brought forth from the viewpoint of the educator, or looking to the welfare of the medical profession. We do not minimize the value of such lines of discussion. It has brought us to the position we have attained. But what of the medical student? Should we not look at education from his point of view? Is he quite able to decide whether he should take up the profession of medicine? We hold that a great duty is due the aspirant for medical honors from teacher and practitioner. It is a kindness due him to point out the best methods of securing such education as will yield him results commensurate with the time and expense required. It would be a greater kindness to be enabled to show him that by reason of intellectual temperament or of physical or moral qualities he is not likely to reap the rewards he is anticipating.

The large majority of medical students do not have a good reason for studying medicine. They are ignorant of the mental and physical demands made on them. They are attracted by an uncertain glamor and a specious glory, and heedlessly they go in. The failure of a large percentage of graduates in medicine to acquire more than a bare existence, and too often not even that, proves that they were not educated properly, not fitted temperamentally or physically to pursue its duties. Should they not have opportunity for learning of the responsibilities and difficulties, rather than to have the brighter phases glorified? Would it not be well to have in our college curriculum a course of lectures for the student who contemplates entering a profession, pointing out the rocks and shoals in his prospective career? An eminent practitioner, not connected with medical schools, would light up and darken the pathway in due proportions. Then, too, should not, as in the Army and Navy, some physical tests be required? The trophy is to the robust, and sad will be the career of the man who is physically handicapped.

If there were any doubt about the value of a college degree to a man entering the medical profession it could be set at naught since the report of the Mosely Education Commission. Quotations like the following, while not pertaining to medicine alone, the result of extensive inquiry and mature deliberation, supported by the statistics they give, uphold the contention of a large employer, that "for 99% of the nonuniversity men, it is hopeless to expect to get to the top." One opinion they express is that "there is still room for the boy of marked ability 'to come through,' but that his difficulties are greatly increasing, and that, useful as he is, his usefulness would have been greatly enhanced had he had the benefit of a college training." Still another commissioner reports that while only "1% of the entire population of America has received a higher education in her colleges and universities, this 1% holds more than 40% of all positions of confidence, of trust, and of profit." It is well known that the "geist" of the individual brings success, for which they say "it is recognized that the educated man takes in a wide horizon and puts more 'soul' into his work."

The essential of success in any department is diagnosis, which requires powers of intellectual penetration and discrimination. President Thwing has again forcefully urged that "the reasoning of mathematics—and mathematics is only reasoning—tends to promote clearness and accuracy in perception, inevitableness in inference, a sense of logical orderliness. The study of the languages represents the element of interpretation. The

study of history means the interpretation of life." Are these not the main studies of a college education? While they may promote scholarship, they surely cultivate thought. It need scarcely be pointed out to this audience that to be a thinker is the salvation of the physician.

To the plea that the acquirement of a college degree takes up too much time and requires too much money, the material answer can be given from other sources to the effect that "the men whom you are surprised to find holding such important positions in factories, though not much over 30 years of age, are the very men who did not leave the technical college till they were 23 or 24; the graduate may have been 25 before he donned a jumper, but in five years he learned more with the college training he had as a foundation than the regular journeyman of 15 years of actual work in the shop." The experience of teachers who have watched the alumni agrees in that the college graduates get quick returns and soon acquire a position of independence.

The poor boy, therefore, need not be deterred, for if he has the spirit and energy to work his way through four years, two years or three years more will be but very little in the final summing up. If the student only knew that the purchase of the best education, whether reckoned in time or money, is the most economic investment, in that as to the former, a thorough education at first is time-saving in later years, and as to the latter, the money outlay is returned more quickly, in more immediate work and larger pay.

There should be one educational requirement—the equivalent of that for which a first-class college degree stands, whether received at a high school or university.

After entering the medical school with, it is presumed, the proper educational attainments, his career the first year should be closely watched. That school has too many students if it does not have enough instructors in the first year to be able to judge with a reasonable degree of accuracy of the character and moral stability of the men. This is not to be taken in a prudish sense or with too critical a scrutiny of habits which are the overflow of the animal spirits or the expiring exuberance of the boy approaching manhood. This can be said, that a student who does not play fair in his exercises, who cheats in one demonstration or evades another, who does not show manliness, frankness and truthfulness in his first-year duties, will not be a good diagnostician. He will cheat himself; he will cheat his patient. The teachers of the first year, or at least the second, should know this and block the student there and then. It would be a kindness. Let us then agitate whether we should not have a certificate of manliness, a certificate of health as well as a certificate of mental proficiency, before we admit students to our medical schools or permit them to go beyond the first year. Let us not be decoys, alluring them on to later destruction, but rather be guardians, wrapping the strong arm of experience about them to lead them to the fitting pathway.

Having permitted the student to pass further in his pursuits, we still owe him much. We must see to it that such course is given him the first two years of his student career that he will acquire such fondness for the science of medicine, such reverence for the exploration of its truths, that until his dying day devotion to it will be his stimulus and solace. As a corollary, we must insist that medical schools secure the best men in the market for these places and pay them salaries commensurate with their ability—good living salaries.

It is in the first and second years of his career that the foundations are laid whereby the student becomes the medical thinker. To quote again: "The power of thinking should not be of a base and barren character. The thinking should represent and be concerned with a fine and rich content of knowledge. It should have the exactness of intellectual discrimination; it should have the fulness of noble scholarship; it should embody a culture which is at once emotional and esthetic and ethical, as well as intellectual."

That a desire to relieve suffering, to extend sympathy, to save life, is the impulse of the physician, we all admit, but where is the man among us who will not also admit that a scientific habit more quickly brings it about and more surely sustains and fortifies the humane instinct through the trials and tribulations of exacting practice? That prosecution of profes-

sional duties soon becomes commercial that does not have for its basis a true spirit of scientific inquiry. How miserable must that life be which conducts an exacting, drudging, daily routine with only material reward in view. Few are the practitioners who have this sordid view; we can be as sure medicine would soon be forsaken if this viewpoint alone were considered. Hence in the laboratory of the first two years must be aroused and fostered the stimulus for lifework.

The final years should be clinical years, and the last should be in a hospital. The medical school that allows its students to think such opportunity is not due them is most unfair to them. As our schools are now constituted, most of them cannot give such requirements. The students should know, however, such requirement is necessary. What has been said regarding the preliminary college education applies equally forcefully to the hospital training. He is thrice armed who enters the arena thus equipped. Medical schools that cannot give such education are cruelly unkind and unjust to the students, by having them think it is not essential. Medical colleges that pass off a hospital training for one that is not truly such, fake their students. The student who pays well for his training has the right to demand such as to fit him for immediate action.

It is not the fault of the medical school alone that he can not get it. The public that cries out when there is mistake in diagnosis, fault in treatment, and that shakes its head at the deficient education of our students, must share the blame with the medical school. The public admits that its individual members may at any moment almost be at the mercy of a half-educated physician. It is not necessary to recount, for it is well known, how on land or sea, by day or night, some event may arise in an individual life, the care of which may mean life or death. Even with this knowledge they withhold means to relieve themselves. They admit the necessity of a hospital training. But they, and particularly the public in control of hospitals not used for teaching, say each medical college should have its teaching hospital. They do not appreciate that to give an education which involves a hospital course would require an expenditure of \$500 a year for four years by each student. It has been estimated that the cost of maintaining a plant and paying salaries sufficiently large to accommodate 600 students would require the above outlay by each student. Unfortunately, it is impossible to expect students to pay such figures, as it would render entrance into the profession almost prohibitive. It is manifestly impossible, as medical schools are constituted now, to educate all the students of the land properly. Hospital training can not be given except by a few favored institutions, because the doors of hospitals are closed either by the governing body of the hospital or by the teachers in the medical schools.

We believe, personally, if a decree should be issued that no medical school, including its hospital, should exist except on the fees derived from students, but little hardship would follow. The lessened supply of students would increase the demands on the practitioner, so that larger returns would follow. The poor student would sacrifice and strive to get a degree, knowing then he had a good asset. A diminution in number and an increase in quality is demanded alike by the public and the profession. Such diminution in number would mean that the student would get back his investment quicker and in larger amount than at present, hence good men would be attracted. If we could abolish sentiment for sense and educate accordingly, there might be betterment all around. As it is now, medical students receive part of their education through the bounty of the State or the charity of the public, as such education can only be given in endowed institutions. The public is taxed so that the prospective physician can make a living. Is it right that it should be? Perhaps a mechanic should demand such right to make his son a good workman. We must all admit it is the duty of the State to educate the youth, so that good citizenship is maintained; we can question whether the State should educate the members to obtain a livelihood.

With the same indifference that the public views an epidemic's march they allow hospitals that are engaged in teaching to suffer for the want of funds. Moreover, they close their doors to the advent of teaching in the hospitals under their control. We must admit, those who do not appreciate the true function

of a hospital have some ground for their contention. Ruled by sentiment chiefly, unfortunately an impracticable master, they sympathize with the patient, who still harbors the belief of old, that the medical student is one of a class that prowls about not unlike harpies. The public does not realize the difference in the student of today and the student of tradition. We cannot hold to account the governing body of the hospital, which has the point of view that it is harmful to a sick person to have him under the surveillance of an alleged student rabble. We must admit some patients become alarmed, particularly in institutions where they know they will have the sympathy of the governing body. An analysis of motive will show that the usual patient who will not allow a judicious amount of clinical demonstration when the sense of delicacy is not offended, is truly selfish, in that there is prevented that increase of knowledge and development of skill whereby suffering of others may be alleviated. A little encouragement from the officials would allay alarm on the part of the patient. The desire to help others is infectious, and when one yields in a ward, others vie in the work.

The truth of the matter is that in hospitals in which teaching is carried on, rarely, if ever, do the patients complain. Indeed, it is the experience of those teaching institutions that judiciously conducted instruction is appreciated by the patient. In one hospital we might name, most of the inmates are pay patients, giving \$7 a week willingly, because they know they are buying the services of the best practitioners in the land—the teachers of medicine—which service they could not get at tenfold the figure. The fact that teaching hospitals are overcrowded, not by the poor alone, but by people independent of charity, shows that clinical instruction is not a bugbear. If the governing boards would know that while a few patients might be alarmed, on the whole most of them would be gratified by the attention paid them, and their sense of rectitude and manliness appealed to by the satisfaction that they are doing some good in enlightening students, so that others could be relieved; that their administration would be stimulated to do work beyond criticism; that the nurses would be aroused to better activity while under the observation of those not connected with the hospital; that the internes would do their very best to have most complete studies of the case, and finally, that the chief in attendance would be compelled to do his best at the risk of his reputation, they would gladly open their doors, even to the discomfort of the few, but to the advantage of the many. In short, the hospital should have teaching not to oblige the medical school, but for its own survival and regeneration. The benefits the student derives by the object lesson of an orderly hospital cannot be estimated. Will not every member of a hospital board admit that his own character, his own sympathies, have been benefited by his connection with the hospital, even though, perhaps, he has not the advantage of an impressionable age? Can he not see, therefore, how the youthful student can be influenced in thought, and character, and feeling? He can not lightly toss aside this responsibility, nor even hide it by putting the onus of medical education on the teaching hospital. Every dollar endowing a nonteaching hospital robs the teaching hospital which is engaged in this larger duty.

It is true a class which is compelled to have hospital attention may not sympathize with this feeling. How can we obtain the confidence of this class? Let us organize such association of prominent people in our teaching centers who will agree to have any operation, any feature of disease witnessed by medical students, at the judgment of their attending physician. It would be well if the individuals of such an organization would agree, first, to undergo hospital treatment; second, to be the object of observation by students; third, to have an autopsy performed in case of untimely end. We feel sure that it would be wholesome individually and publicly if each would agree to ward treatment. Such association would rob hospitals of their terror and teaching of its dread. No one can deny that on the whole the public would be benefited from whatsoever point of view we look at it. Indeed, the public ought to learn that disease is an enemy to themselves and their country. Just as we make sacrifices in time of national warfare, so we should be willing to make sacrifices in the daily battle for life. Just as aristocrat and plebeian, landlord and tenant, fight side by side

in the former, so they should array in solid phalanx in the latter.

But there are hospitals willing to admit students, and yet the privilege is not availed of. This arises because the teaching force of the medical college is not willing to sink its personality and allow the student to go wheresoever he will for his instruction. Courage and some sacrifice is required perhaps. But, when one thinks of the mighty opportunity and the frightful waste, it is saddening. Every hospital should be a school. The fourth year should be so arranged that the student could avail himself of the advantages of hospitals in the immediate vicinity. Let each teaching body have the student understand what he must see and do, and trust you the true student will see it at the best place and with the best men. He must be accountable, of course, with a rigidity that means the exact acquirement of knowledge. To this end the first two years could be well spent in the properly equipped laboratory university, whether in town or country, the third in the authorized hospital of the school, the fourth in extramural hospital work.

Is it not anomalous that the hospital boards give to the nurses who are to act as aids to the physician the highest opportunities, and yet deny it to those who are to give orders to the nurses? This, of course, arises because training schools are the product of modern thought and have not been trammelled by tradition.

But all this talk of the primary education avails but little if we do not see to it ourselves that education is continuous; that from the day of our graduation, forward, we do naught but toil, toil, toil. It should go without saying, as a mere business proposition, that unless we unceasingly labor but little of the fruits do we pluck. It is demonstrated in a practical manner, for when we look about us and find the methods of those of our brethren whose labors are not in vain each one bears the scent of midnight oil.

The development of postgraduate schools, the growth of libraries, the groans of the printing press, the enthusiasm of medical societies, all testify to the spirit of persistent self-education that is abroad. It is not for me to urge further the importance of each of us taking from time to time months for study and reflection. Every active doctor should have his sabbatical year. We dare say, extended observations would uphold that in income a gain is one hundredfold for each dollar invested in educational outings, and for every hour thus employed, ten is added to life. To finance a medical man from first to last successfully, we dare say, spend all net earnings of the first five years on self-education; after ten years, 10% of the annual net earnings for an assistant, continuing a 25% investment for years. Health, happiness, increased usefulness to the community, a success, which never comes from eccentricity, equal to doubling capital every five years, would follow.

In the course of our work it is necessary for us to halt from time to time and review. Not alone must our mental storehouse be swept out and refurnished, but we must constantly "jack up," if the term is permissible, our mental and moral machinery. There are few of us who will not find as our days grow fuller an unconscious tendency to slight our work, to become slipshod, to hurry over matters. It is partly an evidence of overwork. The postgraduate school is the salvation. No obstacle can withstand the continuity of drill, which the earnest of us keep in action. If, to continue the imposition, asked what element of character is perhaps lacking to the greatest detriment to the profession and public, we possibly, one and all, would say courage. This is seen in the hesitancy which members of the profession show in giving an opinion, in advising an operation, and in asking for an autopsy. How much confidence is destroyed by the want of free, frank avowal of the physician that he does not know on the one hand, or of clear, precise statement of his judgment concerning a case on the other! The greatest success in life is confidence. How many lives are lost by the worker in internal medicine not advising early and unequivocally an operation for fear he might be wrong in his diagnosis! And how many more are lost because the surgeon lacks courage to do, either because he fears the patient may die and his record be marred, or because he may operate when it is

not necessary! We must admit we have had some operations done when they were not required, but let it be said to the credit of modern surgery, we have never seen an operation of such character performed by the right man that did any harm to the patient. On the other hand, the resort to operative procedures early, and in cases that even yet are not considered of surgical relief, has saved lives and lessened suffering to a degree that far overbalances the now and then futile measure. It may be assumed, without contradiction, that every case of bad appendicitis that happens to get well without surgical relief has in its wake three to five that die for the want of an operation. In other words, the pernicious influence of a surgical case that recovers without operation is evident in creating the hope that other cases demanding operation might get well without it.

And the man who does not want an autopsy—not only the centers of courage need stimulation, but too often the entire medical storehouse needs refitting. Something, best known to the physician himself, we trust, is lacking in the one who treats an obscure case for a day, six days, six weeks, and then does not want an autopsy. If true to himself, true to the demands of his profession, courage will not fail him. In our mental and physical round-up, we must see to it that courage is given a new backbone from time to time.

But, fellow-members of the Association, not alone as members of this organization may we indulge in self-congratulations, but as members of a profession whose limitation knows no bounds, we may join in felicitation. Neither language, nor creed, nor country, fetters our profession's munificent sway. The thoughts of Ehrlich, in Frankfurt; of our own Welch or Councilman, of Kitasato, in Japan, are correlated. The knife of Mayo in America, of Robson in London, of Kocher in Berne contributes to the relief of suffering in far Cathay. The founts of Lister's genius and Pasteur's divine inspiration bring countless blessings to England, to India, to France and to Africa. What a stimulus it is to realize that, howsoever small the contribution of the humblest of us may be, its impulse will be felt in climes near and far and ages present and remote! What awe cannot but overtake us when we consider each heart throb we study entwines us to Harvey of two centuries ago; with every percussion tone reverberates the sound of Laennec's voice of a century; with each vaccine inoculation, the simple observation and reasoning of Jenner stimulate our question and deductions!

We rejoice together and cherish our history, by the warp and woof of which we are woven to the past. What heritage for us and our children! Dead must be the soul that wearies of communion with the spirits of the past; deep must be its slumber on which palls the thought of centuries; lethargic its activities that are aroused not by the deeds of heroic men! "Honor and fortune exist to him who always recognizes the neighborhood of the great, always feels himself in the presence of high causes." We worship together our science, devotion to which brings forth character, smothers egotism, levels pretension, drives out solitude, develops such loftiness of thought which can see that "against all appearances the nature of things works for truth and right forever." Of our art, let us see to it that when the final summons comes it can be said of us, "Greater love hath no man than this, that a man lay down his life for his friends."

Damages against a Quack Company.—A commercial traveler obtained \$20 (\$97) as damages in the Cardiff County court on May 5 against the Good Health Alliance Company. He purchased two "foot drafts," a form of plaster, which it was said would relieve rheumatism, but he contended that, owing to the irritation which they set up on the soles of his feet where they were applied, he was unable to follow his employment. Mr. Frederick Buckham, who attended him, ridiculed the suggestion of the defendant company that the "foot drafts" drew uric acid out of the system through the pores of the feet, but, according to the newspaper report of the case, Dr. Boyd, who was described as a London consulting physician, said that a good deal of the uric acid could be expelled from the body through the pores of the skin, and that was what the plasters did. The county court judge said that the company was liable for damages, as the plaintiff had not been warned in any way as to the effect which the plaster might have.

PROGNOSIS: ITS THEORY AND PRACTICE.¹

BY

GEORGE DOCK, M.D.,

of Ann Arbor, Mich.

As a text, let me quote from the oldest work we have on this subject,² which, though old, still has the freshness and modernism that genius gives to human productions:

It appears to me [said the Father of Medicine] a most excellent thing for the physician to cultivate prognosis; for by foreseeing and foretelling, in the presence of the sick, the present, the past and the future, and explaining the omissions which patients have been guilty of, he will be the more readily believed to be acquainted with the circumstances of the sick; so that men will have confidence to entrust themselves to such a physician. And he will manage the cure best who has foreseen what is to happen from the present state of matters. For it is impossible to make all the sick well. This indeed would have been better than to be able to foretell what is going to happen; but since men die, some even before calling the physician, from the violence of the disease, and some die immediately after calling him, having lived perhaps only one day or a little longer, and before the physician could bring his art to counteract the disease; it therefore becomes necessary to know the nature of such affections, how far they are above the powers of the constitution. Thus a man will be the more esteemed to be a good physician, for he will be the better able to treat those aright who can be saved, from having long anticipated everything, and by seeing and announcing beforehand those who will live and those who will die, he will thus escape censure.

In this Hippocrates describes the essential importance of prognosis to the patient and the physician in relation to treatment. Beside this, prognosis is often important to relatives and dependents, not merely for reasons of sentiment, but in order to protect property and prevent unhappiness and destitution that would be as painful for the patient to contemplate as for the others to suffer. There is another aspect not present in the time of Hippocrates—giving the patient an opportunity to prepare himself for the anticipated life beyond the grave. In many cases, too, prognosis may have important bearings on political parties or for the Commonwealth.

The patient very often ignores these needs. If he asks for anything, it is usually either the name of the disease or that of the medicine the physician intends to use. He really understands as little of the significance of the name as he does of the action of the drug, and is often more quickly satisfied in proportion as both answers are occult.³ What really should interest him is, as clearly as his mental development permits, some idea of the changes in his body, anatomic and functional, their present seriousness, the chances of death, or of complete or partial recovery, with, in the latter case, the probability of temporary or permanent disability, near or remote, in some organs or functions.

Within the last century prognosis has lost some of its relative importance. Unlike etiology, diagnosis, prophylaxis and treatment, it has no special literature, and is only occasionally the subject of addresses or essays. But much of the so-called prognosis of the earlier periods was really diagnosis, as in Hippocrates' vivid description of empyema, and his remarks in regard to other diseases of the respiratory organs. It also seems a mistake to assume that practical prognosis was more accurate at any period than in later ages of equal enlightenment. While we may admit that great masters, like Hippocrates himself, Galen, Sydenham, and Boerhaave, were remarkably accurate

²The Book of Prognostics; the genuine works of Hippocrates, Adams' translation, Vol. I.

³Striking examples of the virtue of mysterious names are conspicuous in the practice of the popular sect of osteopaths. I could give many examples of the license with medical terms among these people, but as the evidence is derived wholly from patients, I cite only one that can be vouched for by medical eye-witnesses. A hospital patient with typhoid fever, with the neck pain not infrequently felt in that disease, requested that his osteopathic physician be allowed to treat him. I was not unwilling, especially as the osteopath gave assurances that he would not attempt to treat the typhoid fever. Two internes "assisted" at the treatment. The osteopath, one of the *sang azul* of his class, after feeling the neck, announced that the transverse processes of three cervical vertebrae were displaced on one side. After some manipulation, he pronounced the displacement relieved, though I was sorry to see that the pain was not much less than before.

in their prognostications, there is no reason for thinking that the rank and file, following their rules without having their keenness of observation and precision of reasoning, were more accurate, or as accurate as physicians of a later period when the formal study of prognosis was neglected, but when other means of knowledge were greater than before. We must bear in mind a fundamental difference in methods. The older prognosis was based on the observation of symptoms alone, and consciously or unconsciously took the standpoint of humoral pathology or some equally imperfect theory. One charge against ancient prognosis is not as serious as some have thought, viz., that the prognosis was made without a definite diagnosis. Even now we sometimes have to be satisfied with a very imperfect diagnosis, and yet may make a very good prognosis, at least for the immediate future. But the older prognosis was almost wholly lacking in anatomic, and totally without chemic basis. Realizing how far short of accuracy the diagnosis must have been in many cases we can understand that prognosis must have failed almost as often. Moreover, in early medicine, most attention was paid to acute diseases, or the acute terminations of chronic diseases, so that the many important chronic diseases that now make so much of medical practice were comparatively neglected.

Whatever shortcomings medicine may have—and those who cultivate the subject most thoroughly feel the needs most deeply—it must be admitted that diagnosis is much more certain than ever before. Not only are we able to distinguish more quickly and more accurately many diseases long known, such as some of the acute fevers, malarial disease, tuberculosis, diphtheria, and pneumonia; but we have learned the existence and the means of detecting many diseases formerly confused with others. As examples, let me name only a few, such as the diseases originating in the vermiform appendix and the gallbladder, diseases of the pancreas, many diseases of the blood, a large number of diseases of the nervous system and of the ductless glands, and many diseases caused by animal parasites, of which the sleeping sickness is the most striking example at present.

The older prognosis, far from being negligible is really of fundamental importance. It gives the accumulated experience of ages that, untrammelled by detail, carefully noted broad and elementary features of disease. As gathered together in the aphorisms and prognostics of Hippocrates, and in the numerous commentaries on them—not always improving the original—it furnishes a fund of inestimable value, but like everything else in medical art, this knowledge is less useful when applied mechanically than when worked over in the crucible of personal experience, tested by other methods and transposed into current formulas.

Older prognosis was possible to collect into fairly circumscribed space, but this is no longer true.¹ In proportion as diagnosis has become subdivided, specialized, and enlarged, and as knowledge of morbid processes has become more complex, so prognosis has become more intricate. Older prognosis was based on broad symptomatic lines, qualified in practice, we may be sure, by a consideration of the patient's constitution. The present basis is diagnosis, but of a different kind. It means not merely a recognition of the name of the disease, but a knowledge of the nature of the disease, still incomplete, but rapidly gaining in fulness and accuracy. In many cases we know the causes, and a good deal of the nature of the causes; in many more we know the seats of the disease, and the anatomic, chemic, and functional changes that result directly and indirectly. It is by the study of the altered functions that we can make a prognosis and plan useful treatment without knowing the name of the disease. Clinical and anatomic investigations have been aided by experiments and observations on lower animals, without which our knowledge would have been much less certain than it is. Scores of technical methods have been devised for reactions and explorations; natural forces previously unknown, such as the röntgen rays, have quickly been pressed into service. Long and painstaking observations have

thrown much light on complications and sequels, their nature, and detection. From all these things the prognosis proceeds naturally in most cases, but here again an indispensable part is a just recognition of the patient's constitution. It is probably true that in this connection we unduly neglect some prognostic aids furnished by the patient, such as changes of the physiognomy. But, on the other hand, we have much more accurate methods of ascertaining the constitutional factors than were formerly available. Constitution is still a somewhat vague term, but we can speak of it here as the result of the functions of all the organs. While the method of representing these functions is still inadequate, we can safely assert that we have much more accurate means of determining the condition of the heart, arteries, and veins, and the force of the circulation, than we had before; we have gone considerably beyond the recognition of the apopleptic habit in foretelling the danger of vascular disease. We can usually estimate fairly well the efficiency of the blood-forming organs; we can determine with reasonable accuracy the capacity for work of the stomach and intestines, as well as a few details of nutrition and metabolism; we are rapidly getting beyond the limitations of Falstaff's water doctor in fixing the anatomic and functional ability of the kidneys, and we are working toward methods of testing the functions of liver, muscles, and nerves. When we have all these factors thoroughly investigated, it is probable there will be little need of the *vis medicatrix nature*, now an essential part of prognosis.

In the conclusion resulting from these things there is no room for a supposititious clairvoyance, an intangible gift of prophecy, a hypothetic intuition that trained intelligence can not equal or industry surpass. We have a positive foreknowledge, a prescience, a prognosis, corresponding in accuracy and usefulness to our diagnosis, and often in advance of our treatment.

In the foregoing I have spoken of the theory. In the practical use of prognosis the first to profit by that function is the physician. With an accurate prognosis, based on exact and thorough examinations, knowledge of the natural course of the disease and of the patient, the physician foresees the course of the malady and is prepared for changes, emergencies and complications. He is thus enabled not only to preserve his imperturbability, so essential in carrying out necessary measures of treatment, but he can also prepare the patient to meet coming events in better physical and mental condition than otherwise, and, what is often of even greater importance, the self-confidence thus shown stimulates the efforts and the compliance of others concerned in the case.

It is not easy to say how much the patient should share this foreknowledge, and how it should be conveyed to him. In many cases the patient does not ask an opinion, and in many others, either because the present disease seems too slight or for other reasons, the physician does not proffer one. Yet it is good mental discipline to work out the prognosis in every case, as a complement to the diagnosis, and in many the results should be stated to the patient. Many things may conspire to make such statements act either favorably or unfavorably on the patient as on the physician.

Physicians, like other people, can often be classified as either optimists or pessimists. Not that these tendencies affect all parts of the individual's activities. One may be a perfect Pangloss in sociologic, political or climatic matters, and yet take a gloomy view of all his patients. (I am not speaking of those who, rarer in the profession than in some of its parasitic growths, habitually exaggerate the danger of their cases, making every angina a diphtheria, every erythema an erysipelas and every bronchitis a threatened pneumonia.) Another who is perpetually cast down by the failure of democratic government or the need of a stronger one, the immorality of the rich and the rule of the bosses, may meet every case with hope and cheer.

But the practice of prognosis should be cultivated as objectively as any other part of medicine. Not only the therapeutic indications suggested by it, but also the human ones, should be carried out without fear or timidity, without unnecessary harshness, and also without the false benevolence that often does more harm than brutal frankness or ignorance. Here, as in other departments of medicine, the welfare of the patient

¹ I have not attempted to include prognostic details, but would refer those interested to "Observations on Prognosis," by P. H. Pye Smith, Guy's Hospital Reports, Vol. xlv, 1887, as one of the most comprehensive and suggestive articles in modern literature.

must be the touchstone by which the action proposed should be proved.

No disease should be looked on as insignificant. Nothing seems less becoming than to hear medical men speaking lightly of disease in general, or of any disease in particular. It is no consolation to the mother whose child has died of one of the rare complications of chickenpox to find that many physicians think that too trivial to concern themselves with it. Nor does it increase confidence in the profession to have hysteria and neurasthenia considered imaginary and ridiculous evidences of perversity, while the impatience, not to say lack of scientific interest sometimes shown toward other less well-defined neuroses, undoubtedly has some relation with the crowded ranks of followers of isms of all kinds.

In acute diseases the best general rule is still that of Hippocrates (Prognostics; 19, sect. ii): "In acute disease it is not quite safe to prognosticate either death or recovery." A case of this kind, however, should not be considered likely to result in death unless from a complication, or from the effect of a preexisting disease, though in certain diseases, such as scarlet fever and diphtheria, the danger of a sudden change and of death should be made known in the beginning. Of course, in cholera and plague, and even in cholera infantum, such information is rarely necessary. In some other acute diseases the study of prognosis prepares the physician not to be unduly elated by the remissions that are so reassuring to relatives. The temporary amelioration in meningitis and peritonitis, in which the patient seems almost free from symptoms, may be mentioned. Less disappointing, but still ominous, is the occasional lull in bronchopneumonia. But in the cases I have just mentioned it is rarely advisable to bring the unfavorable probabilities too strongly before the patient. In these we often need the effects of reassurance and of hope. For the latter as we see it in medical practice is not merely the "kind nurse of old age—hope—which," as Pindar says, "more than aught else steers the capricious will of mortal man;" in acute cases, especially, it is distinctly stimulating to physical and mental processes. Sir Dyce Duckworth,¹ speaking from a ripe experience, recently gave an address on "Hopefulness in Medicine," in which he emphasized this fact, and Niemeyer, equally successful in his career, at his medical promotion defended among others the thesis *medicus semper hilaris*. On the other hand, it is a serious error not to point out, after recovery from certain acute diseases, the possibility of sequels, sometimes months or years afterward, and the advantage of examinations at intervals for the purpose of detecting them before they become inveterate. The thorough examination of the urine at intervals after scarlet fever, of the lungs after pleurisy and all bronchitic diseases, of the heart and arteries after many infectious diseases, often has great practical value.

In chronic diseases there are few exceptions to the rule that the patient should be told the nature of his case as fully as possible. At least, in patients who can be made to understand, and who have a possibility of recovery, of definite improvement or of long duration, there are only individual exceptions. Patients with tuberculosis, heart disease, kidney disease, and disease of the alimentary tract cannot get the best possible results unless they understand why and how they should do certain things and why they should avoid others. Tact and patience and a knowledge of human nature are essential in this. The statements made should be as simple as possible, as brief as definiteness permits, without pathologic explanations. Better no statement than an unconsidered or an unintelligible one.

In talks of this kind we too often forget how different are the ideas of nonmedical persons, even of those who have studied physiology in the public schools, from our own, regarding the body, its functions and diseases. I am always interested in seeing how soon medical students lose the lay point of view, just as one forgets an unused foreign language, and how sometimes they never recover it. Yet unless they do, they lack valuable means of giving aid. Darwin has noticed how every one who studies profoundly a subject often becomes unaware on what points the ignorant require information. Carlyle, as John Beattie Crozier tells us, imagined his stomach as some old

teakettle, thickly encrusted with fur, and I have seen an otherwise intelligent man on the point of using strong sulfuric acid for a cough, because he found by experiment that oil of vitriol dissolved sputum more quickly than any other reagent he had tried. Nor is it enough to make the explanation. We must ascertain whether the statements are understood, and, if possible, whether they are accepted. How often, even with an intelligent individual, after we have stated the existence of a small tuberculous focus, and described the results of rational treatment, we find the patient shutting himself in a dark and close room, taking "lung cures," cough syrups, and more or less medicated cod-liver oil; and how often, after demonstrating the sufficiency of dietetic treatment in a digestive disease, we find the patient taking bitters, digestive ferments, usually well neutralized by alcohol, antiseptics, and other drugs less easy to classify. So time and patience must be devoted to this part of the work, and we should never be discouraged by failure. I am convinced that there is an improvement in the possibility of carrying out rational treatment, notwithstanding the insidious propaganda of useless or dangerous methods in and out of medical journals.

It is much easier to advise in cases that have a strong tendency to recovery than in those that have not, and there is room for difference of opinion and of practice in the latter, because the conditions vary with patients according to individuality and accidental factors. A number of aspects present themselves for consideration. In the first place, there is often an element of diagnostic or prognostic uncertainty, where the prospects are better than they seem. Sir Dyce Duckworth¹ has formulated universal experience in pointing out the advantages of the "cautious 'if,'" and if the alternative accepted is the hopeful one, much good can be accomplished in many cases. An interesting example is given by Kussmaul in his fascinating "Jugenderinnerungen." Having made a reputation as a zealous dissector, and having won over his confiding peasants to the many advantages of postmortem examinations, he was asked by the father of a girl with advanced tuberculosis of the peritoneum to arrange for an autopsy on the daughter when she died. Although Kussmaul, too, thought the daughter was lost, he retorted that he could not speak of an autopsy until the patient was dead. Notwithstanding many obstacles, the girl recovered. The tendency to take the less hopeful alternative is still shown in some cases of tuberculous disease in stages not far advanced, though it is not so common, fortunately, as it was not many years ago, to see such patients given over either to a life of dissipation or of abject despair. The prognosis of valvular disease of the heart is also in a much more optimistic vein than it was 50 or even 25 years ago. However, in many cases the prognosis needs to be tested by a therapeutic "if" that is not as well recognized as it deserves. The physical conditions may seem hopeless, and yet if the action of the heart can be improved, the case may assume a very different aspect. The advantages of trying were well illustrated by a case in which a woman with aortic and mitral insufficiency and moderately severe loss of compensation was given up as beyond treatment by her family physician. Not knowing this, I told the relatives the impossibility of complete recovery, the danger of sudden death or more probably rapid failure at any time, but also the possibility of improvement and a fairly comfortable life for some time, all the more worth trying to realize, because the condition was not complicated by medicinal action, and the other important organs showed no serious alteration. The family physician then wrote me admitting that he had stated improvement was out of the question, and treatment not worth trying, although under subsequent treatment the patient lived two years and nine months.

In cases hopeless in a more certain degree than such as I have just mentioned, it too often happens that treatment is abandoned too early in the case. Patients with cancer of the stomach or other inoperable tumors, cirrhosis of the liver, and many other diseases are permitted to drag out their existence without relief. There are several reasons for this. Sometimes families, having been told the truth about such a patient, refuse

¹ Duckworth, Sir Dyce: Opening of University of Liverpool Medical School, British Medical Journal, October 3, 1903.

¹ Duckworth, Sir Dyce: Address on Medicine, British Medical Journal, 1890, II, p. 251.

all further medical aid, even when the conscientious physician who gives the information, points out what can still be done.

Many physicians voluntarily discontinue attendance when they realize that the end is inevitable, with the feeling, doubtless, expressed by Sir William Temple. The latter said that "an honest physician is excused for leaving his patient when he finds the disease growing desperate, and can, by his attendance, expect only to receive his fees, without any hopes or appearance of deserving them." This, however, ignores the fact that in such cases the accomplished physician can often do more real good to the patient than in many cases ending in recovery, while the opportunities for obviating despair, alleviating pain and soothing mental anguish, and for exhibiting thoughtfulness, gentleness, persistence and variety of resources, are more valuable to the physician than any fee. Even in acute cases it sometimes happens that the physician is either discharged or withdraws because the indications seem hopeless, and I have known of patients with pneumonia living for one or two days in this way, the family waiting for the end of a life that with greater effort might have been saved. Sir Francis Bacon described this tendency as one of the deficiencies of medicine, "so that Sylla and the triumvirs never proscribed so many men to die as physicians do." For, as he continued, "the office of a physician is not only to restore health, but to mitigate pain, and not only when such mitigation may conduce to recovery, but when it may serve to make a fair and easy passage."

Improvement in methods of treatment has an important relation to prognosis, in that many diseases considered hopeless at one stage of knowledge, may in another, offer many chances for recovery or alleviation. In this connection a critical knowledge of current medical literature is necessary, and a realization of the value of medical evidence. Few things can be more disastrous to the physician's mental development—never completed—than constant change of therapeutic method, but there are differences. One need not try every drug proposed for the treatment of typhoid fever or pneumonia, nor every new antipyretic or hypnotic. But the physician who does not inform himself quickly of the value of surgical treatment in various disease as it is developed, in pelvic diseases, brain diseases, diseases of the appendix, biliary tract, stomach and pancreas, comes very near deserving the reputation of an unscrupulous practitioner. In these departments, too, mistakes are made and exaggerations are inevitable concomitants of progress, but the gain is often distinct and unmistakable and often changes the prognosis from one extreme to the other.

It may seem that I have taken a too purely medical view of the practice of prognosis. Can we always act from the standpoint of simple diagnosis and prognosis, or must we not at times take into consideration the weakness, fears and prejudices of people? In trying to get the best light on this subject I have for many years noticed the opinions of patients and their relatives, as well as of nonmedical writers, and it is instructive to learn how those who are not physicians approach the subject. Many physicians have been influenced by the views of Percival, from whose interesting work on "Medical Ethics" some of the best parts of the old Code of the Association were taken. Percival said:¹

A physician should not be forward to make gloomy prognostications, because they savor of empiricism, by magnifying the importance of his services in the treatment or cure of the disease. But he should not fail, on proper occasions, to give to the friends of the patient timely warning of danger, when it really occurs, and even to the patient himself, if absolutely necessary. This office, however, is so peculiarly alarming, when executed by him, that it ought to be declined whenever it can be assigned to any other person of sufficient judgment and delicacy; for the physician should be the hope and comfort to the sick; that by such cordials to the drooping spirit he may smooth the bed of death, revive expiring life, and counteract the depressing influence of those maladies which rob the philosopher of fortitude and the Christian of consolation.

In general, this furnishes a useful guide to conduct, but nevertheless requires some examination. Part of it reminds

one of the maxim of John Halle, who as far back as 1596 wrote:

With one consent uniformlye
Comfort the wounded man,
But unto some good friend of hys
Express all that you can.

In the first place, the truth is not always so alarming to the patient, painful as it often is to the physician. In fact, it seems to me this is one part of our duties that does not become less trying with increasing experience. To the sick man, whose thoughts have been turned toward the end longer than others suspect, intimation of a fatal end often brings no shock, but rather relief from the ending of a painful uncertainty. According to the rules of the Roman Catholic Church, a timely announcement should always be given, and those who have witnessed the last days of members of this faith can confirm the statement that good often follows, speaking merely from the medical standpoint, and rarely harm, while the same thing is true of many other faiths, or of no faith. Even when we have to give a fatal prognosis, there are certain mollifying influences that can be introduced, aside from those that spring from a tender heart. A hope can be expressed, based on the fallibility of human knowledge in general, and medical knowledge in particular.

The rule in regard to giving the patient a good prognosis and the relatives a bad one, can often be followed, but it is a very fallacious one, on the whole. It is often more necessary to keep up the spirits of the relatives, especially those who have to nurse, than those of the patient, so that sometimes the rule can be reversed with advantage. Darwin¹ cites some interesting and instructive examples of this kind, from his father's practice, and Billroth² has expressed himself with much feeling in one of his letters. Moreover, the relatives informed, either from a feeling of compassion or otherwise, may not bring the patient to act on the information, and I have known of serious financial loss befalling a family because the relative entrusted with the task of breaking the news to the patient did not do this. Another risk is that the relatives may divulge the fatal prognosis in such a way as to put the physician in the light of a heartless deceiver, and thereby cause the patient to lose all confidence in him. On the whole, in cases where the patient should know the truth, the physician is often the best one to state it, and he should see that this is done before it is too late.

Exceptions to the rule of candor may occur in the case of children, in women with no spiritual obligations or business responsibility, or in exceptional cases in men. No general rule can be laid down, but that such exceptions occur can be confirmed probably by every physician. A striking example of this is quoted by Darwin.³

¹The Life and Letters of Charles Darwin, edited by his son, Francis Darwin, New York, 1887, vol. 1. "Called in to see a patient who had been given up to die by the family physician. Dr. Darwin took a different view of the matter and maintained that the man would recover. He was found quite wrong in all respects, and owned his error. He was convinced that he should never again be consulted by this family, and was much surprised at being called in after a few months by the widow. He asked a friend of the widow to find out why he was again consulted. The widow answered that she would never again see the odious old doctor who said from the first that her husband would die, while Dr. Darwin always maintained he would recover. In another case Dr. Darwin told a lady that her sick husband would certainly die. Some months afterward he saw the widow, who was a very sensible woman, and she said, 'You are a very young man, and allow me to advise you always to give, as long as you possibly can, hope to any near relative nursing a patient. You made me despair, and from that moment I lost strength.' 'My father,' continued Darwin, 'said that he had often since seen the paramount importance for the sake of the patient of keeping up the hope, and with it the strength of the nurse in charge.'"

²Briefe von Theodor Billroth, 1902: Speaking of the slow decline of Professor Breisky, and of the attending physician telling the whole truth to the wife, he remarked: "I admit that under certain circumstances this is necessary; but here I do not think it is necessary. How can the poor wife, without a glimmer of hope, bear the weeks until the liberator of all sorrows gently approaches the husband. We should give her courage, and the poor patient morphin. A hard task. But let us remember that every family physician is in this situation hundreds of times, and often has to see his incurable patients daily. If the young man suspected these mental tortures when he enthusiastically enters the temple of Æsculapius he would surely often turn back. To face the unveiled figure of Sais requires all the undaunted resignation that we slowly win in our profession."

³Op. Cit. "He was sent for by Mr. P., who said: 'From all that I have seen and heard of you, I believe that you are the sort of man who will speak the truth, and if I ask you will tell me when I am dying. Now I much desire that you should attend me, if you will promise, whatever I may say, always to declare that I am not going to die.'"

¹Medical Ethics: or a Code of Institutes and Precepts, adapted to the professional conduct of physicians and surgeons, with an appendix containing a discourse on hospital duties; also notes and illustrations, by Thomas Percival, M.D., Manchester, 1803, p. 31.

Of course, this part of the subject is closely related to the theory of ethics, and many writers on this subject have touched directly on the question of medical veracity with, as one might anticipate, diametric differences of opinion. Some moralists of the strict school of Kant and Fichte insist that any deviation from the absolute truth is wrong in medicine, as they assert that it would be wrong even for the purpose of saving the whole race. Others believe with Paulssen, who says: "There is not a physician in the world who does not give deceptive answers to his patients, who does not excite hopes that he does not share. He does not blame himself, nor do others, for everyone does the same." Johnson, "the stern old moralist," in his remarks on the subject, laid open a serious flaw in his own logic: "You have no business with consequences, you are to tell the truth." But surely the physician's chief interest is with the consequences, and if he thinks the patient can gain only by misrepresentation, it is just as proper for him to use it as it would be to give a medicine that in other cases might be quite improper. But the physician in such a dilemma would do well to bear in mind the next sentence in Johnson's *ipse dixit*: "You are not sure what effect your telling him that he is in danger may have. It may bring his distemper to a crisis, and that may cure him." Jonathan Dymond, as strict as any one in his morality, threw a gleam of stern humor into the discussion: "Persons frequently employ falsehoods to the sick man who cannot recover, lest it should discompose his mind. This is called kindness, though an earnest preparation for death may be at stake on their speaking the truth. There is a peculiar inconsistency sometimes exhibited on such occasions. The persons who will not discompose a sick man for his interest in futurity, will discompose him without scruple if he has not made his will."

This part of the discussion might be indefinitely prolonged, but I think we can never get far away from the principle I intimated in the beginning—that in practical prognosis we must individualize, just as we have to in therapeutics, with the patient's welfare ever the object of our activity.

Accidents that follow an unfavorable prognosis occasionally suggest a revision of methods. I have already alluded to the error formerly not uncommon in the treatment of tuberculous patients. More acute results sometimes follow a fatal prognosis, as in two of my patients who resorted to suicide. One was a man with far-advanced carcinoma of the stomach, to whom I recommended palliative treatment and advised against a useless effort at radical treatment. The patient left for his home, but threw himself from a fast train and was killed. In another patient, a man with a large kidney tumor, apparently with many adhesions, my surgical colleague and I advised against an operation. The patient went to another hospital, and apparently received similar advice, for he shot himself through the tumor, and died in a short time. From a broad biologic standpoint it does not, of course, make any difference whether an individual organism dies as either one of these, or as it would if left to its fate. But no matter how one may feel on the subject of suicide, I have always thought these men less fortunate than another patient with carcinoma of the stomach, also far advanced. To him, in advising against an operation, I added that if he could find a good surgeon who was willing to operate, he might submit. He underwent the operation at the hands of one of the most distinguished surgeons in the country, and died on the table. In such a case the result is often unfortunate, because it prevents operations on other and more promising cases, but for the man himself, fighting to the last, it seems to me one can have only respect.

This brings up a question on which a few words may be proper—the question of euthanasia. Every few months some one—usually not a physician—proposes that people with incurable diseases should be killed by some painless method. The plan offers so many opportunities for crime that it would be difficult to carry out, but aside from that it involves important principles. The difficulty of telling when the proper time had come would often be insuperable. Aside from examples of fortitude and other virtues exhibited by the dying, how much the world would have lost if a chronic invalid like Stevenson had the cord of his life snapped at one of the times when the *œs triplex* of his soul seemed battered through! To take a less

selfish view, we can think of the "pictures of human patients, the visions of ripened character, which have been revelations and inspirations to generations of mankind" (Phillips Brooks), and see these repeated daily in sickrooms of all degrees, while the self-sacrifice and kindness developed in others at such times can not but be of untold benefit to the race. To most physicians the suggestion of any planned shortening of life must be abhorrent. For countless generations they have been doing their utmost to lengthen life and lessen disease. They have shown how to prevent the plagues that formerly made life almost as bad as a perpetual illness for the survivors, and they have also shown how many deaths can still be prevented. On the other hand, they can, in most cases, so treat the dying man that the bitter anguish often associated with death is absent, that life is not only less painful, but actually longer, so that they will continue to follow the rule of the Father of Medicine and "give no deadly medicine to any one, even if asked, nor suggest any such counsel."

THE ASSOCIATION OF SURGICAL LESIONS IN THE UPPER ABDOMEN.¹

BY

WILLIAM J. MAYO, A.M., M.D.,

of Rochester, Minn.

Surgeon to St. Mary's Hospital.

Surgery must be judged on three grounds: 1. The mortality of the operation itself, and the question whether this is greater than under the expectant plan. 2. The permanence of cure contrasted with medical treatment. 3. The question of disability, either introduced by the operation itself or the natural length of time which the healing process involves. On each one of these considerations we must answer yes, and we can go still farther and say that earlier operation would reduce the mortality and increase the permanence of cure and lessen the disability.

Certain parts of the body are so closely related in their anatomy, function, and pathology as to be almost necessarily considered as part of the same system. The generative organs of women form so distinct a field of work as to have built up a specialty. Can we separate diseases of the kidney from the ureter, bladder, and urethra? By no means. Each may stand in an etiologic relationship to the others which can not be ignored.

In the upper abdomen we have attempted to study the stomach independent of the associated organs, the liver and bile passages, the duodenum and pancreas. The result has been a confusion in diagnosis and treatment. The palm of a hand may cover a serious lesion of any one of these organs, and that, too, at the point of greatest liability; not only so, but any one of this group may start a pathologic process which may extend to any one of the others, and with fully as great frequency as occurs under similar conditions in either the generative or urinary systems.

Note the disturbance of the stomach which occurs with gallstone disease, the adhesions to the duodenum and the pancreatitis, an association direct as it is vital. Again, let me call attention to chronic ulcer of the stomach with adhesions to the pancreas, secondary ulcer of the duodenum adherent to the bile passages or gallbladder. These are not fanciful pictures, but drawn from everyday work. I have no hesitation in saying that with an operative experience of over 1,400 cases of this description, mistakes in exact diagnosis are still common, and in many instances unavoidable. The history may be the only valuable diagnostic resource when the patient comes to us, and we all know how unreliable that may be. Given a history of painful attacks which have been very severe, but which have completely ceased, with tenderness on deep palpation in the epigastrium, and we may have disease of any one of these four organs, and not infrequently an association either direct or indirect of the pathologic process. If we clearly understand the possibilities of error, we are better prepared to meet com-

¹ Oration on Surgery at the fifty-fifth annual session of the American Medical Association at Atlantic City, June 7-10, 1904. Published synchronously with the *Journal of the American Medical Association* by courtesy of the Editor.

plications or execute a change of front and operate on one organ when another procedure was planned. In the majority of cases a pathologic diagnosis is possible, and one can say with certainty, "this is gallstone disease," or "this is ulcer of the stomach"; but in a considerable minority a surgical diagnosis is the best that can be made. That is, we can say: "In this locality is a diseased process which requires operative treatment, the exact nature of which must be determined by incision." The patient does not come to us for the purpose of having a certain operation performed, but seeks relief from suffering and disability.

The anatomic diagram shows the nearly vertical position of the stomach with the pylorus in the middle line of the body, and but little elevated above the lowest point of the gastric cavity. It is turned upward and to the right just enough to prevent the weight of the gastric contents bearing directly on the sphincter apparatus. The only portion of the duodenum in which we are interested is the four inches lying between the pylorus and the papilla of the common duct of the liver and pancreas. This may be called the vestibule of the small intestines. Its position subjects it internally to the perils of ulcer from the acid gastric juices which its thin tunics but inadequately resist. Externally its function is often interfered with by adhesions to the gallbladder and bile tract, secondary to gallstone disease. This unoffending bit of intestine is so often offended against as to cause it to become the most frequently diseased portion of bowel of the same length. The remaining eight inches of the duodenum is protected by the alkaline secretions of the pancreas and liver. Its fixed position and peculiar horseshoe shape, with its delivery point nearly as high as its origin, enable it to mechanically slow the ingested material during the mixing process for which its large caliber affords accommodation.

The anatomy of the bile tract is equally interesting, and especially the relations of the common liver duct to the pancreatic duct and the duodenum. There is continuity of mucous surface, each protecting itself from the secretions of the others by the mechanical washing effects of its own secretion, the joint discharge and a feeble sphincter apparatus preventing entrance of the duodenal contents.

The gallbladder, as it furnished the initial lesion in more than half of the diseases of this group, is of great interest. Like the appendix, an obsolete organ of storage function and limited outlet, it gives rise to a variety of troubles, which we are only of late beginning to appreciate. It is an old aphorism that "Nature finds mischief for idle hands to do." The gallbladder has a capacity of about an ounce, and as we find almost universally in organs of storage function, the neck is raised slightly about the lowest point to prevent the weight of contents resting directly against the outlet. The little pouch thus formed may be called the pelvis of the gallbladder (Brewer). It is here that the obstructing stone is so frequently lodged in cystic impactions. Murphy observes that the fundus of all organs has but few lymphatics, while the region of the neck has an abundant supply; hence, even with septic contents, there is but a mild reaction when the pelvis is obstructed, as compared with the startling temperature curves of duct stones.

The pancreas, composed of two originally separated parts, has in nearly half of the specimens which have been examined, two patent ducts, that of Wirsung, which is the important one, uniting with the common liver duct. The minor duct of Santorini, however, has a possibility of useful function in certain diseased processes, as pointed out by Opie. The pancreas was originally an intraperitoneal organ, becoming retroperitoneal by a later evolution (Huntington), and in this anatomic peculiarity Brewer believes lies one of the reasons for the diffusion of fat necrosis resulting from acute pancreatitis. Mikulicz has called attention to the fact that adhesions to the pancreas in gastric cancer gave a mortality of 73% in his resection cases. Robson also notes the pancreatic mischief occasioned by perforating gastric ulcer on the posterior wall.

The blood supply of this group of organs is almost entirely from a single source in the celiac axis. It has been experimentally developed that the severance of all connections of the pancreas excepting its blood supply, does not check secretion if food is placed in the gastrointestinal tract. In the nerve

supply from the pneumogastrics and sympathetic ganglion, we find the same direct relationship involved. If we study the function we see the same association. The stomach can be compared to a mill, the fundus the hopper, in which the food is macerated in a weak solution of pepsin and hydrochloric acid, and the muscular pyloric portion the grindstones in which the masses are broken up into a homogeneous whole. The entrance of food into the duodenum causes the outflow of biliary and pancreatic secretions, the absorption returning to the liver by way of the portal vein. This is so elementary that you wonder that I should refer to it, yet the causation of the common surgical lesions lies in perversion of these fundamental functions, and is just as simple. Mechanical injury of the pyloric portion and excessive acidity of the gastric secretions, under anemic conditions, give rise to ulcer and lie behind the precancerous lesions which Ochsner notes are found in the history of cancer of the stomach in the majority of cases. The acidity of the gastric secretions renders the contents of the stomach, when turned into the intestine, relatively sterile, but increases the liability of ulcer of the duodenum. The sterility of the upper intestinal tract is still further increased by intestinal absorption, as shown by Adami, the bacteria being picked up and destroyed in part by the glands. Many germs are, however, carried to the liver, and here either annihilated or screened out of the blood in the portal vein and discharged with the bile. We must look on the bile as always containing a few bacteria, and it is probably this attenuated infection of bile retained in the gallbladder which gives rise to gallstone disease, which in turn is the chief factor in the production of duct inflammation of both the liver and pancreas.

These considerations, so briefly outlined, taken in conjunction with the embryologic origin, justify the grouping of the *surgical lesions of the upper digestive tract*, and at once enable the diagnostician to associate the symptoms, and the surgeon to direct his attention, not to one, but to the entire group of organs. The burden of proof lies with the practitioner, not only to demonstrate that the disease rests in one organ, but to differentiate and show that no other is involved.

The art of the diagnostician lies in the proper valuation of the signs and symptoms of disease in organs of associated function and pathology. The instinct which seems to lead some men to a correct conclusion, and by a mental process they could not themselves analyze, usually depends on few things, the immaterial or inconclusive evidence being unconsciously discarded. For instance, note the value of the colic in the diagnosis of gallstones. The typical attack comes on and stops abruptly, is relieved by vomiting or a feeling of movement of gas, is irregular in time, in regard to food, and not accompanied by temperature or pulse elevation, and leaves the patient able to attend her duties almost immediately after cessation of pain. While the pain lasts, it is excruciating, felt in its greatest intensity in the epigastrium, radiating upward behind the sternum and into the back. The distress penetrates to the right side, but occasionally to the left, and lasts from a few minutes to six or eight hours. When the patient comes to the physician it may have been years since the typical attacks; he may have forgotten them, the present trouble complained of being pain, digestive disturbance, and tenderness on deep pressure over the gallbladder region. The history of the early attack is worth more than the physical examination in many cases. Compare it with the pain in gastric or duodenal ulcer, which may be just as severe, but lasts a day or two longer, especially when due to regional peritonitis, and is accompanied by gastric symptoms and local tenderness. The patient diets, which means he reduces his food supply. The symptoms last more or less for some days or weeks, and the interval of apparent cure gives some weeks or months of comparative health.

Acute perforations of the organs of this group are relatively common and give rise to symptoms which would be at once recognized if they occurred in the region of the appendix, but occurring in the upper abdomen too often go to a fatal issue unoperated. The initial symptoms are remarkably alike, whether of the gallbladder, the duodenum, stomach or acute perforation of the pancreas with fat necrosis. The onset is essentially the same in each. Sudden extreme epigastric pain, with collapse, ushers in the attack, and muscular rigidity, as

a rule, comes on early. The diagnosis of perforation, if we are on our guard, is easy, although it may be difficult to say which organ is affected; but this does not make any difference. The vital consideration is that it has happened, and immediate operation must be performed.

In 811 operations on the gallbladder and bile tract we had four acute perforations of the gallbladder, with but one recovery, although the average mortality in the benign series was but 4.47%. In 45 operations for duodenal ulcer, four acute perforations occurred, with two recoveries, while in the 41 operations for subacute and chronic ulcer there was only one death. In 469 operations on the stomach, five perforations occurred, with two deaths. In 32 operations for diseases of the pancreas, there was only one operation, for acute pancreatitis and fat necrosis, with recovery. This gives 14 cases of acute perforation, with a mortality of 50%, and why? Because the operation was usually too late. The deathrate in over 1,150 operations for subacute and chronic benign conditions of this group of organs averaged a little less than 5%, counting as a death from operation any patient dying in the hospital without regard to cause or time elapsed between the operation and the fatal issue. If we add to this mortality of 50% in operations for acute perforation, the cases seen in a moribund condition beyond even attempt at relief, and the still larger number in which death occurs without an antemortem diagnosis, we get some idea of the appalling nature of the disaster. To be successful, operation must be immediate; the condition is as imperative as hemorrhage from an artery of the third class. Few recover operated on later than ten hours after perforation. The conditions simulating perforation in the upper abdomen, such as thrombosis of the mesenteric or splenic vessels, diaphragmatic and duodenal hernia with strangulation, and so forth, are rare, and likewise call for early operation.

As a rule, the history and location of the early acute pain will furnish evidence as to the origin of the trouble. Preceding perforation of the gallbladder there are often symptoms of several days' duration with a history of gallstones. The acute pain occurs in the gallbladder region. Early drainage with removal of the gallbladder should give a mortality of not to exceed 10%.

Duodenal perforation usually occurs in cases of chronic ulcer with years of symptoms preceding; but the immediate onset is exceedingly acute, and not ushered in by a few days or hours of prodromes, as is often the case with the gallbladder. The location of the early pain is just to the right of the median line. The liquids gravitate at once to the appendiceal region and simulate perforated appendix. The rapid diffusion of escaping contents is fatal to delay. Operation for acute perforation of the duodenum is rarely successful after eight hours. Suture of the perforation with suprapubic pelvic drainage, and after-treatment in the sitting posture (exaggerated Fowler's) in early cases should give 80% or more of recoveries.

Gastric perforations occur on the anterior wall, according to Brunner, 7 times to 1 posterior, and near the cardiac end 5 times to 3 times in the pyloric portion, and near the lesser curvature 122 times to 16 times near the greater curvature. The initial pain is usually to the left of the median line, and early diffusion of fluids is to be expected. Only 10% occur without previous symptoms of chronic ulcer. The results of operation being in direct ratio to the amount of gastric contents, and the length of time which has elapsed, the treatment is similar to the duodenal ulcer.

The term, perforation of the pancreas from inflammation with resulting fat necrosis, is a purely pictorial expression, and not a pathologic entity in the sense the word is used in the preceding remarks, yet it conveys the idea and calls attention to the value of peritoneal drainage in its treatment, as shown by Woolsey. The symptoms are sudden pain in the epigastrium, collapse, and early extreme distention of the abdomen. On opening the peritoneal cavity, free fluid, often of a hemorrhagic character, is evacuated. The little fatty masses in every direction and the enlarged pancreas call attention to the source of the trouble. This particular phase of acute pancreatitis cannot be separated from the hemorrhagic type, in which treatment is as yet in an unsettled state. Those interested in this question will find a mine of information in the Hunterian lectures for 1904 by Mayo Robson.

The group of acute perforations gives an unsatisfactory mortality, with a prolonged period of disability from drainage, and without a certainty of permanent cure of previous underlying conditions. This will not long continue. Like acute gangrenous appendicitis, the condition will be recognized early with corresponding improvement in results.

The diagnosis of the chronic infective lesions of the organs of this group is in a far more satisfactory condition. The general mortality of gallstone operations is not above 5%, taking the cases as they come, but even this is too high. Grouping the cases in which the entire process is limited to the gallbladder, the mortality is from 1% to 2%, and depends to a large extent on the general condition of the patient. Secondary complications, chiefly those which involve the hepatic and common ducts with resultant cholangitis, pancreatitis, and so forth, are responsible for the deathrate. As practically all of the patients have symptoms on which a diagnosis could be based previous to the complications, it will not be long before early operation in patients otherwise in good health will be the rule as it is now in chronic and relapsing appendicitis. Not only is the mortality thereby reduced, but the disability is likewise lessened. The average stay in the hospital for uncomplicated gallstone patients is slightly less than 17 days; the convalescence of the complicated duct cases is prolonged one or two weeks.

Chronic infections of the pancreas are usually secondary to gallstone disease, and, as a rule, do not occur excepting where the common duct has been directly irritated by the presence of calculi, although the consequences may continue for some time after the passage of the offending body. The results of drainage of the gallbladder and bile ducts are extremely satisfactory. In our series of 32 cases there were but 2 deaths; these patients had coincident suppurative cholangitis.

Chronic infective lesions of the stomach with ulcer as a type are becoming better understood every day, as surgical operation discloses the actual conditions present. The primary mortality of operations for their relief is in a fairly satisfactory condition, but as to ultimate results we can not say definitely. For the obstructive complications the result of ulcer, there can be no question as to the relief afforded and at a nominal risk. The dilated stomach with retention or stagnation of food suggests at once drainage operations with gastrojejunostomy as the type. We have patients of this description alive and well more than 12 years after operation.

Chronic ulcer without mechanical obstruction gives a less promising outlook. The very fact that there is normal gastric motility indicates that gastroenterostomy or other drainage operation is less necessary. Our results in operations for this description of lesion have not been wholly satisfactory, and furnish a considerable percentage of secondary operations and failures to relieve.

Cannon's experiments have shown the same results. A gastroenterostomy on a normal stomach of an animal does not drain the gastric cavity, even if placed at the lowest point. The gravity advantage of the gastroenterostomy is overcome by intraabdominal tension, and the food, by muscular action, is carried out the pylorus rather than the artificial opening. The magnificent showing of gastroenterostomy in obstruction has led to the indiscriminate performance of the operation in those cases of ulcer in which gastric drainage is normal. This particular phase of the subject must be further investigated.

Chronic ulcer of the duodenum is relatively more common in the upper two inches than in any corresponding portion of the stomach. It is especially liable to perforate, although its sheltered situation usually leads to adhesive protection. Many pyloric ulcers will be found to have their origin on the duodenal side. Gastroenterostomy is the operation of choice, as it diverts the irritating gastric juices and food products from the sensitive surface, thus promoting rapid healing. We have performed gastrojejunostomy 286 times for all purposes, with a mortality of 5.5% in the benign series. The recent improvements in the technic of gastroenterostomy has greatly reduced the mortality and largely eliminated the causes of failure to relieve mechanically the conditions. Moynihan well says that "the surgeon may not unreasonably expect that from being a last resource, gastroenterostomy may be considered as a method of treatment worthy of consideration in a much earlier stage of

chronic ulcer of the stomach." Excision of gastric and duodenal ulcers would seem to be a wise procedure, but is open to certain strong objections. In 20% of cases more than one ulcer is present, and one or more may be undetected or lie in an inaccessible situation. It leaves the ulcer tendency unrelieved, and more ulcers may form. Rodman has suggested the removal of the pyloric or ulcer-bearing portion of the stomach with complete closure of both duodenal and stomach ends and independent gastrojejunostomy. We have followed this plan in five cases of inveterate ulcer relapsing after gastroenterostomy, with good results. The gastroduodenostomy of Finney is a most excellent operation, and we would predict a wider field of usefulness than it has enjoyed. We have performed this operation 46 times, with one death, and no relapse. The theoretic objection is that in open ulcer the food must pass the ulcerated area before reaching the widened pylorus, and obstruction has no part in the production of ulcer, as is shown by the development of duodenal ulcers. Pyloroplasty must be discarded. While we had no death in 20 operations, we had seven relapses.

In briefly calling attention to the malignant diseases of this group of organs, the writer would emphasize the possibilities of cure by means of operation. In the gallbladder we found 4% of cases at the operating table had malignant disease, and all of these cases had gallstones present or evidence that they had been present at one time.

Since it has become the practice to remove all thick-walled gallbladders as useless and a possible source of future trouble, many cases of malignant disease in an early stage have been in this way, as one might say, accidentally cured. We have met with several such instances.

Cancer of the stomach is the most common type of malignant disease in the human body, constituting a fourth to a third of the total number. The radical treatment of gastric carcinoma is now on assured ground, with a mortality of 10%, or less in favorable cases, to 20% in late but still operable disease. The only necessary thing for success is an early diagnosis, and this must be on clinical grounds, supplemented by early exploratory incision. In 46 gastric resections for pyloric cancer we had seven deaths.

The profession may well look on the surgical achievements in this new field of work with pardonable pride. That there are many shortcomings must be admitted, but in the history of surgery there has never been a territory opened up with equal rapidity, nor one in which the physician and surgeon have worked together in such harmony for the common good. The statistics on which this paper is based represent the operative experience of Dr. Charles H. Mayo and myself.

PREVENTIVE MEDICINE: ITS ACHIEVEMENTS, SCOPE, AND POSSIBILITIES.¹

BY

HERMANN M. BIGGS, M.D.,

of New York City.

General Medical Officer, New York City Department of Health; Professor of Therapeutics and Clinical Medicine and Adjunct Professor of Medicine, University and Bellevue Hospital Medical College.

The terms sanitary science, public or State medicine, and preventive medicine, have frequently been used as almost synonymous. The latter term, "preventive medicine," however, has sometimes been restricted in its application to the prevention of the infectious diseases. In the broad sense, preventive medicine comprises both general prophylaxis and individual prophylaxis, and applies to all forms of disease, not simply to the infectious diseases. Preventive medicine is an applied science, which deals with the preservation of the health both of the individual and of the community.

No subject more vitally concerns the welfare of a community than that pertaining to its healthfulness. How the inhabitants live and how and at what age they die, what is the extent and character of the morbidity occurring among them

and what are its causes, are questions of momentous importance. They are essential features in the problem, whose solution will teach men how they may live longer, healthier, and therefore happier lives.

In rural districts the average healthfulness of the inhabitants depends largely on natural conditions, such as elevation, climate, soil, and to a much less extent, on the artificial conditions produced by the handwork of man. In densely populated cities, on the contrary, the natural conditions become relatively unimportant features in determining the degree of healthfulness, so much do they become subordinated in many cases to the artificial conditions which have resulted from the lives, labor and occupations of the inhabitants. It may be said with certain limitations that the inhabitants of any city in the temperate zone now have it largely within their power to determine what degree of healthfulness their city shall have. A high morbidity and a high mortality in any urban population depend largely on some remediable features of an unsanitary character, such as the sewerage of the city, the occupations, habitations, food, and water-supplies, and the habits of the inhabitants—all factors which lie to a great extent within their control. Hence, when any city in modern times has a high annual deathrate—for example, 30 to 35 per 1,000, as was formerly the case in New York, Liverpool, and other cities, instead of a deathrate of 17 to 18 or 19 per 1,000, as now exists in London, Berlin, and New York, it is because conditions are permitted to exist partly from the neglect, indifference, and ignorance of the people, and partly from the lack of proper facilities and necessary efficiency on the part of the authorities.

The achievements of scientific medicine have now placed at the disposal of the sanitary authorities such full knowledge as to the causation of so large a proportion of the diseases producing death, and of the means by which they may be restricted or prevented, that the determination of the average deathrate is in their hands. This statement is not, of course, intended to mean that it is now possible to prevent or stamp out local epidemics of influenza, pneumonia, cerebrospinal meningitis, and some other infectious diseases, but it is intended to cover the average general deathrate of a city for a series of years.

The expectation of life at birth in certain manufacturing cities of England has been but little more than half that of the healthiest districts of England. Until recent years it was 25 or 26 years in Liverpool and Manchester, 37 years in London, and 46 years in Surrey, a healthy country district. Even at the age of 30, the expectation of life was seven years more for England, as a whole, than it was for the inhabitants of Manchester. I have estimated that the expectation of life at birth in New York City in 1866 was only a little more than 25 years, while in 1903, calculated on the deathrate for that year, it had almost doubled, and equaled about 42 years. For the seven-year period ending in 1873 the deathrate under 5 years in New York City was 123 per 1,000 of the population at these ages. For the year 1903 the deathrate under 5 years was 56. On the present estimated population at these ages, this reduction equals a saving of more than 28,000 lives annually.

These considerations suggest the vast importance of the healthfulness of the community to the individual at every age, and to the community as a whole, for on this depends not only the relative freedom from illness, but also the probable lifetime of each member.

In the casual consideration of the healthfulness of communities as compared with the conditions existing in earlier times, we are inclined to think without investigation that there has been but little advance in modern times, and that while some diseases have been greatly restricted or entirely stamped out, these have been replaced by others equally as fatal to the human race. A little study, however, shows how erroneous are these views. In the seventeenth and eighteenth centuries the average annual deathrate throughout the civilized world was at least 50 per 1,000 of the population, and probably it was much more than this. From 1628 to 1635 in London, these years being free from pestilence, the average deathrate was 50 per 1,000, and the absolute annual mortality for 24 years, from 1620 to 1643, was over 70 per 1,000.

The deathrate during 1902 in London was only 17 and a fraction per 1,000. The mean expectation of life in London for

¹Address on State Medicine at the fifty-fifth annual session of the American Medical Association at Atlantic City, June 7-10, 1904. Published synchronously with the *Journal of the American Medical Association* by courtesy of the Editor.

the decennial period, 1771-1780, as calculated by Price's table, was 19.6 years, the annual mortality being 51 or 52 per 1,000; while from 1831 to 1835, although an epidemic year is included, the deathrate had decreased to about 32 per 1,000. In 1894 the mean expectation of life at birth for all England had more than doubled that of 1780 in London, so that it was nearly 41 years, and for London alone it was 37 years. From 1771 to 1780 in London not less than 5 in each 1,000 of the population died annually of smallpox; in 1810 this mortality had sunk to 2 per 1,000, and in 1835 to 0.8, and in recent years it has been an absolutely insignificant decimal. Fever as a cause of death declined in almost the same ratio, from 6.21 in the decennial period ending in 1780 to 2.64 in 1810, and 1.14 in 1835. In the sixteenth century, fever, plague, cholera, and dysentery destroyed annually 31 out of every 1,000 of the population of London, or nearly twice the total deaths occurring now from all causes. These diseases at the present time, as causes of death, do not equal in London 2 per 1,000 annually of the population.

According to the English life-tables up to 1875, 518 out of every 1,000 children in Liverpool died during the first 5 years of life; 351 died in London and 205 in the healthy rural districts of England, while in the whole of England 297 out of every 1,000 died during this period of life. In old New York City (comprising the boroughs of Manhattan and the Bronx), for the seven-year period ending in 1873, 616 out of every 1,000 children born, died during the first 5 years of life. As computed by the deathrate under 5 in 1903, 280 would have died during the same 5 years. This mortality, while still far too high, equals a reduction of nearly 60%, and as calculated for the estimated population at these ages, means a saving of about 20,000 lives a year in these boroughs. The deathrate in the period over 5 years of age has naturally shown a much smaller decrease, although it has fallen from 19 or 20, as it was in 1865 and 1866, at the time of the organization of the Department of Health of New York City as at present constituted, to about 14 for the year 1903, being a reduction of nearly a third. This has been accomplished notwithstanding the fact that the old city has increased during this time from a population of about 750,000 to more than 2,200,000.

It does not seem necessary or desirable for our present purpose to consider in detail the causes of this decrease or the special diseases in which it has taken place, but the facts suffice to indicate the great achievements of preventive medicine during the past four decades. Expressed in human lives, it means in the boroughs of Manhattan and the Bronx a saving of over 30,000 lives a year, and, computed at the same rate for the whole city, a saving annually of more than 50,000 lives. I would not be taken as intimating that all of this has been accomplished through the agencies which we usually include under the head of preventive medicine, or that it has been the result solely of the action of the sanitary authorities. Such an interpretation would be very far from the truth, for many agencies have been at work in the production of these results. But preventive medicine, as I conceive its purposes and scope, should include all of those agencies which are essential and direct factors in the prevention of disease and the preservation of life. These agencies are not necessarily all under the direct control of the sanitary authorities.

In these introductory remarks, and in much that follows, I have taken many illustrations from conditions which exist in New York, because I have been familiar with the sanitary affairs there for many years, and the illustrations which it furnishes serve our purpose as well as if selected from many different States or communities.

It has long seemed to me that the work of the sanitary authorities in this country was too much restricted and the general conception of the scope of their functions was narrow and out of harmony with the spirit and development of modern scientific medicine.

Sanitary work has been pretty well limited along certain old and well-defined lines, much to the detriment of the public health. The medical profession has unconsciously contributed no small part to this condition, because of the existence too often of a certain antagonistic attitude toward the action of the sanitary authorities and the feeling that the occupation of a

larger field by them would be detrimental to the best interests of the medical profession. The latter has too often resented and opposed any movement to enlarge the field of preventive work, and has often insisted that its operations should be kept within the traditional narrow lines. Until in very recent years the operations of the health officers have been chiefly confined to the measures adopted for the prevention of the more readily communicable diseases, commonly called contagious. These usually included smallpox, diphtheria and scarlet fever, and at intervals, yellow fever, cholera, epidemic dysentery and typhus fever. More recently typhoid fever and measles, and indirectly the diarrheal diseases of infants, have been generally added to this list. But even in regard to the diseases referred to, the measures adopted have been of an elementary and most unsatisfactory character. It must be admitted, however, that until our knowledge of the causation of many of the infectious diseases was rendered more exact by the discoveries in modern bacteriology, sanitary procedures were of necessity largely empiric, and disinfection was either entirely wanting or the methods employed were quite inefficient.

The scope of the sanitary measures in force with reference to the ordinary infectious diseases has in recent years been greatly broadened. More than ten years ago the Board of Health in New York assumed the position that all facilities and procedures looking to the prevention and cure of the infectious diseases should be afforded by the Department of Health. The establishment of the methods for bacteriologic diagnosis and the facilities for the serum treatment had their origin there, and have since been widely followed.

General prophylaxis, or that portion of preventive medicine which should come directly under the supervision of the health authorities, has or should have, a broader scope than that indicated, and should include the supervision, not only of those diseases which have generally come within sanitary surveillance, but also all the infectious diseases which from their nature are to a greater or less extent preventable, in addition to all other forms of disease which are the result of unsanitary living, occupations, habitations or surroundings, including those diseases arising from manufacturing, mining, and other industries which, on account of their nature, are peculiarly or especially injurious to health. It should also include with greatly increased powers and breadth of jurisdiction, the surveillance of the water and food supplies and the sewage disposal.

To return for a moment to the consideration of the infectious diseases to be included in this list, there is a large class of different types of the infectious diseases which are well recognized as being more or less preventable, which are not included in the registration returns. These are not dealt with at all by the sanitary authorities, or only to a very limited extent. Mention may be made in this connection not only of tuberculosis in all its forms, whoopingcough, mumps, chickenpox, and cerebrospinal meningitis, which have been included in the registration returns by some authorities, but have not, as a rule, been dealt with by them, but also of puerperal fever, erysipelas, pneumonia, the diarrheal diseases of infants, dysentery, malarial fever, influenza, the contagious diseases of the eye, and certain parasitic diseases of the skin, as well as some of the rarer diseases occurring in both animals and man, such as rabies, tetanus, anthrax, and glanders.

The inclusion in the registration returns of such a long list of infectious diseases as has been here indicated requires considerable modifications and expansion of the ordinary sanitary procedures, and such action at first thought is likely to arouse opposition and unfavorable criticism from the medical profession. Such opposition and criticism, however, I believe are without proper justification and arise from an erroneous conception of the proper scope and functions of the authorities and their relations to the medical profession and the people.

There has long existed a belief in the medical profession, and to a considerable extent it has also been a part of the conception of the sanitary authorities of their functions, that the registration of a case of any kind of infectious disease involved some surveillance of such case by the authorities. The slightest consideration would at once show that with relation to many of the diseases mentioned, no such surveillance could be of any

real service, and it might be a source of annoyance to the sick person, the family, and the attending physician. Much good, however, would result, in my opinion, by such a broadening of the scope of sanitary work, without causing annoyance or being detrimental to any one. I should like, however, to point out that more than a year ago the Board of Health of New York City in the revision of its sanitary code included a number of new sections in relation to the infectious diseases, covering to a large extent the diseases above mentioned. These sections with the accompanying notes, read as follows:

INFECTIOUS DISEASES.

SEC. 133. It shall be the duty of every physician to report to the Department of Health, in writing, the full name, age and address of every person suffering from any one of the infectious diseases included in the list appended, with the name of the disease, within 24 hours of the time when the case is first seen:

A. *Contagious* (very readily communicable): Measles, rubella (rötheln), scarlet fever, variola (smallpox), varicella (chickenpox), typhus fever, relapsing fever.

B. *Communicable*: Diphtheria (croup), typhoid fever, Asiatic cholera, tuberculosis (of any organ), plague, tetanus, anthrax, glanders, epidemic cerebrospinal meningitis, leprosy, infectious diseases of the eye (trachoma, suppurative conjunctivitis), puerperal septicemia, erysipelas, whoopingcough.

C. *Indirectly Communicable* (through an intermediary host): Yellow fever, malarial fever.

NOTE.—In this provisional classification of the infectious diseases, arranged for practical purposes, the most readily communicable of these diseases, embracing the exanthems and typhus fever, have been placed in a group by themselves and called contagious. This has been done with a view to emphasizing a distinction, which is not only of scientific significance, but of practical importance, in dealing with the sanitary features of administration. This distinction is furthermore of importance because it avoids the misunderstanding and alarm frequently caused by including in the same class the very readily communicable diseases (such as smallpox), and the much less communicable diseases (such as tuberculosis), which require very different sanitary measures for their control.

SEC. 134. It shall be the duty of the commissioners or managers, or the principal, superintendent or physician, of each and every public institution or dispensary in this city, to report to the Department of Health, in writing, the full name, age and address of any person suffering from any one of the infectious diseases included in the list appended, with the name of the disease, within 24 hours of the time when the case is first seen:

A. *Communicable*: Influenza, lobar pneumonia, bronchopneumonia, infectious diseases of the gastrointestinal canal (dysentery, cholera morbus, cholera infantum, summer diarrheas of infants).

B. *Parasitic Diseases of the Skin*: Scabies, tinea tonsurans, impetigo (contagious), favus.

NOTE.—In this list of diseases reporting is required by the Department of Health in order that data may be obtained for general and special investigation of the modes and sources of infection and as to the prevalence and distribution of these diseases. The Department of Health does not propose to exercise a sanitary surveillance in these cases, but desires information with a view to the ultimate removal or improvement in the conditions which foster them. Notification is required in certain of these diseases because of the liability to their extension among children in the schools.

It will be noted, first, that two main groups of diseases are specified. In the first group, including the more readily communicable diseases, and some others which are not so regarded, registration is compulsory in all cases coming under the observation either of a private attending physician or an institution. These are separated for convenience under three heads: (a) The contagious or very readily communicable; (b) the communicable, including diphtheria, typhoid fever, Asiatic cholera, tuberculosis, and a number of others; and (c) the indirectly communicable, including only two diseases—yellow fever and malarial fever—which are transmitted solely through an intermediary host. In these three classes compulsory registration is required, because in all of the diseases in these classes preventive measures, properly executed, are certainly efficient to a very large extent. As to the propriety of the compulsory registration of all of the diseases included under the first heading, "The contagious or very readily communicable diseases," I assume that there can be no reasonable difference of opinion. Measles, rötheln, scarlet fever, varicella, variola, typhus fever, and relapsing fever, certainly without question, should be reported to the sanitary authorities. The necessity for reporting rötheln and varicella rests more in the danger of confusion of these diseases with measles and varioloid, respectively, than because of the importance of the diseases themselves. Our

experience in New York has shown again and again that outbreaks of smallpox have resulted from the failure of inexperienced physicians to recognize mild cases, these having been mistaken for varicella and treated as such. Every case of varicella occurring in the city must, therefore, be reported, and all cases occurring in adults be immediately seen by a trained diagnostician. I say all cases of varicella in adults, because experience has shown that very frequently varicella in an adult is a mild case of variola.

In the second class, called simply "the communicable diseases," there might be some question as to the propriety of the reports in some instances. There would be none, however, with regard to diphtheria, typhoid fever, Asiatic cholera, plague, tetanus, anthrax, glanders, and leprosy. All of these diseases are under some conditions communicable, and of the greatest importance, yet they are much less communicable than the first class, the contagious.

There can not now be, nor can I conceive that there ever will be again, any serious question as to the necessity or propriety of the registration and sanitary surveillance of tuberculosis, although this has been a subject of very bitter dispute, and although this disease has come actually under the close supervision of the sanitary authorities in only three or four cities in the United States, and of practically none in Great Britain or on the Continent. Pulmonary tuberculosis was included in the list of communicable and reportable diseases by the New York City Board of Health 10 years ago, and the measures adopted for its surveillance have been gradually extended and the lines for its restriction have been drawn closer and closer as each year has passed. Some doubt, however, might properly arise as to the necessity of the inclusion of other forms of tuberculosis than pulmonary tuberculosis in the registration returns, because for the most part these other tuberculous diseases are not communicable, or very slightly so. Bone, joint, intestinal, and gland tuberculosis are practically never sources of infection in other persons, but cases of tuberculosis of the types mentioned indicate the previous exposure to infection of the individual, and they thus point out a probably infected site or family, concerning which the sanitary authorities should have information. Such cases may also disclose unrecognized instances of pulmonary disease. Furthermore, knowledge of all cases is absolutely essential to a comprehensive recognition of the extent and prevalence of the infectious disease, *tuberculosis*. During the past year measures to ensure the registration of tuberculosis in all its forms have been adopted in New York.

The importance of the registration of epidemic cerebrospinal meningitis arises not so much because of the evidence of its communicability as because of the importance of fuller information as to the condition under which it arises and becomes disseminated. We have in New York City just been passing through an epidemic of this disease, the first serious one for 30 years. During the month ended May 15, more than 300 deaths occurred in New York City from this cause.

The infectious diseases of the eye—trachoma and suppurative conjunctivitis—should be included because of the importance of the adoption of preventive measures in the public schools. Few persons had any conception of the great prevalence of these diseases of the eye in the public schools of New York until after the Department of Health adopted some comprehensive measures for their surveillance. Such a vast number of cases was found that the Board of Health was forced to establish special dispensaries and provide special hospital facilities for their care. Only within a few weeks a second hospital and dispensary has been opened, and in the original one in connection with Gouverneur Hospital an average of about 500 patients a day were treated during the year 1903, and nearly 5,000 persons were operated on for trachoma.

Puerperal septicemia should be included in the registration returns because modern aseptic midwifery has shown that in most instances this is a strictly preventable disease, and excepting in rare cases of difficult or prolonged labor, its occurrence may be regarded as the result of uncleanness, negligence or incompetence. The registration and the investigation of these cases by the sanitary authorities should soon result in the exclusion from practice of incompetent midwives, restrict the

work of the criminal abortionist, and foster the practice of aseptic midwifery.

No one, I fancy, would seriously question the propriety of including erysipelas and whoopingcough in the registration returns. So far as this country is concerned, I assume that typhus fever, Asiatic cholera, plague, leprosy, and yellow fever are diseases which will never again call for anything more than occasional or emergency measures for the disposal of isolated cases or small groups of cases. But with reference to one disease in the third class, *i. e.*, malarial fever, some remarks may be in point to show the advantages which are likely to result from the interference of the sanitary authorities. We now all believe that malarial fever is not only an infectious disease and indirectly communicable through an intermediary host, but that it is also distinctly preventable.

The registration of cases of malarial fever should be required, not because close surveillance of individual cases is necessary, but because the sanitary authorities should know where the sites of infection are, where the breeding-places of the anopheles mosquitos are to be found, in order that they may adopt proper means for determining the cause of such areas of infection and the proper measures for their removal. In certain sections of New York City investigation has shown that in some instances almost every person living within certain small areas had suffered from malarial fever during the spring and summer months of a single season. Such outbreaks are without any question the result of local remediable unsanitary conditions, which furnish the breeding-places for the mosquitos. But without special information as to the existence of the cases, only to be obtained through the registration of malarial fever, knowledge of the presence of such unsanitary conditions, and their removal, may become difficult or impossible. The surveillance in their homes of the individual cases reported is, of course, not contemplated. That conditions similar to those found in New York exist in other communities, I have no doubt.

Section 134 of the Sanitary Code of New York, covering the second group, deals with infectious diseases of a somewhat different type, and in these the Sanitary Code requires the reporting to the department by public institutions of all cases coming under their observation; but it only requests physicians to report them and does not require such reporting.

Class (a) in this group includes some of the more important acute infectious diseases of the upper respiratory tract, namely, influenza, lobar pneumonia and bronchopneumonia, and certain of the more common acute infectious diseases of the gastrointestinal canal, namely, dysentery, cholera morbus, cholera infantum, and the summer diarrheas of infants.

The acute diseases of the respiratory tract referred to, should, in my opinion, be registered, because they are infectious, because they are of prime importance as causes of death, and in order that general and special investigation may be instituted for the collection of data bearing on the modes of infection and the sources and causes of their prevalence and their distribution. New York City has during the last winter experienced the greatest prevalence of these diseases which it has had for many years. In the first four months of the year more than 6,000 deaths occurred from influenza, lobar pneumonia, bronchopneumonia, and acute bronchitis.

I firmly believe that these diseases can be to a very considerable extent prevented, but the means and the methods are yet to be determined, and it is hoped that registration will assist in the acquisition of knowledge for the attainment of this end.

A large new field has just been opened by recent observations with regard to the specifically infectious character of many of the cases of summer diarrhea and dysentery, both of infants and of adults. The results of the investigation of the sanitary authorities in recent years in many large cities have shown in the most conclusive way that these diseases are to a very large extent preventable, and it seems probable, or at least possible, from recent investigations, that some forms at least are preventable and curable by the use of a specific curative serum.

Investigations in New York and other localities have shown that serious outbreaks of diarrhea and dysentery have occurred in various institutions and in local areas which were

probably, if not certainly, preventable, but concerning which the sanitary authorities have had no information. It seems evident, therefore, that these diseases should be made notifiable. A practical difficulty in this connection exists in the lack of definiteness as to what cases should be included and how the differentiation is to be made between the diarrheas due to simple digestive disturbances and those of a more serious nature caused by infection. This, however, is a matter for further investigation.

Notification of the parasitic diseases of the skin should be required chiefly because of the liability to the extension of these diseases among children in the public schools.

There are certain very large and important questions of prophylaxis connected with the prevalence of typhoid fever and the milk and water supplies of our large communities. The occurrence of great outbreaks of typhoid fever, such as the epidemics at Ithaca, N. Y., and Butler, Pa., during the last year, the prevalence in Philadelphia, Pittsburg and some other cities of the United States and the extensive distribution in the rural districts, constitute a disgrace to American preventive medicine and should arouse the sanitary authorities, the medical profession and the people to the provision of efficient measures and the enactment of suitable legislation for its prevention.

The annual cost of typhoid fever in sickness and death throughout the United States would be computed in terms of tens of millions of dollars. All of this loss we know is certainly preventable. If only a small portion of the annual outlay made by the country for sickness and death from this cause were expended in the education of the people as to the cause and the methods of prevention of this disease, and the provision of proper water and sewerage systems, typhoid fever might soon become a rare affection. Unfortunately the city sanitary authorities are often almost powerless in this matter, as their jurisdiction does not extend over the watersheds which supply with water the people under their care, and a supervision by them of the sources of the milk supply is also frequently absolutely impossible.

In New York City detailed investigations of all the cases of typhoid fever occurring within the city limits were instituted several years ago, and have been continuously carried on. These show that at least 25% of the cases occurring in the city have *certainly* received their infection outside of New York City, and a considerable percentage more have *probably* received it outside. Five or six percent are the result of contact with other cases, and the remainder are in all probability almost wholly the result of infection through milk or oysters. Some more comprehensive measures are urgently demanded to extend the jurisdiction of the authorities in the supervision of the supplies of milk and oysters and other foods.

A serious objection which may be urged against the adoption of the measures here recommended in regard to the registration of many infectious diseases is the increased labor thrown on physicians which their enforcement would involve. The question may properly be asked: Whether the sanitary authorities in the interest of the general public may call on the medical profession for the expenditure of so much time and labor without making any compensation in return? There are 35 diseases included in the New York list. The English authorities pay a fee for the notification of each case of infectious disease, and I believe that this course might properly be pursued in this country; but this has not been the custom here, and the authorities generally are not now provided with the funds necessary for this purpose.

When the Department of Health of New York City established its bacteriologic laboratories in 1892, measures were adopted to make some return to physicians for their interest and labor in connection with the sanitary surveillance of the infectious diseases. A systematic plan was then inaugurated, and has since been consistently followed, to secure their co-operation, by offering free bacteriologic examination in the diagnosis and surveillance of various forms of infectious disease. This was first applied to Asiatic cholera in 1892, during the outbreak in New York Harbor, and has since been extended to all of the diseases in which existing scientific knowledge made it possible, cerebrospinal meningitis being the latest disease added to this list. The establishment of this system of

free bacteriologic examinations in the diagnosis and surveillance of the infectious diseases, and the provision of facilities throughout the city for the collection of specimens and the sending of reports to physicians, constituted an entirely new departure in sanitary work and has been of the greatest value. The example of New York has been followed by the sanitary authorities in most of the large cities of this country, by many State authorities, and by authorities generally, in Great Britain and to a certain extent on the Continent. These examinations constitute the return which the authorities here have made to physicians for the reporting of cases and for their assistance and cooperation in their care. This return has a very considerable money value, when we remember that for such examinations the usual fee is \$5, and as physicians can not, as a rule, make such examinations themselves, they must work without the assistance thus afforded, unless they appeal to the regularly constituted laboratories.

What now are the possibilities of preventive medicine as concerns the larger centers of population? In answering this question we may first take as the basis of our reply the conditions found in some of the large cities with the lowest death-rates, or still better, the conditions found in some healthy rural districts. In considering the crude deathrates, as ordinarily reported, however, one must not ignore the influence of the sex and age distribution of the population on the death-rate. As is well known, the deathrates in the periods of life between 5 and 45 years of age are very low, and the deathrate among women is lower than among men. If, then, in a city there is a relative excess of the population in the middle periods of life, or an unusual preponderance of women, we may have a crude deathrate which seems very low, but which when corrected may be relatively high. For example, the deathrate of New York City, as corrected by the English life-tables, would probably be at least three points higher than it is. For 1894 the gross rate was 22.76, and the rate corrected by the English tables was 26.46. The corrected deathrate of some of the large, rapidly growing western cities would probably be five or six points higher than the crude deathrate reported. The deathrate of London at present averages about 17 per 1,000, and when corrected about 18.5 per 1,000, while the Berlin deathrate is somewhat lower than this. The crude deathrate of Surrey, a healthy rural district in England, is 14 and a fraction, and when corrected would probably be 15.

We can hardly use for a basis of comparison the conditions in any of the cities of this country with very low rates, because the rates have not been corrected, and the basis on which they are calculated cannot always be accepted as correct. Taking all the facts together, and judging of the duration of human life as we know it, we may accept a corrected deathrate of 14 or 15 in a large city as a goal toward which preventive medicine should strive and hope to achieve. If we consider the question from another point of view, as to what is possible in the reduction of the deathrate from distinctly preventable diseases, we would reach a conclusion not unlike the previous one.

In New York City it may be assumed that the present tuberculous deathrate of 2.7 may, under proper surveillance, with certainty be reduced to 1.2, and 1.5 points would thus be subtracted from the crude rate. The diphtheria deathrate, already reduced 65% by the use of antitoxic serum, should certainly be reduced to a third of what it is at present; it is now about .6 per 1,000 population. Similar reductions should be possible in the deathrate from typhoid fever, measles and scarlet fever. The diarrheal diseases of infants have already been reduced in the last 12 years to half of their former prevalence, and should still be reduced more than 50%. Thus more than three points may be subtracted from the crude rate in New York, which in 1903 was 18.18. The rate would then be 15+. The rate for 1903 was the lowest in the history of the city.

The most fatal affections with which we have now to deal in New York are the acute respiratory diseases, including influenza, lobar pneumonia, bronchopneumonia and acute bronchitis. The average death from this group of diseases now exceeds three per 1,000 of the population, and in years when there is an epidemic prevalence of these diseases the deathrate may be four or more, as seems likely to be the case this year.

The advances in preventive medicine have as yet not only

had no influence in reducing the deathrate from this group of diseases, but, on the contrary, there has been a slow and continuous increase. I can not at this moment point out the method or the means by which a reduction is to be brought about, but still I firmly believe that with fuller knowledge such a reduction will become possible in the great cities where these diseases are so prevalent.

Something can be accomplished through the closer sanitary surveillance of the occupations and conditions under which the lower classes work, especially the noxious trades. Something, too, may be done through a closer supervision of foods to ensure their purity and freedom from adulteration.

A very difficult problem arises in connection with the diseases of the circulatory apparatus and the kidneys. My investigations have shown that in New York City a large increase has taken place, due to these causes, during the last 20 years. The acute respiratory diseases, cancer, and diseases of the circulatory apparatus and the kidneys are the only important causes of death which have shown an increase during this period. The increase in cancer amounts to about 15%, and the increase in the acute respiratory diseases amounts to about 15%, while the increase in the diseases of the circulatory apparatus and kidneys combined equals about 40%. In making this statement I have taken fully into consideration the possible influence of greater accuracy in the death returns, *i. e.*, the inclusion formerly of these under other causes of death; but after making all allowances, it seems to me without question that an increase equaling 40% has taken place.

A very important sanitary problem is here presented to the health authorities. What are the factors in the lives of the inhabitants of our large cities (for I have found that similar increases, less extensive, however, have taken place in London, Paris, and Berlin) which have caused such a remarkable increase in the prevalence of these affections, and how are these factors to be removed?

The time at our disposal does not permit of more than this elementary and cursory review of the work in preventive medicine. Sufficient facts have, however, been adduced to show how great have been its achievements, and some of the directions have been indicated in which its scope should be extended. With such extensions, and many others not mentioned, the future possibilities of preventive medicine seem to be even greater than the past achievements, for almost every development in bacteriology opens up a new field of work for the sanitary authorities.

SOCIETY FOR EXPERIMENTAL BIOLOGY AND MEDICINE.

Proceedings Reported by the Secretary,

WILLIAM J. GIES, PH.D.,
of New York.

The seventh regular meeting of the society was held on Wednesday, May 18, at 8.30 p. m., in the physiologic laboratory of the New York University and Bellevue Hospital Medical College, at 338 East Twenty-sixth street. Dr. S. J. Meltzer presided.

MEMBERS PRESENT.—Adler, Burton-Opitz, Dunham, Ewing, Gies, Jackson, Levene, Lusk, Meltzer, Murlin, Richards, Salant, Wadsworth, Wallace, Yatsu.

MEMBERS ELECTED.—P. B. Hawk, W. G. MacCallum, A. R. Mandel, R. M. Pearce, Franz Pfaff, William Salant, H. U. Williams, A. S. Warthin.

ABSTRACTS¹ OF REPORTS ON ORIGINAL INVESTIGATIONS.

"*The lecithin content of fatty extracts from the kidney*" (preliminary communication): E. K. DUNHAM.

Rosenfeld has shown that the percentage of the alcohol-chloroform extracts from the dried kidneys of dogs, both normal and "fatty," fluctuates within very narrow limits. He calls these extracts "fat," and regards the microscopic examination as entirely untrustworthy for gauging the amount of fat in the kidney.

¹The authors of the reports have furnished the abstracts. The secretary has made only a few abbreviations and minor alterations in them.

His work on other organs has led him to the conclusion that, when the fat content is increased in the cells, it has been transported from the fat depots of the body. It appeared to the author of interest to compare the extracts obtained from the kidney by Rosenfeld's method with similar extracts from the depot fats. It was at once evident that they differed markedly in the percentage of phosphorus they contained, as is shown by the following analytic results:

Alcohol-chloroform extracts.	Percentage of Phosphorus.
Human kidney (mean of 28 analyses).....	1.3849
Panniculus adiposus (4.2288 gms.).....	0.0026
Perinephritic fat (5.6750 gms.).....	0.0069

The extract from the kidney contains from 200 to 500 times as much phosphorus as the extract from depot fat. These facts suffice to show that the two extracts are not directly comparable, and to throw doubt upon the idea advanced by Rosenfeld that the fat in "fatty" organs is a simple infiltration from the depots of the body.

The phosphorus in these extracts was found to be wholly organic in character. Protagon could not be detected even in 400 gms. of the tissue. The quantity of jecorin that may have been present was too small to influence materially the analytic results. The most probable compounds containing the phosphorus are forms of lecithin. The barium hydroxid-platinic chlorid method for the separation of cholin was employed, with the following results:

	Extract grams.	Phosphorus %.	Platinum grams.	Lecithin in the extract (calculated as distearyl lecithin), %.
I.....	0.4600	1.43	—	37.23
	0.4600	1.47	—	37.45
	1.5859	—	0.0660	34.50
II.....	0.6032	1.12	—	29.11
	0.6032	1.11	—	28.99
	2.1556	—	0.0711	27.40

Before incineration, in the first case, the platinum salt in the crucible weighed 0.2009 gm. The platinum, therefore, constituted 32.7% of the salt. Cholin platinic chlorid contains 31.6% of platinum. It appears highly probable, however, that some of the platinum salt was decomposed during the concentration of its solution with heat. It is also possible that some of the cholin suffered decomposition, or was lost, in the manipulations preceding its precipitation with platinic chlorid. With these considerations in mind, the foregoing results render it highly probable that the phosphorus is present in some form of lecithin, but, although these calculations are based on distearyl lecithin, it is certain that this is not the only lecithin present. The fact that lecithin obtained in moderate purity (about 99%) from the kidney extract promptly blackens with osmic acid, indicates that the oleic acid radicle is present. The recognition of this fact would make but trifling changes in the calculations in this report.

The foregoing analyses appear to justify the conclusion that one may, at least tentatively, assume the phosphorus content of the extracts obtained to be dependent upon the presence of some form of lecithin.

Upon this assumption the calculations given in the following table¹ are based:

	<i>Extract.</i>	<i>Phosphorus.</i>	<i>Lecithin.</i>	<i>Lecithin.</i>	<i>Autopsy Cause</i>	<i>Report. Weight</i>
	% of dry organ.	% of the extract.	% of the extract.	% of dry organ.	of death.	of kidney. Grams.
<i>Human Kidneys.</i>						
I.	11.42	2.11	55.07	6.29	Pneumonia and hepatic abscess.	200

¹The author presented a large number of data. The table here given shows only a few examples of the many results obtained.
²2.24% of the fresh kidney.

These analyses demonstrate that even in the kidney, which cannot be regarded as one of the fat depots of the body, and which probably plays little, if any, part in the general fat metabolism, the lecithin content must be taken into consideration in any study of the fatty extract. The limited number of the observations here referred to, do not justify conclusions bearing upon the question of the nature of the fatty changes met with in the kidney, but it is the author's intention to continue the study of this subject.

"On the phloridzin test in Bright's disease:" P. A. LEVENE and L. B. STOOKEY.

Investigation of the action of phloridzin in Bright's disease has a theoretic as well as a practical interest. The mechanism of kidney diabetes is as yet imperfectly understood. The original idea that it was due to a change in the permeability of the kidney epithelium has gradually lost support, and instead there is a growing belief in the hypothesis that, in kidney diabetes, the sugar owes its origin to an exaggerated katabolic condition of the kidney. This view was first expressed by one of the authors in 1894. In support of this theory, evidence was brought forward to show that in animals with injured kidneys, phloridzin fails to bring about glycosuria, or causes it in less degree than in normal animals. However, it is impossible to injure, by means of drugs or by mechanical interference, only one special part of the kidney. In the course of Bright's disease there are known conditions under which the involvement of either the epithelium or of the glomeruli predominates to a very great extent, and this, of course, enables one to study the seat of the sugar formation within the kidney. The observations of most authors tend to show that when the epithelium of the kidney is injured, administration of phloridzin fails to cause glycosuria or does so in very slight degree.

The authors injected simultaneously phloridzin and methylene-blue, and compared the course of the elimination of the dye with that of the sugar. The results of their observations in a general way corroborate the statements made by other writers. In acute parenchymatous Bright's disease, sugar fails to appear in the urine after the administration of phloridzin. In chronic forms of the disease, when only a trace of albumin can be detected in the urine, and when the permeability of the kidney for methylene-blue is normal, there is frequently a diminished sugar elimination—diminished as compared with that in health under the influence of phloridzin. In no case was there observed an impaired permeability for methylene-blue with a normal sugar elimination, but the contrary was often the case.

Levene's modification of Allihn's method was used for the sugar determinations. Further work in this direction is in progress.

"Effect of blood-serum in pneumonia upon the heart" (preliminary report): ISAAC ADLER and RICHARD WEIL.

The object of these experiments was to determine whether blood-serum in pneumonia has a specific effect upon the heart, and also, whether there is any difference in action between the serum taken *before* and the serum obtained *after* the crisis. The experiments were made upon the heart of the turtle, use of the mammalian heart being impracticable, in this connection, for many reasons. The fluids to be tested entered the heart through a glass canula, introduced through the right aorta into the corresponding ventricle, passed through the septum into the left ventricle and flowed out through a canula in the left aorta. Care was taken to keep the temperature, concentration and hydrostatic pressure uniformly constant. The veins were all carefully ligated. The small diaphragmatic vein at the apex was tied and cut, the ligature connected with a writing lever and the contractions of the heart thus recorded upon a drum.

Normal human serum acts upon the heart of the turtle as a violent inhibitor, but it was found that in a dilution of 1 to 20, or, better still, 1 to 15, it does not

differ greatly in effect from "normal saline." All serums were thereupon tested in dilution of 1 to 20 or 1 to 15, and the routine of each experiment as ultimately adopted was as follows: Infusion into the heart (a) "normal saline," (b) normal blood-serum, (c) "normal saline," (d) serum *before* crisis, (e) "normal saline," (f) serum *after* crisis. In this manner after considerable preliminary experimentation very characteristic tracings were obtained.

Two cases of lobar pneumonia and one case of bronchopneumonia have thus far been studied. The tracings obtained were demonstrated, and it appeared from them that the serum in pneumonia before the crisis, at least in the cases tested, acted upon the heart of the turtle as a most violent poison. The contractions at once became extremely weak and slow, and the pauses very long. The serum taken after the crisis gave tracings not very materially different from those obtained with normal serum.

"*The influence of alcohol on biliary secretion:*" WILLIAM SALANT.

In the author's experiments, fasting or well-fed dogs were the subjects. Operation and collection were conducted in the usual manner. Ether narcosis was employed in every instance without previous injection of morphin. The rate of secretion was studied by comparing the amounts collected during periods of 15 minutes. The rate of secretion during the first four or five periods was used as a control, at the end of which time alcohol was injected by means of a buret into the femoral vein. Varying strengths of alcohol were used—4½%, 30%, and 60%. The quantities administered were usually about 4 cc. per kilo of body-weight.

After the injection of alcohol, it was found in all cases, that the secretion of bile continued to diminish, the diminution in the rate of secretion being, however, somewhat greater than in the two or three control periods immediately preceding the administration of alcohol. Since the much larger quantity of bile of the first and second periods probably represents bile that has been held back during the operation, it could not be considered as a control. The author, therefore, regarded as a control the rate of secretion during the following two or three periods. Whether this slightly diminished secretion is to be ascribed to the influence of alcohol can only be decided by further comparisons of the rate of secretion in alcoholized and normal animals. Thus, in three dogs without alcohol the rate of secretion corresponding to the alcohol periods was as follows: A decline during the fourth, fifth, and sixth periods, succeeded by a rise in the next period. In the second experiment the rate of secretion remained practically steady during the fifth, sixth, seventh, and eighth periods. In the third experiment there was a variation, but the average rate of secretion was about the same in the fifth, sixth, and seventh periods as in the preceding time. It would seem, therefore, that the diminished secretion following the intravenous injection of alcohol might be due to the effect of alcohol.

A study of the effect of alcohol on biliary secretion after injection into the stomach was also begun. It would seem a priori, in the light of recent investigations by Bayliss and Starling, Fleig, and Henriot, on the relation of secretion to the secretion of bile, that the author's method of administering alcohol ought to provoke secretion of bile. In the few experiments the author has made thus far, he has observed that when 60% alcohol was introduced into the stomach there was a slight, transitory increase of biliary secretion. With 30% alcohol there was in some cases an increase, in some a decrease of the secretion of bile as compared with pre-alcoholic periods. At this stage of the work it would be premature to form any conclusion regarding this point. Whether this slight increase is due to increased gastric secretion and consequent formation of secretin, or is reflex in nature, will next be investigated.

"*The influence of repeated external hemorrhages on the general composition of the blood:*" G. M. MEYER and W. J. GIES.

Various observers have noted the fact that the composition of the blood changes after hemorrhage, but no systematic study has been made of these modifications. The authors have begun such an investigation for the purpose of establishing a more definite basis for comparative blood analysis. They reported the results of their observations on posthemorrhagic changes in the percentage content of water, total solids, organic solids, and ash. Further study is in progress.

Healthy, well-nourished or fasting dogs in light morphin-atropin narcosis were used, and quantities of blood ranging from 0.2% to 1.0% of body-weight were taken. These amounts were drawn from the femoral artery, and approximately the same quantity was taken in each experiment at regular intervals, varying from 15 minutes to two hours until death ensued. In one experiment a continuous fatal hemorrhage was effected and the blood analyzed in portions. Thus far 20 experiments have been carried out. In some of them the serum was also analyzed.

The following conclusions were reported: Hemorrhage causes increase of water and decrease of solids in the remaining blood. Hemorrhages of about 0.6% of body-weight cause little or no change in general composition of the blood until after 2.5% has been taken. Under the conditions of these experiments it was generally found that the longer the intervals between withdrawals the less the maximal differences between composition of the first and last fractions. Short intervals between bleedings, all other conditions being equal, favored the largest total withdrawals before death ensued.

The differences in the serum ran parallel with those in the blood, but were less marked. The ash did not vary very much in either the blood or serum, no matter how much blood was taken. The blood ash and that from the serum were practically the same in relative amount, though different in composition.

When small quantities of blood, equal to about 0.2% of body-weight, were removed at intervals of about a half-hour, little change was noted in either blood or serum until after 3% had been taken. After this quantity had been lost the changes following further hemorrhage were such as usually occur. The maximum differences in percentage composition of the first and last fractions varied somewhat. The differences in the amounts of solids, for example, ranged from 1.5% to 3.5%. In fasting animals the influence of hemorrhage on chemic change in the remaining blood was somewhat more marked than in well-nourished ones. The effect on the serum was about the same.

Other influences in the experiments were carefully controlled. The observed effects were due only in slight degree to the narcotics and the conditions attending the operations.

"*Demonstration of a new portable sphygmomanometer:*" T. C. JANEWAY.

Dr. Janeway's instrument was designed with the object of securing a thoroughly portable clinical sphygmomanometer, in which nothing essential to accuracy should be sacrificed. It employs the method of circular compression of Riva-Rocci, and Hill, with the 12 cm. width of armlet proved necessary by von Recklinghausen. The special construction of the cuff allows of adaptation to arms from 15 cm. to 34 cm. in circumference. The original feature of the instrument is the folding U tube manometer. This is a jointed U tube manometer (copied from Cook), fastened to the under surface of the box-lid, so arranged that, when closed for carrying, it measures 10½ x 4½ x 1½ ins., and, with armlet and inflator, weighs 2½ lbs. The manometer is perfectly secure when closed and stands firmly when open. The tube caliber is 3 mm. The sliding

scale is empirically graduated for each instrument, to compensate for variations in the glass tubing, and is accurate. All connections are of heavy pressure tubing. For inflation a Politzer bag is used, as by Erlanger, except that one with valve is necessary to fill the large armlet. The gradual release of pressure is provided for by a stopcock, with needle-valve of special construction, the work of Mr. Charles E. Dressler, who is making the sphygmomanometer for sale.

The method of use, as of the other modern sphygmomanometers, is based on the criterion of the return of the pulse after obliteration (Vierordt), for systolic pressure, and is similar to the Riva-Rocci and its modifications. A fair approximation of diastolic pressure may also be obtained in most cases, using the criterion of maximum pulsation (Marey, Mosso). This is especially useful in cases of aortic insufficiency, or marked hypertension. For experimental work upon the systolic and diastolic pressures, it cannot compare with Erlanger's more elaborate and costly instrument, but aims to serve the clinician by providing him with an accurate, yet not bulky or costly instrument, for general use. Stanton's sphygmomanometer, which appeared after this one had been begun, answers the same purposes. The only criticism to be made of it is, that 8 cm. width of arm-piece does not afford a guarantee of complete accuracy on large arms.

"*Demonstration of cytologic preparations:*" NAOHIDÉ YATSU.

Mr. Yatsu exhibited seven preparations demonstrating important cytologic structures found both in eggs normally fertilized, and in those treated chemically. He spoke on the achromatic figure in mitosis, with special reference to the morphology and cycle of the centrosome.

Preparation I.—Metaphase of the first polar mitosis with two centrioles at each pole (egg of *Cerebratulus*).

Preparation II.—Sperm nucleus with sperm aster, in which each daughter centriole has acquired a new system of rays (egg of *Cerebratulus*).

Preparation III.—Anaphase of the first cleavage mitosis, showing two centrioles in each centrosome (egg of *Cerebratulus*).

Preparation IV.—Telophase of the first cleavage mitosis, showing typical centrosomes (egg of *Ascaris*, Prof. Wilson's preparation).

Preparation V.—Mitosis without chromosomes in a late blastula (egg of *Asterias*, unfertilized and etherized.) In one of the blastomeres the aster is dividing, forming a typical central spindle, but devoid of chromosomes.

Preparation VI.—Cytasters (egg of *Asterias*, unfertilized and etherized). Many cytasters are found in the cytoplasm, some dividing, some forming synthetic triasters.

Preparation VII.—Cytasters (egg of *Cerebratulus*, unfertilized and treated with a solution of calcium chlorid). Many cytasters have appeared, the first polar mitosis being disturbed.

"*The influence of subcutaneous injections, and of instillations of adrenalin upon the pupils of frogs, with demonstrations:*" S. J. MELTZER and CLARA MELTZER AUER.

Many observers have established the fact that subcutaneous injections as well as instillations of adrenalin exert no influence upon the width of the pupil in normal mammals. In a series of experiments published recently by the authors of this report it was shown that from 24 hours to 48 hours after the removal of the superior cervical ganglion a subcutaneous injection or an instillation of adrenalin caused considerable dilation of the pupil, which lasted an hour or longer.

In the present communication the authors report that in frogs a subcutaneous injection or an instillation of adrenalin into the conjunctival sac causes an unmistakable dilation of the pupils of a normal animal. The dilation lasts a good deal longer than was ever observed

in mammals even after removal of the ganglion; after instillation some dilation may be perceptible as long as 36 hours. The maximum dilation may even continue as long as 12 hours.

When the cord is severed just below the medulla oblongata, the pupils usually become small and ellipsoid in shape. A subcutaneous injection causes them to become wide and round. Instillation has the same effect. Finally, the effect of instillation can be well observed also on the excised eyes, even when the adrenalin is applied some hours after excision, provided the eyes are kept moist. The experiments were demonstrated.

THE WORLD'S LATEST LITERATURE

Journal of the American Medical Association.

4. The Problems of the Technic of Ureteral Catheterization. GUSTAV KOLISCHER and LOUIS E. SCHMIDT.
5. The Business Side of a Physician's Life. H. BROOKER MILLS.
6. Surgical Treatment of Pulmonary Abscess. VAN BUREN KNOTT.

1.—Chorioepithelioma.—G. Schmauch presents the following conclusions from his study of these tumors: The syncytium is of fetal origin. It and the Langhans cell are different stages of the same cell, the trophoblast. The chorioepithelioma malignum is a growth consisting of fetal cells only without connective tissue or bloodvessels, and has to be placed in a class by itself. It is always a consequence of pregnancy; it has nothing to do with teratomas, as these are inborn growths. The chorioepithelial formations in teratomas of the testicle and the ovary prove the fetal origin of the syncytium, but are totally different. The masses in these tumors proceed from the ectodermal cells and are in their histogenesis equal to all other ectodermal products in teratomas, as the neuroepithelium, etc. The deportation of parts of villi and their epithelial layer is a physiologic fact, and probably takes place during the whole of pregnancy. The epithelial layer of the villus preserves its embryonal energy of proliferation until birth. Therefore, a chorioepithelioma may arise at any time of pregnancy, when the natural protective forces of the maternal organism become deficient. [H.M.]

3.—Asthma.—T. F. Reilly recommends suprarenal spray when the asthma is of nasal origin. Many attacks seem to bear a direct relation to disturbances in the gastrointestinal tract. Careful dieting will keep some people free. In others the use of a simple HCl mixture seems to answer. In severe cases if relief does not follow the suprarenal spray in 5 to 10 minutes morphin may be given. [H.M.]

4.—Ureteral Catheterization.—G. Kolischer and L. E. Schmidt discuss the different methods and instruments used. The best instrument should allow catheterization of both ureters with one introduction of the instrument, and should permit of leaving the catheters in place after the cystoscope has been removed. They show the undesirable features of air dilation. The most satisfactory results are always achieved by sterile water or other transparent fluid. Catheters and cystoscopes may be lubricated with glycerin or any sterile lubricant which readily dissolves in water. It is important not to have the hip-joint too forcibly flexed. Contamination of the collected urine by fluid from the bladder can be avoided by leading the catheters up an inclined plane to the receptacles used. In most cases no local anesthetic is necessary. In the very sensitive, a morphin suppository may be inserted in the rectum. General anesthesia is required only in extreme cases. When there are pelvic misplacements or growths, a few special maneuvers facilitate introduction. When the mucosa bleeds easily, adrenalin may be applied. The authors recommend a cystoscope allowing direct view, having part of the conducting canal removable, so that the first inserted catheter can be

thrown out and the canal then be reconstructed for insertion of the second catheter. They describe a Brenner cystoscope modified by themselves after Caspar's principle by adjusting to it a slide bar, the catheter slipping out of the canal when this slide is withdrawn. Swelling of the ureteral lining can be overcome by adrenalin if due to infection and inflammation; if due to trauma from instrumentation or stone, wait until the injuries have healed. [H.M.]

6.—Surgical Treatment of Pulmonary Abscess.—Van Buren Knott considers the treatment of only single abscesses. He believes it inadvisable to open without the aspirator as a guide. Local anesthesia may be used. If pus is not found on the first attempt, the needle should not be withdrawn completely from the lung, but as nearly so as possible, and reinserted in various directions until it enters the cavity. This prevents multiple punctures of the pleura, and diminishes the danger of septic extravasation into the pleural cavity. When pus is found the needle should be left as a guide, chloroform be administered, a free incision be made with resection of two ribs, well exposing the diseased area. If pleural adhesions are absent the pleura must be sutured, using the "back stitch," and gauze packing used for walling off. For opening the lung, the author prefers probe-pointed dressing forceps introduced alongside the needle, followed by opening of the blades. After the pus has been evacuated the opening may be cautiously enlarged. The cavity should be thoroughly wiped with gauze pledgets. Gauze covered with rubber tissue to prevent sticking may be used as a drain. [H.M.]

1. A Study of Certain Cases of Sarcoma of the Long Bones from the Massachusetts General Hospital Clinic. CHARLES L. SCUDDER.
2. Disinfection of the Clinical Thermometer. FRANCIS P. DENNY.

1.—Sarcoma of the Long Bones.—Charles L. Scudder reports the final results in a series of 15 cases, and concludes that if the giant-cell sarcoma of a long bone is limited to and localized in the bone, involving only a small area, a resection or partial operation is justifiable; but if the soft parts are in any way involved, or if the disease in the bone is extensive and of long duration, then an amputation is the best treatment; an amputation in the continuity of the bone if the lower end of the diaphysis is involved, or an amputation at the joint above the disease if the disease is high in the shaft. Exarticulation at the joint above the disease, at the shoulder or at the hip, is indicated only in those cases in which the disease cannot otherwise be completely removed. [H.B.C.]

2.—Disinfection of the Clinical Thermometer.—Francis P. Denny calls attention to the method, originally promulgated by W. H. Dyer, of disinfecting the clinical thermometer by putting a few drops of formalin in the thermometer case, and reports the results of a number of tests proving its efficiency. [H.B.C.]

Medical Record.

June 4, 1904. [Vol. 65, No. 23.]

1. Some Thoughts Suggested by the Statistics of the Health Department, Especially Concerning Typhoid Fever and Smallpox. GEORGE L. PEABODY.
2. Pathologic Distinctions Discernible in the Radiograph in Certain Diseases of the Long Bones. EUGENE H. EISING.
3. The Treatment of Epidemic Cerebrospinal Meningitis by Intraspinal Antiseptic Injections. CHARLES E. NAMMACK.
4. Myocardial Change from the Clinical Side. JOHN W. BOYCE.
5. The Use of Rubber Tissue and Boracic Acid in the Treatment of Surface Granulating Wounds, and Especially of the Varicose Ulcers of the Leg. W. SCOTT SCHLEY.
6. A Case of Bilharzia Hematobia Infection. T. N. RAFFERTY and H. N. RAFFERTY.
7. Röntgen Ray Diagnosis of an Interesting Case. L. D. WEISS.

1.—The Health Department, Typhoid Fever, and Smallpox.—G. L. Peabody notes the high death-rate from these diseases in Manhattan and Brooklyn, and believes it is owing to the fact that many cases are not reported. The increasing number of cases in Manhattan is attributed to the greater consumption of water compelling direct transmission of surface water without storage as was formerly possible. He is opposed to forcible removal of smallpox patients from their homes when they can be suitably isolated. Dread of this regulation has led

to concealment and thus to much greater exposure. The possibility of erroneous diagnosis is a serious aspect of the question and practitioners are unwilling to subject their diagnoses to official review. The risk incurred by a physician in reporting what he believes to be smallpox is not trivial, a mistake may involve a lawsuit, and his temptation to conceal it becomes proportionately great. [H.M.]

2.—Pathologic Distinctions Discernible in Diseases of the Long Bones, when Using the Radiograph.—Eugene H. Eising confines his remarks to inflammatory and nonplastic conditions of bone. When the periosteum becomes irritated, its osteoplastic function becomes stimulated and new periosteal bone is formed upon its osteal surfaces; when the periosteum becomes disturbed to the point of destruction or approaching that point, no such change occurs. A good radiograph will present various phases of periosteal alteration, consonant with these conditions. A hemorrhage into the periosteum, or between it and the bone, will be recognizable or not in the radiograph, depending on the age of the lesion. The radiograph of carcinoma in bone shows an area of rarefaction which is circumscribed and demarcated from neighboring bone; the area of rarefaction is medullary, and not cortical. In sarcoma of bone there seems to be two distinct groups from the radiographic standpoint. The one, in his experience, is always myeloid, or giant-celled sarcoma. In this the radiograph shows an area of erosion of bone and periosteum, and not of rarefaction, as in the case of carcinoma. The line of demarcation between the diseased and normal bone is clean cut, and gives the appearance of having been removed with a gouge. The spindle and round-celled osteosarcomas occur in the length of long bones, and present pictures different from the foregoing. They usually cause a fusiform outline of the shaft of the bone, the periosteum is much thickened, and shows no proliferation of new bone. The features characterizing osteomyelitis in the radiograph are a general swelling occupying a segment of the bone, or perhaps the entire length, irregularly fusiform, or else the tumor may be limited to one aspect. The area of disease presents a mottled appearance, the periosteal involucrum will stand out prominently, when present. [A.B.C.]

3.—Cerebrospinal Meningitis and Antiseptic Injections.—C. E. Nammack considers that as the mortality has varied from 20% to 75% in various epidemics, it is difficult to draw conclusions from any treatment. He discusses the bactericidal values of lysol and reports five cases in which he used it with one recovery. [H.M.]

4.—Myocardial Change from the Clinical Side.—J. W. Boyce cites cases illustrating the unimportance of valvular lesion in the presence of a normal myocardium. The larger life insurance companies see enough of them to calculate an average expectation of life and offer insurance on moderate terms. For the morbid anatomist there are 30 or more varieties of cardiac myopathy, but most of them are indistinguishable from one another clinically. It is usually possible to guess whether the condition be fatty degeneration, fibroid heart or sclerosis of the coronary arteries. Acute myocardial change seldom is the sole cause of death. It occurs oftenest in articular rheumatism. Scarlet fever affects the endopericardium and pericardium oftener than the myocardium. In chronic conditions acute infections as rheumatism, diphtheria, pneumonia, typhoid and septicemia are usually the starting point. The symptoms are pain, loss of strength, a gray pallor, a look of anxiety, premature grayness of the hair. The apex impulse is broad but feeble, the heart may or may not be enlarged, sometimes there is a murmur, a trace of albumin comes and goes in the urine. Irregularity or intermittence often marks the fibroid heart. Such cases are of relatively favorable prognosis. A very slow pulse of low tension is of great value, which is much increased if it is found that change of position or slight exertion alter its rate unduly. [H.M.]

5.—Rubber Tissue and Boric Acid in the Treatment of Leg Ulcers.—W. Scott Schley gives the result of his experience in treating ulcers of the leg in the Out-Door Department of St. Luke's Hospital, New York. Following the suggestion of Abbe, they have, for some time, employed boric acid and over this rubber tissue, the whole covered by gauze and a bandage, in the treatment of granulating ulcer, particularly of the vari-

cose type. The method in brief is as follows: The ulcer having been cleansed, upon the granulating surface well-powdered boric acid is generously sprinkled; this is covered smoothly with rubber tissue overlapping the edges of the ulcer by one or two inches and secured in place by adhesive plaster strapping; absorbent gauze covers the tissue, again overlapping its edges and a snug supporting bandage is applied. A point of much importance is the length of time such dressings should be left undisturbed; they are rarely changed oftener than once in five days, usually once a week, and occasionally longer. Schley has been impressed with the rapid rate of epithelial growth under this dressing, the smooth surface of the rubber tissue insures a smooth surface to the granulations. The boric acid acts as an antiseptic astringent diminishing and sweetening the discharge and preventing excessive transudation and exacerbation of granulations, which two factors undoubtedly act as the greatest checks to epithelial growth and covering. His success has been so marked in this form of treatment that within the past few months Schley has extended this treatment to a number of ulcers the result of tuberculous inflammation with the characteristic flabby granulations and undermined bluish edges. Here also the results are reported to be gratifying. [A.B.C.]

New York Medical Journal.

May 28, 1904. [Vol. LXXIX, No. 22.]

1. The Construction of the Valvular Part of the Aorta and the Significance of Its Elastic and Collagenous Tissue. FRITZ SCHWYZER.
2. Examination of the Bladder in 20 Cases of Ventral Suspension. SWITHIN CHANDLER.
3. The Surgery of Nephritis. (Concluded.) GEORGE M. EDEBOHLS.
4. A New Method to Facilitate Operations in the Mouth, for the Purpose of Minimizing the Danger of Aspiration of Blood during General Anesthesia. ALFRED W. HERZOG.
5. What Should the General Practitioner Know of Ophthalmology? H. H. SEABROOK.

1.—Construction of the Valvular Aorta.—Fritz Schwyzzer says that the elasticity and ductility of the aorta depend upon three factors: The network construction of the elastic fiber systems of the media; the elasticity and great yielding power of the collagenous substance; and the great elasticity and moderate ductility of the elastic elements. The elastic elements can only in their combination as a construction be considered as the carriers of ductility. They are themselves highly elastic, but have relatively little yielding power, and their function is first of all to prevent exaggerated distention. The other fibers of connective tissue are either very ductile, as in the semilunar valves, or they are more tendinous, unyielding, as in the valvular ring. The elastic ligament on the ventricular side of the semilunar valves is probably not only made to strengthen, but in connection with the elastic endocardium, it could be considered as a steering apparatus for the position of the semilunar valves, and in combination with the main part of the valves it forms the joint at the base of the same. Nature appears to make use of the elastic mesh tissues whenever there is any initially large ductility desired, and where afterward elastic inhibition is necessary. [C.A.O.]

2.—The Bladder in Ventral Suspension.—Swithin Chandler reports the operation and bladder examination in 20 cases requiring the operation of ventral suspension and offers the following deductions: 1. In all cases requiring ventral suspension the bladder should be thoroughly examined by a cystoscope. 2. In no case reported among this number was there any trouble with frequent micturition after the operation of ventral suspension, except when there was some evidence found which would cause such disturbance. 3. The new position of the bladder after ventral suspension aided and relieved, rather than caused, frequent micturition. 4. The operation may have caused this relief by removing pressure from the neck of the bladder, which pressure undoubtedly helps to cause frequent micturition. 5. The left ureter opening and surrounding parts were often affected, but the cases are too few to state positively why this existed. 6. Immediate and prompt treatment saves much suffering and adds much to the surgeon's reputation, and to that of the operation. 7. By examining the bladder and surrounding parts we may find cases in which suffering may be relieved, when for some reason an operation for uterine disease cannot be performed. 8. To make such

examination eliminates errors, and is more scientific; and the more exact we become, the firmer ground we tread. [C.A.O.]

3.—The Surgery of Nephritis.—G. M. Edebohls says that for the present in view of the helplessness of medicine in the presence of established chronic Bright's disease, the advance in treatment represented by renal decapsulation should be welcomed by every physician called upon to treat chronic nephritis. This operation applied early in the course of a chronic nephritis, and in the absence of complications, is almost free from danger in expert hands, and is almost a certain cure. Of 72 persons whose kidneys were decapsulated by the writer for chronic Bright's disease up to the end of 1903, 10 were physicians, and two others were members of the immediate families of physicians. The author has followed 69 of these cases either to the termination of their lives or to the present writing and the results reported are very satisfactory. A fourth publication will soon be issued giving the history of each case in full detail, including urinalyses, and an analysis of the results thus far obtained. [C.A.O.]

4.—Operations in the Mouth.—A new method to facilitate operations in the mouth, for the purpose of minimizing the danger of aspiration of blood during general anesthesia is described by A. W. Herzog. The method is to intubate the patient and connect the intubation tube by means of a tightly fitting end-piece with a rubber tube, which is passed through the patient's nose, so that the inspired air or anesthetic is taken into the lungs through the tube passed through the nose. [C.A.O.]

1.—Infection and Immunity.—Thomas E. Satterthwaite states that there are certain epochs in the study of vexed questions when a knowledge of their *status præsens* is desirable. We have now reached such a period with reference to the somewhat obscure topics of infection and immunity, and it is the purpose of his paper to supply this information so far as a brief statement of facts makes it possible. He refers to the early work of Pollender, Davaine, Pasteur, Koch, and others, which brief outline introduces us to the present bacteriologic aspect of infection. This he reviews at some length, stating that the discovery of antitoxins we owe to Salmon and Smith of this country, but the method of preparing them is generally attributed to Behring. The infecting bodies in tuberculosis, typhoid, glanders, gonorrhea, anthrax, tetanus, bubonic plague, suppuration, erysipelas, lobar pneumonia, influenza, diphtheria, ordinary dysentery, cholera, and relapsing fever are believed to have been discovered, although they cannot all stand the test of Koch's wellknown law. There is also a strong presumption that the infecting agent is bacterial in syphilis, mumps, measles, whoopingcough, typhus, hydrophobia, dengue, inflammatory rheumatism, and beriberi, but the proof is still lacking, just as in yellow fever, scarlet fever, and smallpox. Attention is called to the fungi and the part which they play in the etiology of disease. He speaks particularly of an acquired and inherited immunity of the former. There are two kinds, active and passive. The following rules of immunity are discussed at some length: The exhaustion theory; the retention theory; phagocytic theory of Metchnikoff; the humoral theory of Fudor; the cellulohumoral theory; Ehrlich's side-chain theory, etc. Latency in infective diseases is also considered at some length. The paper is especially interesting and instructive in giving a review of that which has been accomplished in the subject under discussion. [A.B.C.]

2.—Epidemic Meningitis.—H. D. Chapin describes the abrupt onset with vomiting and chills or severe convulsions. Prolonged convulsions quickly followed by coma warrant a

grave prognosis. There is severe pain in the head and back of the neck. Retraction of the head is an early symptom. Contraction and rigidity usually continue during the disease. Cases that appear to be approaching rapidly a fatal ending may suddenly show improvement and in those with less urgent symptoms the patients may unexpectedly die. Hyperesthesia occurs. The mental state varies from apathy to irritability, delirium, and coma. Kernig's sign is generally present. Temperature and pulse show remarkable variations. The eyes are often involved and frequently the ears. Sometimes the patient never regains former mental and physical strength. In the epidemic which Chapin reports, the skin was rarely involved. The port of entry of *Diplococcus intracellularis* is uncertain. Mild cases can be diagnosed only by lumbar puncture. The disease does not behave as though contagious. [H.M.]

3.—Clinical Features of Epidemic Meningitis.—H. Koplik states that 60% of the patients are under two years. The most lucid classification of the types of meningitis is given by Osler. The writer's cases were of the primary epidemic form, including the posterior basic meningitis of Still. The onset is generally abrupt. Slight or marked rigidity is present in all cases. Opisthotonos occurs in 70%. The skin, tendon, and plantar reflexes tend to disappear in fatal cases. Babinski's reflex was found in only 4 out of 25 cases, while in the tuberculous form it was demonstrated in 20 out of 26 cases. In the latter the child is stuporous; in the epidemic form, when not in coma, he is irritable. Percussion of the inferior frontal or parietal bone gives a tympanitic note. Facial paralysis occurs only in the severest types, whereas it is quite constant in tuberculous disease. The temperature is intermittent, and at times is wildly irregular. Sometimes a roseola resembling typhoid is seen. In the majority of the author's cases there was no change in the optic papilla. In all cases there was some leukocytosis. The physical characteristics of the fluid obtained by puncture aid little in diagnosis. The writer has found the diplococcus from the first 24 hours to the fifteenth week. Lumbar puncture is indicated when irritability and headache are severe, and when rigors are frequent, but is inefficient in rigidity and opisthotonos. Antiseptic injections have not lessened mortality. Hot baths may be given for the rigors, sponging for temperature. The writer administers calomel as a laxative, and iodids in full doses. [H.M.]

4.—Organization of a "Society of Sanitary and Moral Prophylaxis."—Prince A. Morrow proposes to form in this country such a society, the object of which is the study of the means of every order—sanitary, moral and legislative, which promises to be most effective in preventing or diminishing the spread of diseases which have their origin in the "social" evil. This society is to be composed of medical men, representatives of the clergy, of the law, public educators, sociologists and public-spirited men generally, similar to societies which have been organized in various cities and countries of Europe. The subject is considered under several headings such as the need of such a society, the magnitude of the venereal peril, extensive prophylaxis, effects upon the individual, effects upon the family, frequency of marital contamination, remedial measures, attitude of society, etc. He states that it is now generally recognized that the class of disease comprehended under the general term venereal, together with alcohol and tuberculosis, constitutes the three great modern plagues which afflict humanity. Practically nothing is being done to control the ravages of venereal disease. Morrow makes a strong plea for the organization of such a society. Concerning remedial measures he states that the cardinal points of prophylaxis are (1) to preserve the healthy from infection; (2) to prevent those already infected from infecting others. The dissemination of knowledge concerning the dangers of venereal diseases and their proper hospital treatment are urged. [A.B.C.]

5.—Management of Occipitoposterior Positions of the Vertex.—James D. Voorhees advises as prophylactic measures in the management of occipitoposterior cases, postural treatment and external manipulations either before or at the beginning of labor; for nature often needs only the slightest aid to work wonders. The correction of the malposition may be aided by keeping the patient upon her feet, by moderate out-of-door walks before labor, or about the room during the first

stage of labor. Also small doses of quinin and strychnin, singly or combined, for one or two weeks before labor, or during the first stage, may help by strengthening the pain. One should not be alarmed by the occipitoposterior position, since according to some observers, as high as 90% rotate anteriorly spontaneously. In order to do this, certain conditions are necessary; the head must not be too large for the pelvis, the flexion must be good, the pelvic floor must be resistant, and the uterine contractions must be strong. Lack of the last condition is the most frequent cause for interference. If the head is movable and high and the pelvis normal, Voorhees advises that one first obtain as complete a dilation of the cervix as possible, then under deep anesthesia carry the hand into the uterus and manually rotate the occiput anterior. This can often be accomplished if the lower uterine zone is not retracted about the child. Then holding the head in position by the hand inside the uterus, and aided by an assistant making strong pressure on the fundus, apply the forceps to the side of the head. If, after rotating the head, and using moderate traction with the forceps, the head does not descend, or if the pelvis is found to be flattened, version would probably be the better operation, safer for both mother and child. In those cases in which the head is engaged in the superior strait or is in the midpelvis, sometimes the manipulation of pushing up the forehead and thereby increasing the flexion will allow the occiput to come down low enough during a pain to meet the resistance of the pelvic floor, and so start the rotation. Voorhees describes minutely the method of using the forceps when necessary. [W.K.]

6.—Scurvy in Infants.—W. F. Cheney reviews the clinical picture of the disease, having found some physicians unable to interpret the symptoms, although the condition is not uncommon. Just three measures are indicated for cure. Discontinue the proprietary food, substituting fresh milk diluted with plain or oatmeal water. Give orange juice and fresh beef juice, one or two teaspoonfuls three times daily. [H.M.]

A. O. J. KELLY

REVIEW OF LITERATURE

Value of Statistics in Connection with Venereal Diseases in the Army and Navy.—Valery Havard¹ states that in the army the rate of admissions to the hospital for venereal disease during the normal peaceful decade, 1889 to 1898 was 71.45 per 1,000; after the Spanish war the rate rose greatly, and has been steadily increasing, being 127.35 for 1900; 155.39 for 1901; and 160.94 for 1902 with a mean of 147.89 for the past three years. These rates are higher than those reported by the army of any other country. In the navy and marine corps for the period 1896 to 1902, the mean yearly rate is 51.6, ranging from 46 in 1897 to 57 in 1899, with an average for the last three years of 53.33. It is noticed that the mean for the army is nearly three times that for the navy. Havard questions why this disparity exists, since the army and navy are made up of practically the same class of individuals, and their opportunities for contracting disease are relatively the same. In the army during the last three years the number of cases of gonorrhea is more than double the total for syphilis and chancre, while in the navy during the same period the number of cases of gonorrhea is less than the total of syphilis and chancre. In the army during the last 10 years the number of cases of chancre invariably exceeds that of syphilis, the ratio during the last three years being 30 of chancre to 80 of syphilis. In the navy these figures are completely reversed, syphilis exceeding chancre in the proportion of 539 to 238. [A.B.C.]

Fetal Endocarditis; Pulmonary and Mitral Stenosis Persisting.—G. Baccelli² gives the clinical history of this case, occurring in a young farmhand, aged 20. The author, incidentally, emphasizes a sign of mitral stenosis, little credence to which is commonly given: A sharp murmur which supplants the first cardiac sound, and is transmitted from its point of origin at the surface over the mitral valve, to the apex. He has taught this for more than 15 years, though opposed by the German writers. [T.H.E.]

PUBLISHED WEEKLY AT 1321 WALNUT STREET PHILADELPHIA BY THE AMERICAN-MEDICINE PUBLISHING COMPANY

VOL. VII, No. 25.

JUNE 18, 1904.

\$5.00 YEARLY.

The work of preventive medicine is admirably presented in the masterly address of Dr. Biggs, published in our last week's issue. Discriminating and yet enthusiastic, scientific and yet unselfishly sociologic, always and persistently practical, the cause itself and, unconsciously, the worker in the cause, stand out with sharp distinctness as great agents in the task of social betterment. No subject, as is said, more vitally concerns the welfare of a community than that pertaining to its healthfulness. How the inhabitants live and how and at what age they die, what is the extent and character of the morbidity occurring among them and what are its causes, are questions of momentous importance. They are essential features in the problem, whose solution will teach men how they may live longer, healthier, and therefore happier lives. With all the cautions emphasized, there can be no doubt that the professional labor in preventive medicine has been the chief cause in lessening the expense, suffering, and death due to disease and unnecessary death. Taking New York City as a typical illustration—and how much of the progress has been due to Dr. Biggs himself!—there has in recent years been effected a saving of at least 50,000 lives a year as the outcome in great part of practical medical and sanitary science. The somber and warning note is struck when one faces the increase instead of the decrease of certain diseases. In New York Dr. Biggs finds that during 20 years there has been a great increase in the acute respiratory diseases, cancer, and diseases of the circulatory apparatus and the kidneys. The increase in cancer amounts to about 15%, and the increase in the acute respiratory diseases amounts to about 15%, while the increase in the diseases of the circulatory apparatus and kidneys combined equals about 40%. The profoundly important question still remains unsolved as to the causes of these increases, and then of the methods of obviating them. Our gratification, for instance, at the 65% reduction of the diphtheria mortality by means of the antitoxic serum is tempered by the harassing counterweight, but it by no means lessens the unflinching determination to fight the enemy at all points—if it should take all the century.

The postponement of national systematic drug analyses by the House of Delegates is, under the circumstances, a wise movement. The difficulties in any

practical execution of the task seem at present insuperable. Perhaps, after all, the existing agencies, if properly and adequately utilized, are enough to bring about the reform in a slow and more certain manner than by any complex and official organization. While such widespread and powerful interests exist against thoroughgoing reform, and while even chemist experts in one way or another may still be bribable, there must be recognized great dangers in carrying out the absolutely exact analyses and complete publication of the results. Any plan that gives only the analyses of the good and really "patent" products while remaining silent as to fraudulent and secret ones, cannot command much following or bring about revolutionary changes. One of the essential conditions of progress seems to be the enactment of the Hepburn Pure Food Bill by Congress, and to this end physicians should give every aid in their power. Why should not Drs. Ellis, Jones and others establish their bureau without the sanction and support of the American Medical Association and the American Pharmaceutical Association, and give the professions the benefit of its workings? In the meantime there is a vast deal of practical reform possible, based upon the reports of the published analyses of State Boards of Health and of the United States Department of Agriculture.

A National Medical Legislation Committee.—

Devotion to professional interests rather than to those of personal ambition is shown by physicians who give time and energy to medical reforms after their terms as president and chairman have expired. Dr. C. A. L. Reed is happily illustrating the truth, by giving his splendid ability to a task which is perhaps not destined to bring much popularity and honors, but which is all the more needed and, well executed, is bound to be productive of good. It has long been noticed and deplored that we as a profession have no representative in Congress. "Not one," emphasized an antiprotester when an *apparent* exception was suggested. It has also been as old a matter of regret that until the medical profession could bring its influence to bear upon our legislative bodies the imperatively needed medical reforms could never be even commenced. The law, or legal permission at least, must authorize the fundamental conditions. By banding together the scattered individuals who

recognize this truth, by making as it were a national committee to influence the enactment and execution of laws concerning medical progress and hygiene, Dr. Reed has placed the profession and the country itself under profound obligation. With a reunited and reorganized profession to support there should be great advances made in our national medical progress. Every earnest and unselfish worker in medical sociology should apply to be a helper in Dr. Reed's work.

Scientific Exhibit, American Medical Association.—One of the most successful features of the American Medical Association was the exhibit of all varieties of scientific preparations, which was well arranged in a large room at the end of Young's Pier. The exhibit was in charge of a committee, under the direction of Frank B. Wynn, of Indianapolis. To Dr. Wynn belongs the credit of having conceived this department, and of having perfected it in spite of a primary lack of enthusiasm on the part of the Association. The exhibit contained a large number of gross and microscopic pathologic specimens, a large and unusual collection of photomicrographs, röntgen-ray photographs, wax models, etc. Demonstrations were held on Tuesday and Wednesday afternoons. The director outlined the growth and purpose of the exhibit in his address on Tuesday afternoon. It is a most democratic feature; the worker along special lines will perhaps derive the most benefit from the study and comparison of the collections from different schools; yet every practitioner will find it equally valuable for his own work, since it is intended to contain complete series of organic lesions; for example, this year a complete series of kidney lesions was exhibited. An important work accomplished by this exhibit is a stimulation to neater and better ways of preserving specimens; an example of perfect technic was offered by the beautiful collection of Kaiserling specimens from Jefferson Medical College, mounted in gelatin. The exhibit further offers an incentive to the collection of specimens, for while the larger medical schools, because of their greater opportunities, will be able to demonstrate a greater number of specimens, there is always room for anyone to demonstrate even a single specimen; and the specimens need not necessarily be rare, for examples of the most ordinary lesions will be instructive to all who are not in touch with a museum. As examples of the work done at this meeting we would mention the demonstration by Dr. William H. Welch, of Baltimore, of arteriosclerosis and consecutive visceral lesions, forming an almost necessary complement to the symposium on arteriosclerosis. Great interest was shown in the demonstration of Dr. W. T. Councilman, of Boston, of lantern slides and photomicrographs of malaria, aleppo boil, scarlatina, vaccinia and variola. Hodgkin's disease was demonstrated by Dr. W. T. Longcope, of Philadelphia. Dr. H. A. Christian showed lantern slides and photomicrographs illustrative of various pathologic conditions, typhoid, cirrhosis of the liver, tuberculosis, diphtheria and neuralgia. We have not space to give the entire program, but the above will be sufficient to show the character and scope of the work. The demonstrations were well attended. A final point

may be mentioned—and the audiences at both demonstrations proved this—such an exhibit forms a place where the general practitioner and the special worker may meet on common ground with a common subject of interest, which is, unfortunately, not always true in this day of extreme specialization.

Two Kinds of Section Work.—The American Medical Association presidential address was in large part a capital and practical review of the present conditions and achieved reforms of the Association itself. Progress has come through the comparative abrogation of the general session and the concentration of power in the House of Delegates, the elimination of politics, and the rise of scientific work in the sections. Dr. Musser makes a most noteworthy suggestion: The devoting of one morning to a reformed general session on the practice of medicine in which the whole Association could take part; a second morning on surgery; a third on the specialties; a fourth on sanitary science. We hesitate to suggest a word of criticism as to this plan, but it cannot be forgotten that section work would be curtailed, and, as is admitted, it is this which has so largely made for progress in the past. Already it is found that all efforts at concentration of papers, lessening the time of readers and speakers, etc., cannot meet the growing demand for opportunity to read papers in the special sections. It seems even now that it will soon become imperative that contributors read only brief epitomes of their articles, leaving the complete papers to be published later in the official organ of the Association. If Dr. Musser's suggestion is carried out the sections must hereafter meet in the evenings in order to give time even for the epitomes and for the following discussions, which, it should be remembered, are often as valuable as the original papers. On the whole, it would seem a doubtful proposal. The progress of medicine rests largely in special work and not in the general questions which would interest all the members. And finally, as to the specialties themselves, those general relations which would interest, say, the oculist and the aurist, or the dermatologist and the orthopedic surgeon, are relatively few, and the deeper problems would be left untouched. It is a pity that, as we have suggested, and as in the *British Association*, a popular evening, both for the lay and professional public, could not be given to some question of universal medical importance and comprehensibility. Few things are more needed than practical methods of bringing the laity into sympathy with professional work.

The Public Should Pay the Physician for Public Work in Preventive Medicine.—In his address at Atlantic City Dr. Biggs urges that when a physician does especial work in the interests of the entire community he should receive payment for his labor. He said:

A serious objection which may be urged against the adoption of the measures recommended in regard to the registration of many infectious diseases is the increased labor thrown on physicians which their enforcement would involve. The question may properly be asked: Whether the sanitary authorities in the interest of the general public may call on the medical profession for the expenditure of so much time and labor with

out making any compensation in return? There are 35 diseases included in the New York list. The English authorities pay a fee for the notification of each case of infectious disease, and I believe that this course might properly be pursued in this country; but this has not been the custom here, and the authorities generally are not now provided with the funds necessary for this purpose.

In New York City free bacteriologic examinations in the diagnosis and surveillance of the infectious diseases, and the provision of facilities throughout the city for the collection of specimens and the sending of reports to physicians, constituted an entirely new departure in sanitary work and has been of the greatest value. The example of New York has been followed by the sanitary authorities in most of the large cities of this country, by many State authorities, and by authorities generally, in Great Britain and to a certain extent on the Continent. These examinations constitute the return which the authorities here have made to physicians for the reporting of cases and for their assistance and cooperation in their care. This return has a very considerable money value, when we remember that for such examinations the usual fee is \$5, and as physicians can not, as a rule, make such examinations themselves, they must work without the assistance thus afforded, unless they appeal to the regularly constituted laboratories.

Improvements Needed in Medical Education.—

We have frequently called attention in these columns to many changes needed in our modern methods of medical education. In his presidential address, at the Fifty-fifth Annual Session of the American Medical Association, Dr. John H. Musser (*American Medicine*, June 11, 1904) set forth very admirably and clearly many of these needs, and called attention to some matters which we believe have not previously been brought to the notice of the medical profession. The most needed reforms are: A more careful discrimination as to the character, physical and mental fitness of the student who is to undertake medical studies; the desirability of a higher standard of preliminary education, and Musser believes that a preliminary college course should be the ideal; improved facilities for laboratory teaching and increased opportunities for hospital study. To this end he suggests extramural hospital teaching as a substitute for part or whole of the fourth year of medical study. These changes would cut down materially the number of students undertaking the study of medicine and would, in this way, indirectly remedy the present overcrowding of the profession. All of these changes are urgently needed in greater or less degree in all of our medical schools. Under the present conditions of overcrowding in the profession there is no excuse for the existence of a large number of medical colleges throughout the country that are not in the position to give either satisfactory laboratory teaching or the clinical facilities necessary for the training of the modern medical man. A chief object of the founders of the Association was improvement in medical education:

"The object of this Association shall be for the purpose of elevating the standard of medical education.

"This Association has been, should be, and we trust will be, the storm center of legislation for reform in medical education."

When we remember that 15 years ago there was no uniform requirement for entrance to medical study, many students being admitted without even a high school education; that no medical college was requiring over three years' study for a degree, and most were graduating their students after a two years' course; that the majority of the States of the Union required no examination for qualification to practise, we see that very much has been accomplished. Further improvements are being made at the present, but we cannot afford to stop where we are, and this surely will not occur. At the rate of progress made in American medical education during the past decade, we confidently predict that our country will soon as surely lead the world in medicine and surgery as is at present the case in many other fields of thought and action.

The Problem of Dealing with Unfit Students: Overcrowding in the Medical Profession.—Important suggestions are given by Musser as regards our duty to those contemplating the study of medicine and to students, who show during the first years of study, that they have not adaptability for the work. He questions whether the average student is quite able to decide whether he should take up the profession of medicine, and asks if it would not be well to have in our college curriculum a course of lectures for the student who contemplates entering a profession, pointing out the rocks and shoals in his prospective career.

The majority of students have no good reason for studying medicine. They are ignorant of its mental and physical demands. They are attracted by a glamor and specious glory, and heedlessly go in. The failure of a large percentage of graduates in medicine to acquire more than a bare existence, too often not that, proves that they were not educated properly, not fitted temperamentally or physically to pursue its duties. It would be a greater kindness to show the student that by reason of intellectual temperament or of physical or moral qualities he is not likely to reap the rewards he is anticipating than to allow him to enter a career in which he will probably fail.

If we could thus weed out even a small proportion of those manifestly unfitted for medicine, it would be a great gain. All practitioners, whether teachers or not, should keep this in mind when asked for advice by those considering the advisability of studying medicine. Musser further urges that those who enter the medical school be not permitted to continue their studies if they show themselves unfit.

That school has too many students which does not have enough instructors in the first year to be able to judge with reasonable accuracy of the character and moral stability of the men. A student who does not play fair in his exercises, who cheats in one demonstration or evades another, who does not show manliness, frankness, and truthfulness in his first year duties, will not be a good diagnostician. He will cheat himself; he will cheat his patient. The teachers of the first year, or at least the second, should know this and block the student there and then. It would be a kindness. Let us then agitate whether we should not have a certificate of manliness and of health, as well as of mental proficiency, before we admit students to our medical schools or permit them to go beyond the first year.

We have long considered it a great injustice to do as has so often been done in certain medical schools, permit a student to continue his studies until his final year, and then refuse to graduate him. The harsh things students

say of their professors under such circumstances are not altogether unjustified. Only under exceptional circumstances should a student unfit to receive a degree be allowed to study medicine over one, or at the most, two years.

Higher Tuition Fees.—Another means of cutting down the number of medical students which Musser suggests is by raising the tuition fee. An education which involves a hospital course requires an expenditure of \$500 a year for four years by each student. It is manifestly impossible, as medical schools are constituted now, to educate all the students of the land properly. He believes, if a decree should be issued that no medical school, including its hospital, should exist except upon fees derived from students, but little hardship would follow. The lessened supply of students would increase the demands on the practitioner, so that larger returns would follow. The poor student would sacrifice and strive to get a degree, knowing then he had a good asset. A diminution in number and an increase in quality is demanded alike by the public and the profession. Such diminution in number would mean that the student would get back his investment quicker and in larger amount than at present, hence good men would be attracted. As it is now, medical students receive part of their education through the bounty of the State or the charity of the public, as such education can only be given in endowed institutions. The public is taxed so that the prospective physician can make a living. Is it right that it should be? Perhaps a mechanic should demand such right to make his son a good workman. We must all admit the duty of the State to educate, so that good citizenship is maintained; we question whether the State should educate the members to obtain a livelihood. Under present conditions we decidedly question the desirability of raising the tuition fee, for this would certainly exclude many most valuable men from medicine. The medical man and his education should not be compared with a mechanic; in preventive medicine the medical profession saves yearly thousands of lives, worth inestimable thousands of dollars to the State, and in gratuitous services to the poor alone the medical profession by preventing people from becoming permanently crippled, repays many times over, all State appropriation and private beneficence. The public can never repay a tithe of the debt it owes to medicine. Such institutions as the University of Michigan, where the standards are high but tuition a nominal fee, or Cornell, which gives free State scholarships to a considerable number of its medical students, have contributed much both by well-trained practitioners and scientific work to the progress of American medicine. There is little danger of overcrowding by the graduates of such institutions. Few of the best men study medicine because of the financial rewards it promises, and there can be little question that those who are really successful financially would have earned many times more had they chosen a business career and put into it the money and time they devoted to preparation for their profession. A high tuition fee shuts out just this class of idealists. The requirement of a degree in

arts or science preliminary to medical study should accomplish the reduction of the number of graduates and at the same time improve the quality of the graduate, we believe, much more satisfactorily than would raising the tuition fee.

An Academic Education Preliminary to Medical Study.—Musser urges very forcibly and makes a strong plea for its advantages. There should be one educational requirement—the equivalent of that for which a first-class college degree stands, whether received at a high school or university. To the plea that the requirement of a college degree takes up too much time and requires too much money, the material answer can be given that while only "1% of the entire population of America has received a higher education in her colleges and universities, this 1% holds more than 40% of all positions of confidence, of trust, and of profit." It is well known that the "Geist" of the individual brings success, for which they say "it is recognized that the educated man takes in a wide horizon and puts more 'soul' into his work." The poor boy, therefore, need not be deterred, for if he has the spirit and energy to work his way through four years, two years or three years more will be but very little in the final summing up. The purchase of the best education, whether reckoned in time or money, is the most economic investment. We have recently discussed this question in these columns, and hardly need say that this is an ideal which we have frequently and strongly advocated.

Dedication of the Rush Monument.—In the presence of a distinguished gathering of American physicians, the statue of Dr. Benjamin Rush was unveiled in Washington, D. C., on Saturday afternoon, June 11. Delightfully simple but impressive ceremonies were held on the grounds of the old Naval Observatory, now occupied by the United States Naval Museum of Hygiene and Medical School. Dr. John H. Musser, of Philadelphia, President of the American Medical Association, conducted the ceremonies and made the presentation address. The orator of the occasion was Dr. James C. Wilson of Philadelphia, Chairman of the Rush Monument Committee, who delivered an eloquent eulogy of Dr. Rush. In accepting the statue on behalf of the nation, President Roosevelt showed a thorough appreciation of the great services of Dr. Rush. Such a patriot, philanthropist and indefatigable scientist as Rush may well be considered his ideal of an American citizen, and the President emphasized the literal dependence of the country's growth and safety upon the active participation in public affairs by citizens of the intellectual class. The statue stands on a prominent elevation in the adjacent park, and though rather remote from the line of travel, the impression gained from its first view on a rare June afternoon bespeaks the wisdom of the Secretary of the Navy in selecting the site. The figure is of heroic size in bronze, and is mounted on a pedestal of Indiana limestone. In keeping with the surroundings the general scheme is a simple one, and represents the celebrated physician in a walking attitude, deep in meditation with his favorite note book in hand—the personification of

his favorite Latin motto "*Studium sine calamo somnium*," which is inscribed on the rear panel of the pedestal. Congratulations are due to the committeemen of the American Medical Association, to the sculptor, Mr. R. Hilton Perry, of New York, to the architect, Mr. Louis R. Metcalfe, and to the builders for the fruition of this worthy tribute first planned over two decades ago.

Prognosis: Its Theory and Practice.—It was a happy thought on the part of Dr. George Dock to select for the subject of his oration before the American Medical Association that much neglected field of medical practice—prognosis. There is an unquestionable tendency at the present time to permit diagnosis to monopolize the field of action, even at the expense of treatment, and prognosis, which our medical forbears considered a fine art, has fallen into disuse. It is to be hoped that the admirable address of Dr. Dock will serve to revive a proper interest in this phase of medical science. "With an accurate prognosis," to quote his words, "based upon an exact and thorough examination, knowledge of the natural course of the disease and of the patient, the physician foresees the course of the malady, and is prepared for changes, emergencies, and complications." Moreover, it is good mental discipline to work out the prognosis in every case, as the complement of the diagnosis. Having done so, the question arises: To what extent shall the patient be made cognizant of the physician's conclusions? Upon this point Dr. Dock's advice is both thoughtful and timely. In many cases, he holds, it is distinctly proper to tell the sufferer with a chronic disease the nature of his malady. The statements made should be simple and as brief as definiteness will permit, without pathologic explanations. It is possible to tell a patient that he is suffering with tuberculosis or cancer without causing a great shock; and, "by dwelling upon the fallibility of human knowledge in general, and of medical knowledge in particular," to quote Dr. Dock, the sharp edge, as it were, of the information may be dulled. One should never, even in conveying the saddest tidings, utterly crush hope in the heart of one's patient. In dealing with a person of average intelligence, one can inform him of the possible fatal termination of his illness in such a way that, while he will take all the necessary steps to prepare for the end, he will still have left a ray of hope that the worst may not happen. Dr. Dock very justly inveighs against the practice of some physicians—a practice springing, perhaps, from the otherwise worthy motive, not to take unearned fees—to abandon cases that appear to be hopeless. Very much may be accomplished by the physician in such circumstances. His visit cheers the patient and banishes, even if only for a short time, gloom and despair. If the disease is a hopeless one, the physician is able to lessen the physical suffering entailed by it. This is not to be construed as expressing approval of the attitude of some laymen that in a hopeless case attended with pain, the physician should bring about a speedy euthanasia. In the long run, that physician will be the most successful who, other things being equal, habitually looks upon the bright side in making prognosis. To

what extent a consultant should indulge in optimism cannot be decided dogmatically. Both he and the family physician must always consider the patient, as well as his dear ones; and Dr. Dock is surely right in saying that it is often more necessary to keep up the spirits of the relatives, especially those that have to do the nursing, than to consider the feelings of the patient. The code of the strict moralist that any deviation from absolute truth is wrong is unthinkable in medicine, when the subject of prognosis is under consideration. The physician's chief interest is with the consequences, and if the patient can gain only by having the true nature of his case misrepresented, the physician is assuredly justified in misrepresenting it.

Interstate Reciprocity in Medical Licensure.—Since the divorce of the license-granting from the degree-conferring power, this subject has engrossed the attention of the profession with increasing insistence. It was an aphorism of Socrates that the penalty which the good must suffer for not taking part in the government is that they must live under the government of worse people than themselves. The crux of the whole subject of interstate reciprocity has at last been resolved into the question of uniformity of requirement; and this means at last a minimum standard of education. Except for the growth and multiplicity of commercialized medical colleges, the diploma of a reputable institution might still carry with it the right to practice. But today these reputable schools must suffer for the sins of their disreputable sisters. Fulfilling at once the functions both of judge and executioner, the power of the State Medical Examining and Licensing Board is beginning to dawn upon the medical schools, the profession and the public. Confronting different conditions in the several States, these boards have raised diverse standards. The result, for the moment, is but confusion worse confounded. That practical need will be met through the application of sound pedagogic principle is evidenced in the fact that these problems are now being grappled with, simultaneously and conjointly, by such organizations as the American Medical Association, the Association of American Medical Colleges, the National Confederation of State Medical Examining and Licensing Boards, the American Confederation of Reciprocating Examining and Licensing Boards and the like. The Association of American Medical Colleges has already adopted a minimum standard of requirement, as to the medical student's preliminary education. The next step is sought in similar uniformity of medical curriculum. Three important resolutions, passed at its recent meeting in Atlantic City on June 7, mark progress in this direction: 1. The Association approves the so-called combined system of college and medical education, and proposes to give a time credit, not exceeding one year, to the holder of the A.B., B.S., or equivalent degree from a reputable college or university; *provided*, such student has had at least 900 hours in Physics, Chemistry, Osteology, Histology, Embryology, Anatomy and Physiology; *and provided* the applicant for such time credit satisfies the professors attached to the medical school as to his proficiency in these first-year medical

studies. 2. In case of transfers of students between the associated colleges, the dean of the recipient institution must secure an official statement, from the school from which the student comes, as to the latter's educational and moral status. 3. A committee was appointed to confer with a similar committee from the National Confederation of State Medical Examining and Licensing Boards, upon the subject of a minimum standard of medical education and the proper distribution of subjects in a four-year, graded, medical course.

The plea for a standard medical curriculum, presented by Dr. George M. Kober, of Washington, deserves attention, if not endorsement. Recognizing the lack of uniformity in State Board requirements, as well as in college curriculums, and pointing to the minimum standard of preliminary requirement already adopted, he suggests that the adoption of a standard prescribed medical course may open the door to an equitable reciprocity. Failures before State Examining Boards may be attributable to one or more of three causes: (1) Noncompliance, by the colleges, with State Board requirements; (2) deterioration, on the part of the student, after graduation; (3) dishonesty in college examinations leading to the medical degree. McIntire's composite presentation of the work of State and college examiners shows them to be alike conscientious in their gradings and in their desire for better things. The fault must lie in the method by which the product of the colleges is evolved. Kober presents a composite of State Board requirements and of actually existing college curriculums. The result is a 4,000 hour course, distributed over four years, with such allotment of hours for each subject and in each year as practical experience and rational theory would seem to indicate. It may be questioned, for instance, whether general physics and general chemistry should not be an absolute prerequisite for the medical matriculant. The fact remains, however, that the average medical student is sadly lacking in knowledge of these branches. Again, there seems to be no real reason why the general biologic studies should not be thoroughly mastered before the student enters upon the medical course proper. This would open the way for a much needed revolution: The teaching of anatomy, chemistry and physiology, in the medical school, only from the standpoint of their practical application to medicine and surgery, not as abstract sciences or specialties. Still another question may be raised, that no two classes should be taught any one subject simultaneously, in a properly graded course based upon sound pedagogic principles. But, art is long, time is short, we cannot crowd too many topics into any one year without making it topheavy. The proposition that a uniform national curriculum will effect a more uniform distribution of students in the various medical centers is, at first, startling, if not repellant. But, after all, is it not an end devoutly to be desired? No argument is needed to prove the advantages of smaller classes, closer personal contact, a more uniform and economic utilization of laboratory and clinical material. May it not be true that some of our best colleges have gone to the extreme of producing unilateral specialists, when all-round prac-

tioners are in demand? The State Board requirements for these schools are no higher than for those less pretentious. There have ever been good men and true turned out from these small colleges. And, in these same small schools, there have ever been good men, true to the Hippocratic tradition, willing to give of their knowledge without cost. By all means, let us have *some* schools which shall be unsurpassed in certain lines; but let us at the same time see to it that *no* school falls short of a reasonable requirement in *all* lines. Large endowments, palatial buildings, elaborate equipment, desirable and necessary though they be, do not in themselves constitute a teaching institution. It is the old story of the men behind the guns. Let these men get together, determine upon the nature of their ammunition, the weight of their several charges, the caliber, range, and angle of fire, the order and distribution of their batteries, and American medical education will be victorious. Judging by recent events, the State Boards have the power, and in some instances the inclination, to drive recalcitrant schools into line. But compulsory compliance with rule must ever be more or less futile. The better schools owe it to themselves, to the profession, and to the public to resume their rightful initiative in matters educational. Concerted action, based upon firm and intelligent conviction, will soon attain the end desired.

Dedication of the Medical Laboratories of the University of Pennsylvania.—The dedication of the new medical laboratories of the University of Pennsylvania, which took place on Friday, June 10, constitutes an epoch in medical education in America. The ceremonies were dignified and simple, and were attended by a large number of physicians, principally members of the American Medical Association that had accepted the courteous invitation extended to them by the University to be its guests. A special train brought the visitors from Atlantic City and took them back at night. To those that had not previously visited Philadelphia, as well as to the old graduates of Philadelphia's medical schools, their visit to the University must have been a revelation. Dr. Horatio C. Wood, in his eloquent address at the dedication of the new laboratories, alluded to the magnificent material progress that the University has made in the last generation—a progress, one may add, in which Dr. Wood has been an important factor. The new laboratories are intended for the Departments of Pathology, Physiology, and Pharmacology, and everything has been done to give these important departments an ideal home. The building is architecturally attractive, and is in harmony with the general plan of the newer buildings, especially the dormitories. Mr. J. Vaughn Merrick, in the absence of Dr. S. Weir Mitchell, the chairman of the Medical Committee, delivered the presentation address, to which Provost Harrison responded. Dr. H. P. Bowditch, professor of physiology at Harvard University, spoke for physiology, and emphasized the importance of the physiologic laboratory in medical instruction, although he did not fail to say a good word for didactic teaching, which must still have a place in the medical curriculum. It should be borne in mind, he said, that it is quite as

possible to abuse the laboratory as the didactic method of instruction; and that in all schemes of education a good teacher with a bad method is more effective than a bad teacher with a good method. Professor R. H. Chittenden, director of the Sheffield Scientific School of Yale University, dwelt upon the importance of physiologic chemistry to medicine, and illustrated it by describing the epoch-making work of Hoppe-Seyler and his school. Dr. George Dock, professor of medicine at the University of Michigan, decried the tendency to magnify the place of the laboratory, and to encourage students to do advanced original work before the foundation is laid. He also spoke of the neglect into which pathologic anatomy has fallen, and urged the importance of performing autopsies whenever possible. The difficulty in regard to autopsies does not depend upon public sentiment alone, but upon a certain neglect upon our own part. He thought that as pathology gets everywhere out of cellars and back rooms and has a local habitation like the new laboratories, its cultivation would assume a broader and more independent character. The laboratory building is quadrangular in shape, two stories in height above a high basement, and measures 340 feet front by nearly 200 feet in depth. All along the front are arranged small rooms for research, rooms for the professors and assistants, a library, etc.; these open into a private corridor, so that the men employed in these rooms may pursue their work without interruption from students passing through the main halls. The second floor is devoted exclusively to pathology. The entire north front of the building is devoted to laboratories for advanced students in pathology and pathologic bacteriology, and to the special research and assistants' rooms.

Prizes for Scientific Discovery.—The contention made in *American Medicine* (May 28, page 839) that the hope is vain of stimulating medical research by means of prizes, receives an unexpected confirmation in the announcement of the abandonment of the American Medical Association medal. No essay had been submitted for four years worthy of the medal, although the demands were by no means high. The plan was essentially childish, and its failure is not to be regretted. One may hope that the money and energy being devoted to manufacturing what are held to be the conditions of medical discovery—we allude to laboratories, research endowments, etc.—may not also prove failures. They may at least train a larger number into a condition of mind capable of receiving new medical truths. But it must not be forgotten that they may not. Many minds, even "leading authorities," are impervious to such truths, and exhibit the most intense prejudices, and even opposition to the reforms until such opposition is no longer possible. Then they "always knew and recognized this"—at least, in words, and the forgotten discoverer may remain forgotten—until after his death. "Let us honor the Walter Reeds and Lazears," they seem to say, "but let us ignore them until they have succeeded in discovering and in dying without us!" The clinical discoverer of puerperal septicemia was bitterly persecuted by his scientific colleagues.

AMERICAN NEWS AND NOTES

GENERAL.

An examination of candidates for the position of assistant surgeon in the army will be held at the Army Medical School, in Washington, D. C., June 20. It is hoped to fill the 14 vacancies that exist in the army, and to this end several examinations will be held following that of the present month.

United States Officials Take Action against Packers.—The report comes from Washington that Dairy and Food Commissioner Warren will take action against several of the large packing houses, for the use of various chemic agents in the preservation of meat. Dr. Warren is quoted with the following statement: "We will swear out warrants for about 100 dealers whom our agents have made cases against, according to our experts and our attorneys. The chemists have found that the Western concerns, some of which are large factors in the beef trusts, are using preservatives containing sulfites in comparatively large quantities. These sulfite preservatives are the most injurious to health that have as yet come to our notice, and we are determined to drive them out of the market."

Miscellaneous.—General: Dr. John S. Fulton, secretary of the Maryland State Board of Health was elected president of the State and Provincial Boards of Health at the nineteenth annual meeting, June 4. The other officers elected were M. K. Foster, San Francisco, vice-president; J. A. Egan, Springfield, Ill., treasurer; Gardiner T. Swartz, Providence, R. I., secretary. —Dr. Anita Newcomb McGee, who left Philadelphia several weeks ago in charge of ten Red Cross nurses to assist the Japanese, has been appointed superintendent of nurses by the Japanese Red Cross Society. She has also been given the rank of an officer by the Japanese Government. In her letter to the Red Cross Society, Dr. McGee, says she and the nurses will soon go to Hiroshima, the main base, on the Inland Sea. Baron Ozawa, vice-president of the Japanese Red Cross Society, under the direction of the Minister of War, will accompany the American nurses to the front. Each American in the party will have a Japanese nurse to accompany and instruct her in the language, customs and other details. —**New York:** The sixth annual commencement of the Cornell University Medical College was held in the Carnegie Hall on Wednesday, June 8. Fifty-five students received their degree. Dr. W. W. Keen delivered the address of the evening.

Bequests to Charity.—Philadelphia: By the will of the late Hiram Brooke, his residuary estate was left to be distributed by his executors, Fidelity Trust Company, to such charitable institutions as they may think most deserving. The testator in his will left some small legacies from \$500 to \$2,000 each to nine hospitals, and the executor increased these gifts to \$5,000 each, and in addition gave the same sum to 15 others, making 24 hospitals in all, for the endowment of free beds in the name of Hiram Brooke, so as to establish permanent memorials of the testator. The hospitals are as follows: Hospital of the Protestant Episcopal Church in Philadelphia, Jefferson Medical College Hospital, German Hospital of Philadelphia, Hahnemann Medical College and Hospital, Jewish Hospital Association of Philadelphia, Contributors to Pennsylvania Hospital, St. Joseph's Hospital of Philadelphia, St. Timothy's Memorial Hospital and House of Mercy of Roxborough, Friends' Asylum for the Insane, University of Pennsylvania Hospital, Methodist Episcopal Hospital in the City of Philadelphia, Medico-Chirurgical Hospital, Presbyterian Hospital in Philadelphia, West Philadelphia Hospital for Women, Howard Hospital and Infirmary for Incurables, Children's Hospital of Philadelphia, Germantown Dispensary and Hospital, Kensington Hospital for Women, Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, Rush Hospital for Consumption and Allied Diseases, Woman's Hospital of Philadelphia, Philadelphia Polyclinic and College for Graduates in Medicine, St. Agnes' Hospital in the City of Philadelphia, St. Christopher's Hospital for Children. —By the will of the late John L. Devereux, an aggregate of \$141,000 was left to various hospitals and church organizations in Philadelphia.

The National Association for the Study and Prevention of Tuberculosis was organized June 6, at Atlantic City. A constitution and by-laws were adopted, which had been prepared by a committee appointed in Philadelphia, March 28 to organize the society. E. L. Trudeau, of Saranac Lake, N. Y., known as the "Father" of the antituberculosis movement, was elected president. Thirty directors were chosen, as follows: Massachusetts, Bowditch and Otis; Connecticut, Foster; New York, Biggs, Trudeau, Devine and Knopf; Pennsylvania, Lawrence Flick, Mazyck Ravenel, Howard S. Anders and Leonard Pearson; New Jersey, Hoffman; Maryland, W. H. Welch, William Osler, Jacobs and Pullon; District of Columbia, Sternberg; North Carolina, Minor; Colorado, Soley; Illinois, Klebs and Babcock; Minnesota, Bracken; Missouri, Porter; Indiana, Harty; Michigan, Vaughan; Ohio, Probst; California, Briggs; Texas, M. M. Smith; Marine-Hospital Corps, General Wyman, and United States Army, Major Bushnell, of Fort Bayard. William Osler, of Baltimore, presided; The question of the best means for preventing tuberculosis was

discussed at length by Biggs, of the State Board of Health, New York; Minor, of Asheville, N. C.; J. Solis Cohen, of Philadelphia; Huber, of New York; Devine, of the New York Charity Organization, and Hinckley, of Washington, D. C. They described the efforts being made to reduce mortality from the disease, advocated dispensaries for its treatment in its incipient stages, and instruction of the people by free lectures. Biggs, while detailing the work done in New York, said that since the Health Board had adopted its present system mortality from tuberculosis in New York had been reduced 40%. He would not be surprised to see a further reduction of 40% within the next 10 years, though at present the new cases reported in New York City aggregated 16,000 a year.

EASTERN STATES.

National Conference of Charities and Corrections convened in Portland, Maine, June 15, and will continue in session till June 22. The president of the conference is Dr. Jeffrey R. Brackett, who recently resigned the presidency of the Department of Charities and Correction of New York to become a director of the new school for the training of social workers, to be conducted under the joint auspices of Harvard University and Simmons College. The chief aim of the conference is to bring together workers who observe from various points of view the problems of lessening want, suffering, and crime.

NEW YORK.

Hospital for Treatment of Pulmonary Tuberculosis.—By July 1 next, the State Hospital for the treatment of incipient tuberculosis, at Raybrook, Essex county, will be so far completed that 80 patients may be received. The wings of the hospital are yet unfinished, but when they are ready for patients 150 more can be accommodated. All applications of patients must be made to the Overseers of the Poor, for the intention is to give preference to the indigent persons who are suffering in the first stages of the disease. The overseer shall certify patients, who will then be examined by the local examiners, and will be certified by them, if a proper case, for admission. Patients in advanced stages of the disease will not be admitted. The State has expended \$215,000 for the construction of the hospital, and has appropriated \$55,000 for its maintenance. In addition to these sums an appropriation of \$5,000 has been secured for the establishment of a camp for outdoor treatment.

PHILADELPHIA, PENNSYLVANIA, ETC.

Wrong Diagnosis.—Under instructions from the State Board of Health the smallpox committee of Salem, N. J., has made a thorough investigation, and has learned that the disease, which for awhile was epidemic there, originated from an overcoat made in a sweat-shop district and purchased by the first victim who died with the disease. A physician pronounced the malady ptomain poison; a large public funeral was held and the disease thus spread.

Homeopaths to Join in the Fight.—The Homeopathic County Medical Society will cooperate with the Philadelphia County Medical Society in the crusade which the latter organization is conducting against illegal practitioners in Philadelphia. At a meeting held by the Homeopathic Society, in Hahnemann College recently, the movement against illegal practice of medicine by nonregistered physicians in this city was discussed at some length, and the action of the Philadelphia County Society upheld. A committee was appointed to cooperate in apprehending and prosecuting the illegal practitioners.

WESTERN STATES.

Persons Afflicted with Pulmonary Tuberculosis Debarred from Teaching.—The Indiana State Board of Health has decided that hereafter no one afflicted with tuberculosis may be employed to teach in the public schools of Indiana. According to the investigations of the Board there are now in the State 250 teachers in the public schools who have tuberculosis.

Decrease of Pneumonia in Chicago.—The Bulletin of the Chicago Health Department, for the week ended June 4, says: For the first time since last October the weekly pneumonia deaths have not exceeded the deaths from tuberculosis. The 67 deaths from each cause represent 14.8% of the total mortality, instead of as heretofore, 10.7% for tuberculosis and 22% for pneumonia. In New York City the reduction of pneumonia is even greater; at the close of office hours on Saturday, June 4, there had been 1,265 deaths from all causes reported, of which number only 161, or 12.7%, were from pneumonia, and 172, or 13.6%, were from tuberculosis. The previous ratios had been 20.98% for pneumonia and 11.12% for tuberculosis. The reign of pneumonia is over until next November, and tuberculosis is again the "captain of the men of death."

Pneumonia in Chicago.—The bulletin of the Chicago Health Department for the week ended May 28, states that the term of pneumonia as the "Captain of the Men of Death" is nearly over for the present season. Since November 1, 1903, there have been 3,703 deaths from this cause out of a total of

16,780 deaths from all causes—a proportion of more than a fifth (22.06%) of the total mortality. From pulmonary tuberculosis during the same period there have been 1,806 deaths, or less than half those from pneumonia. Following is an extension of the table of these two causes of death for Chicago and New York City between November 1, 1903, and May 28, 1904:

	New York.	Chicago.
Total deaths, all causes	46,999	16,780
Deaths from pulmonary tuberculosis ..	5,228	1,806
Deaths from pneumonia	9,865	3,703
Proportion percent of all deaths—		
From pulmonary tuberculosis	11.12	10.76
From pneumonia	20.98	22.06

New York's estimated midyear population for 1904 is 3,888,024. Chicago's is 1,932,315.

FOREIGN NEWS AND NOTES

GENERAL.

Remedy for "Sleeping Sickness."—M. Guien, agent for culture of the Colonial Society of the Upper Congo, has drawn attention to a native remedy for "sleeping sickness." It is an infusion of the wood called "iboga," which is common in the Gaboon. It is claimed that this infusion acts as a stimulant which counteracts the sleeping sickness.

Centenarians.—An exchange states that in Germany there are 778 persons who claim to be 100 years old or more; in France there are 213; in England, 146; in Scotland, 46; in Norway 23; in Sweden, 10; in Belgium, 5; and Denmark, 2. In Switzerland there is not one centenarian, but, on the other hand, there are 401 in Spain, and as many as 575 in Servia.

Russian Physicians Fear Epidemics in Manchuria.—News from St. Petersburg states that the greatest precautions are being taken to prevent the outbreak of epidemics among the troops in Manchuria. Men specially trained in disinfecting are dispatched to all the big camps by the Red Cross Society, and according to reports received, the sanitary conditions are fairly good. Some sporadic cases of typhus and smallpox were segregated early. Apparently there is no danger of an epidemic. Letters received here from Liao-Yang say the conditions there are much improved, dry weather prevailing in April and early in May. Harbin was being cleaned up. The conditions in Korea, on the other hand, are described as terrible, and doubtless are responsible for the sickness prevailing in the Japanese army. The Red Cross Society has established over 10,000 beds in Manchuria for the purposes of war. In addition to the hospital trains, 18 barges are being fitted for the transportation of the wounded and sick by the Sungari and Amur rivers. Much is expected of the flying detachments, each made up of a surgeon, four medical students, and eight men trained to apply the first aid to the wounded and operate under fire.

OBITUARIES.

Henry D. Ingraham, in Buffalo, N. Y., May 23, aged 62. He was graduated from the University of Buffalo, Medical Department, in 1896; was a member of the American Medical Association, New York State Medical Society, American Association of Obstetricians and Gynecologists. He was gynecologist to three hospitals in Buffalo, and was also professor of the practice of medicine in the University of Buffalo from 1898 to 1902.

P. W. Beale, from paralysis, at his home in Camden, June 7, aged 47. A graduate of the Jefferson Medical College, in 1876; one time coroner of the city of Camden; member of the City Council and Pension Commissioner under the administration of President Harrison. He was prominent in the Odd Fellows, Masonic and other fraternities.

Oliver E. E. Arndt, of intermittent fever, at his home in Easton, Pa., May 29, aged 41; he was a graduate of the University of Michigan, and graduated in medicine at the Medico-Chirurgical College, Philadelphia, in 1888. He was a member of the Northampton County and the Pennsylvania State Medical Societies.

James W. Keiser, at Reading, Pa., of cardiac exhaustion superinduced by pneumonia, June 6, aged 43. He was graduated from the University of Pennsylvania in 1882. For fourteen years he served as secretary of the Berks County Medical Society, and was a member of the State Medical Society.

George W. Green, at his home in Battle Creek, Mich., May 27, aged 67. A graduate of the University of Michigan, Ann Arbor, in 1862. Member of the Michigan State Medical Society; of the American Medical Association; and a prominent specialist in diseases of the eye, ear, nose, and throat.

George M. Stiles, of Conshohocken, Pa., at the University Hospital, Philadelphia, June 8. A graduate of the College of Physicians and Surgeons, Baltimore, in 1882. He was Inspector of the Montgomery County Prison and Trustee of the State Hospital for the Insane.

Peter E. Griffin, in Columbia, S. C., May 18, aged 73. He was graduated from the University of Pennsylvania, Philadelphia, in 1855; served as surgeon in the Civil war, and for thirteen years was superintendent of the South Carolina State Hospital for the Insane.

George W. Burke, at his home in Middleton, Conn., June 6, aged 82. A graduate of the Yale Medical College, in 1848. From 1869 to 1881 he was United States Deputy Collector of Customs; he was one of the oldest and best known practitioners in Connecticut.

Philander Daugherty, of Junction City, Kan., May 23, aged 70. He was graduated from the Rush Medical College, Chicago, in 1866; was a member of the American Medical Association, and served as health officer of Junction City for several years.

Robert H. Stirling, a retired physician, in Baltimore, May 24. He was graduated from the University of Baltimore, in 1859, and was an acting assistant surgeon in the United States army during the Civil war.

James Robinson Gray, of Youngstown, Ohio, at the home of his mother in Pittsburg, Pa., May 26, from pulmonary tuberculosis, aged 32. A graduate of Jefferson Medical College, in 1897.

William Mulherin, of organic disease of the heart, at the home of his father in Philadelphia, Pa., April 7, aged 25. A graduate of the Kentucky School of Medicine, Louisville, 1902.

George Washington Brooks, at his home in New York City, June 7, aged 87. He retired from practice some eight years ago, and before his death suffered several strokes of apoplexy.

John C. Sill, at his home in Argyle, N. Y., May 23, aged 80. A graduate of the University of New York, in 1848; ex-president of the Washington County Medical Society.

Henry J. Hutchinson, a graduate of the University of Minnesota Medical Department, May 28, 1904, was drowned in the Dalles of the St. Croix River, Minn., May 29, aged 25.

Henry M. Replogle, at his home in Udell, Ia., May 27, aged 38. A graduate of Rush Medical College, Chicago, in 1895. Member of the American Medical Association.

Wilbur R. McKnew, a retired physician of Baltimore, May 31, aged 65. He was graduated from the University of Maryland School of Medicine, Baltimore, in 1862.

Lyman M. Beckes, from septic meningitis, at his home in Vincennes, Ind., May 25, aged 42. A graduate of the Medical College of Indiana, Indianapolis, in 1887.

Clinton L. Shoemaker, at his home in Philadelphia, May 29, from spinal meningitis, aged 33. A graduate of the Medico-Chirurgical College, Philadelphia, in 1903.

Clinton D. Baker, committed suicide, at his office in Conneaut, Ohio, May 26. A graduate of the Medical Department of Western Reserve University.

James N. McNutt, in Southville, Va., May 23, aged 60. He was graduated from the Washington University School of Medicine, Baltimore, in 1869.

Thomas J. Fitzmaurice, of Paterson, N. J., May 29, aged 35. He was graduated from the Bellevue Hospital Medical College, New York City, in 1893.

Rollo Campbell, of Montreal, at the Western Hospital, in that city, May 80. A graduate of the University of Bishops College, Montreal, in 1887.

M. White, in Ashburn, Mo., May 17. He was graduated from the Keokuk Medical College, College of Physicians and Surgeons, Keokuk, Ia., in 1901.

John L. Johnston, at his home in Craig, Mo., recently, aged 86. He was surgeon in the United States army in both the Mexican and Civil wars.

Theodore Osgood Cornish, at his home in South Boston, Mass., May 23, aged 80. A graduate of Vermont Medical College, Woodstock, in 1851.

L. B. Andrews, at Rochester, N. Y., May 21, aged 40. He was graduated from the medical department of the University of Buffalo, in 1885.

Arthur M. Line, Wilmington, Del., May 29, aged 33. He was a graduate of Harvard, and College of Physicians and Surgeons, New York.

Reginald Henwood, in Brantford, Ontario, May 22, aged 66. He was graduated from the College of Physicians and Surgeons of Toronto in 1877.

A. E. Williams, in Cottageville, S. C., May 18. He was graduated from the Medical College of the State of South Carolina, Charleston, in 1854.

R. Harmon, in Oakland, Cal., May 19. He was graduated from the medical department of the University of California, San Francisco, in 1879.

Richard G. Lightle, in Searcy, Ark., May 22, aged 32. He was graduated from the Kentucky School of Medicine, Louisville, in 1898.

M. Taylor Powell, in Newburg, W. Va., May 15. He was graduated from the College of Physicians and Surgeons, Baltimore, in 1883.

D. E. Walker, of Iilon, N. Y., May 18, aged 49. He was graduated from the medical department of the University of Buffalo, in 1882.

Tyler W. Richmond, at Bear Lake, Mich., May 15, aged 56. He was graduated from the University of Michigan, Ann Arbor, in 1874.

Robert Johnstone, in Milford, Mich., May 14, aged 65. He was graduated from the Medical College of Ohio, Cincinnati, in 1882.

Thomas N. Clark, of heart disease, at his home in Reagan, Texas, May 20. A graduate of the Galveston Medical College, in 1871.

John E. Maucher, in Carrolltown, Pa., May 21, aged 73. He was graduated from the University of Munich, Germany, in 1851.

Francis Patoel, in Williamssett, Mass., May 11, aged 58. He was graduated from the Trinity Medical College, Toronto, in 1872.

Charles L. Parker, at his home in Onondaga Hill, N. Y., May 23, aged 47. A graduate of the Albany Medical College, in 1892.

Joseph W. Sharp, at his home in Dayton, Pa., April 3, aged 80. He was graduated from the University of Pennsylvania in 1850.

Elias VanCourt, at his home near Kingston, Miss., June 5, aged 74. A graduate of the University of Pennsylvania, in 1853.

H. C. Williams, of Sanford, N. C., May 16. He was graduated from the College of Physicians and Surgeons, Baltimore, in 1882.

C. H. Kinnaman, in Cleveland, May 22, aged 46. He was graduated from the Jefferson Medical College, Philadelphia, in 1886.

R. T. Dean, in New Sharon, Ia., May 22, aged 81. He was graduated from the Medical College of Ohio, Cincinnati, in 1872.

Frank P. Blair, of Allegany, N. Y., May 21, aged 61. He was graduated from the Albany (N. Y.) Medical College, in 1877.

Robert LaGrange, in Marion, Ia., May 23. He was graduated from the Rush Medical College, Chicago, in 1871.

H. N. Stanley, in Atlanta, Ga., May 23, aged 44. He was graduated from the University of Louisville in 1881.

James Lawless, at his home in Chicago, June 9, aged 60. A graduate of Rush Medical College, in 1877.

Augustus W. Duke, at his home in Baltimore, June 8, aged 76.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended June 10, 1904:

SMALLPOX—UNITED STATES.		Cases	Deaths
California:	San Francisco.....May 21-28.....	4	
	Jacksonville.....May 27-June 4.....	1	
Florida:	Macon.....May 28-June 4.....	5

Changes in the Medical Corps of the U. S. Army for the week ended June 11, 1904:

QUINTON, Captain WILLIAM W., assistant surgeon, is relieved from duty at Camp Connell, Calbayog, Samar, P. I., and will proceed to Camp Bumpus, Tacloban, Leyte, P. I., for duty.

FIPE, First Lieutenant JAMES D., assistant surgeon, is relieved from further duty in Iloilo, P. I., and will proceed to Camp Connell, Calbayog, Samar, P. I., for duty.

BOWMAN, M. H., contract surgeon, is relieved from further duty at Camp Bumpus, Tacloban, Leyte, P. I., and will proceed to Camp Connell, Calbayog, Samar, P. I., for duty.

GIBSON, Major ROBERT J., surgeon, will proceed to Fort William McKinley, Rizal, for duty.

RICHARDSON, FREDERICK W., contract surgeon, will proceed to Liago Albay, for duty.

SPRINGWATER, SAMUEL A., contract surgeon, is relieved from duty at Fort William McKinley, Rizal, and will proceed to Guinayangan, Tayabas, for duty, relieving Contract Surgeon Herbert M. McConathy, who will proceed to Manila, P. I., for instructions.

COWPER, HAROLD W., contract surgeon, will proceed to Camp Wallace, Union, for duty.

EUTROPPE, ARTHUR, sergeant first class, now at Mariveles, Bejaan, will proceed to Nalc, Cavite, for duty.

MEISEL, JOSEPH, sergeant first class, will proceed to Mariveles, Bataan, for duty.

GARDNER, FLETCHER, contract surgeon, will proceed to Bulalacao, Mindoro, for duty, relieving Contract Surgeon John L. Burkart, who will proceed to Pilar, Sorsogon, for duty.

GUITTARD, VIRGIL D., sergeant first class, will proceed to Camp Morrison, Ilocos Sur, for duty.

WATKINS, VICTOR E., contract surgeon, now at Fort Miley, will proceed to Fort Apache, for duty.

The following-named surgeons were detailed to represent the medical department of the Army at the annual meeting of the American Medical Association, held at Atlantic City, N. J., from June 7 to 10: Major William G. Borden and Major Guy L. Edie.

FORD, First Lieutenant CLYDE S., assistant surgeon, will report to Major William H. Arthur, surgeon, president of the examining board at the Army Medical Museum Building, Washington, D. C., for examination for promotion.

GREENE, EARL F., sergeant first class, office of the attending surgeon, New York City, will be sent at once to the transport Sumner, New York Harbor, for duty.

JONES, GEORGE B., contract surgeon, is granted leave for one month.

REBERT, MICHAEL A., contract surgeon, now at York, Pa., will proceed to Governor's Island, and report for assignment to duty as surgeon on the transport Sumner.

MUNSON, Captain EDWARD L., assistant surgeon, is relieved from duty with the civil government, as assistant to the commissioner of public health, Manila.

The following assignments to duty of contract surgeons are made: Contract Surgeon Harold W. Cowper is relieved from temporary duty at the convalescent hospital, Corregidor Island, and will report to the commanding general, department of Luzon, for assignment to duty. Contract Surgeon Frederick W. Richardson is relieved from duty at Camp Downes, Ormoc, Leyte, and will report to the commanding general, department of Luzon, for assignment to duty.

MAHVIN, MARION F., contract surgeon, is relieved from duty at Camp Hartsborne, Laguan, Samar, and will report to the commanding general, department of Luzon, for assignment to duty.

BROWN, POLK D., contract surgeon, is granted leave for three months, with permission to visit the United States.

LOVE, JOSEPH W., contract surgeon, is granted leave for two months, with permission to visit the United States.

RAYMOND, Major HENRY L., surgeon, is relieved from duty in the department of Luzon, and will report to the chief surgeon of the Philippine Division for assignment to duty in charge of the medical supply depot, Manila.

WILKINS, ARCHIBALD M., contract surgeon, is granted leave for three months, with permission to visit the United States.

MCCONATHY, HERBERT M., contract surgeon, is granted leave for three months with permission to visit the United States, to take effect about May 15, 1904.

TRUAX, J. P., contract surgeon, is granted leave for one month.

REBERT, MICHAEL A., contract surgeon, is assigned to duty as surgeon on the transport Sumner.

REYNOLDS, Captain FREDERICK P., assistant surgeon, is relieved from duty at the U. S. Army General Hospital, Washington Barracks, to take effect about July 1, and will then proceed to the Presidio for duty.

DALE, First Lieutenant FREDERICK A., assistant surgeon, is granted leave for one month, from about June 15.

HOGUE, GUSTAVUS I., contract surgeon, leave granted May 2 is extended one month.

TORNEY, Lieutenant-Colonel GEORGE H., deputy surgeon-general, having reported to the military secretary, war department, in compliance with orders heretofore issued, will return to his proper station at the U. S. Army General Hospital, Presidio.

TORNEY, Lieutenant-Colonel GEORGE H., deputy surgeon-general, is granted leave for one month.

BROWN, HENRY L., contract surgeon, is granted leave for fourteen days, to take effect June 18, with permission to apply for an extension of seven days.

The following-named officers will report to Major William H. Arthur, surgeon, president of the examining board at the Army Medical Museum Building, Washington, D. C., for examination for advancement: First Lieutenants Eugene H. Hartnett and George W. Mathews, assistant surgeons.

Changes in the Medical Corps of the U. S. Navy for the week ended June 11, 1904:

GUTHRIE, J. A., passed assistant surgeon, detached from the Franklin and granted leave for three months—June 3.

HART, G. G., acting assistant surgeon, detached from duty with recruiting party No. 5, and ordered home and to wait orders from June 4—June 3.

SELLERS, F. E., acting assistant surgeon, ordered to the Franklin—June 3.

FAUNTLEROY, A. M., assistant surgeon, ordered to the Lancaster June 22—June 6.

ANGWIN, W. A., assistant surgeon, appointed assistant surgeon with rank of lieutenant, junior grade, from June 2, 1904—June 8.

ROSS, J. W., medical director, detached from the Naval Museum of Hygiene and Medical School, Washington, D. C., and ordered to duty with the Isthmian Canal Commission—June 7.

MUNSON, F. M., assistant surgeon, detached from the naval station, Polloc, P. I., and ordered to the naval station, Olongopo, P. I.—June 8.

KITE, I. W., surgeon, orders detaching from the Maine revoked; ordered to continue duty on the Maine—June 8.

SMITH, C. G., assistant surgeon, ordered to the naval hospital, Mare Island, Cal., June 28—June 9.

ABEKEN, F. G., assistant surgeon, detached from the naval station, San Francisco, Cal., and ordered to the Adams—June 9.

NELSON, H. T. JR., acting assistant surgeon, detached from the Naval Hospital, Sitka, Alaska, and ordered home and to wait orders—June 9.

MILLER, J. T., acting assistant surgeon, detached from the naval hospital, Mare Island, Cal., and ordered to the naval hospital, Sitka, Alaska—June 9.

Changes in the Public Health and Marine-Hospital Service for the fourteen days ended June 9, 1904:

PURVIANCE, GEORGE, assistant surgeon-general, granted leave of absence for twenty days from May 31—June 1, 1904.

VAUGHAN, G. T., assistant surgeon-general, detailed to represent the service at meeting of American Medical Association, Atlantic City, N. J., June 7-10—June 1, 1904.

GEDDINGS, H. D., assistant surgeon-general, detailed to represent the service at meeting of American Medical Association, Atlantic City, N. J., June 7-10—June 1, 1904.

CARTER, H. R., surgeon, directed to report to chairman of Isthmian Canal Commission for duty—May 25, 1904.

CARMICHAEL, D. A., surgeon, bureau letter of May 28, 1904, granting Surgeon Carmichael leave of absence for fifteen days from May 12, amended to read twelve days from May 12—May 28, 1904.

PECKHAM, C. T., surgeon, granted leave of absence for seven days from May 28, 1904, under paragraph 191 of the regulations. Relieved from duty at the Immigration Depot, New York, N. Y., and directed to proceed to Buffalo, N. Y., and assume command of the service, relieving Surgeon Eugene Wasdin—May 27, 1904.

WASDIN, EUGENE, surgeon, upon being relieved by Surgeon C. T. Peckham, to proceed to Memphis, Tennessee, and assume command of the service, relieving Surgeon G. M. Magruder—May 27, 1904.

WASDIN, EUGENE, surgeon, granted extension of leave of absence, on account of sickness, for sixteen days from May 1—June 1, 1904.

MAGRUDER, G. M., surgeon, upon being relieved by Surgeon Eugene Wasdin, to proceed to Cincinnati, Ohio, and assume command of the service—May 27, 1904.

YOUNG, G. B., passed assistant surgeon, two days' leave of absence under paragraph 189 of the regulations.

ROSENAU, M. J., passed assistant surgeon, detailed to represent service at meeting of International Association for Study and Prevention of Tuberculosis, Atlantic City, N. J., June 6-June 1, 1904. Detailed to represent the service at meeting of the American Medical Association, Atlantic City, N. J., June 7-10, stopping at Philadelphia, Pa., for special temporary duty—June 6, 1904.

NYDEGGER, J. A., passed assistant surgeon, granted extension of leave of absence, on account of sickness, for fifteen days from May 21—May 26, 1904. Granted extension of leave of absence, on account of sickness, for five days from June 5—June 6, 1904.

OAKLEY, J. H., passed assistant surgeon, directed to proceed to Vancouver, B. C., for special temporary duty—May 27, 1904.

ANDERSON, J. F., passed assistant surgeon, directed to proceed to Detroit, Michigan, for special temporary duty—May 27, 1904.

GWYN, M. K., assistant surgeon, directed to report to chairman of board at Manila, P. I., August 8, 1904, for examination to determine his fitness for promotion to the grade of passed assistant surgeon—June 6, 1904.

BAKES, E. C., acting assistant surgeon, granted leave of absence for fourteen days from June 13—June 8, 1904.

DELGADO, J. M., acting assistant surgeon, granted leave of absence for ten days—June 1, 1904.

FOSTER, J. P. C., acting assistant surgeon, granted leave of absence for four days from June 5—June 7, 1904.

GOLDSBOROUGH, B. W., acting assistant surgeon, granted leave of absence for four days from June 7—June 4, 1904.

HALLETT, E. B., acting assistant surgeon, granted leave of absence for four days from June 7—June 7, 1904.

MASON, W. C., acting assistant surgeon, granted leave of absence for five days from June 27—June 3, 1904.

RODMAN, J. C., acting assistant surgeon, granted leave of absence for seven days from June 7—June 2, 1904.

Promotions.

HALL, L. P., pharmacist of the third class, promoted to be pharmacist of the second class, effective April 19, 1904—June 8, 1904.

Board Convened.

Board convened to meet at Washington, D. C., June 1, 1904, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Assistant Surgeon-General L. L. Williams, chairman; Assistant Surgeon-General W. J. Pettus, recorder.

SOCIETY REPORTS

AMERICAN MEDICAL ASSOCIATION.

Fifty-fifth Annual Meeting, Held at Atlantic City, N. J.,
June 7 to 10, 1904.

[Specially reported for *American Medicine*.]

(Continued from p. 950.)

House of Delegates.

Officers of the American Medical Association for 1905.

President, Lewis S. McMurtry, M.D., of Louisville, Ky. Vice-presidents, Edward Jackson, M.D., of Denver, Col.; James H. Bell, M.D., of San Antonio, Tex.; F. C. Shattuck, M.D., of Boston; B. C. Pennington, M.D., of Atlantic City, N. J. Secretary, George H. Simmons, M.D., of Chicago. Treasurer, Frank Billings, M.D., of Chicago. Trustees, T. J. Happel, M.D., of Trenton, Tenn.; W. W. Grant, M.D., of Denver, Col.; Philip Marvel, M.D., of Atlantic City, N. J. Place of meeting for 1905, Portland, Ore.

The new constitution and by-laws presented by the committee were adopted with a few unimportant alterations and additions.

The report of the Board of Trustees showed that the Association owned real estate valued at over \$100,000, and further investments in more convertible securities, to the amount of \$40,000, almost providing for the Reserve Fund of \$150,000, which the Association desired should be set aside for emergency use. The average weekly circulation of the *Journal of the Association* was 28,615 copies, which indicated an increase of 3,615 copies for the past year. The appropriation of \$500 for the Rush Monument Fund was ready for the committee when needed. The treasurer, Henry P. Newman, of Chicago, who had held this position for the past 10 years, relinquished the funds in his possession and tendered his resignation. In February, 1903, J. N. McCormack was appointed national organizer. Nearly every State has accepted the plan of organization proposed and was complying with every requirement of the constitution and by-laws adopted at St. Paul in 1901. The work has been so completely done that it can now be left in the hands of the several State associations to complete by organizing a county society in every county in each State and Territory in the union.

Committee on Branch Associations.—J. N. McCORMACK recommended that permission be given for the creation of seven branches at the discretion of the governing authorities of the State associations composing them, and so arranged as to cover the entire country. A provisional division was made and a form of constitution and by-laws was submitted, under which the presidents of the respective State associations become vice-presidents of the branch associations, and the presidents of these larger bodies in turn become the vice-presidents of this Association. Membership in the branch associations should be voluntary, and the branch associations should hold their meetings at the same time with that of the State associations of the jurisdiction in which the meeting is held. The Committee on Organization recommended that all State associations hold their annual meetings during the fall and during the winter months, so as not to conflict with attendance on the national Association. In debate the following day the plan for the formation of seven branches met with considerable opposition and after much discussion was referred to the Committee on Organization, with instructions to obtain an expression of opinion from the various State societies and to report next year.

Section and Section Work.—A. P. OELMACHER recommended that a permanent committee be appointed for this work whose experience would be effective in maintaining reforms.

Prophylaxis of Venereal Diseases.—HENRY D. HOLDEN (Brattleboro, Vt.) said that national, State and municipal authorities would be willing to cooperate in securing legislation for the prevention of the spread of this class of diseases. At present, 33 States had no laws whatever on this subject except municipal ones. All the large cities were deficient in hospital accommodations for those patients. Maine had agitated the question of reporting such cases to the Board of Health. Michigan had a law forbidding the marriage of those venereally diseased, fixing a fine of from \$500 to \$1,000 for its violation, and compelling physicians who had attended in these cases to testify. It was urged that the Association lend its influence in assisting the study of venereal diseases and in securing legislation for the prevention of their dissemination.

Miscellaneous.—ALFRED STENGEL (Philadelphia) reported that the Association was contributing funds to several members for the purpose of carrying on promising researches, and that some satisfactory results had been obtained. H. WOODS (Baltimore) recommended that recognizing the deleterious effects of wood alcohol and liquors containing it, the federal authorities be invoked to designate the substance a poison and to formulate regulations regarding its sale. E. E. HARRIS (New York) requested that as the New York Association and Society had affiliated, members be allowed to register as guests

of the Association. It was resolved that the Association endorse the action of the Postmaster-General in regard to the use of mails for the distribution of quack medicines and appliances, obscene literature, etc.

[To be concluded.]

Section on Practice of Medicine.

SECOND SESSION.

The entire session was devoted to a symposium on arteriosclerosis.

Pathology of Arteriosclerosis.—WILLIAM H. WELCH (Baltimore) first emphasized the prime importance of combining clinical and anatomopathologic studies for the purpose of elucidating obscure points regarding arteriosclerosis, and then gave a short historic sketch of the subject. Many anatomically distinct diseases of vessel walls are classed under this name, and their separation is of the greatest importance. Welch believes that this can be done with some degree of accuracy, and hence described three types: 1. True arteriosclerosis. This in some respects resembles inflammatory changes; new elastic tissue is formed in the intima by the splitting off of the internal elastic layer of the artery or even of the musculoelastic coat, and there is hypertrophy of the muscle coat. An important feature of this type is the marked degenerative (fatty or hyaline) changes in the arterial wall, with subsequent calcareous infiltration. This type occurs in advanced age. 2. A second type may, to a certain extent, be called physiologic. In this there is a newgrowth of connective tissue and of elastica, but the latter is not formed by a splitting off of the existing lamina as in the first type; it is developed the same as elastica in scar tissue anywhere in the body. This regenerative newgrowth of connective tissue occurs in small arteries, and occasionally in the larger vessels; there is not the tendency to undergo fatty degeneration as in the first type, and the lesion is really that of obliterative endarteritis, instead of arteriosclerosis. 3. There is an affection of the aorta, first described by Heller, which represents the cicatrizing form of the disease. It is found particularly and almost solely in the thoracic aorta, and is characterized by marked changes in the adventitia and media of the vessel. To the naked eye there are presented depressions or scar-like pits in the internal coat, and elevated patches are also seen, as in arteriosclerosis. The intima is at the same time thickened. Welch thinks it definitely proved that this third type is syphilitic aortitis. We have then three anatomically distinct affections, that are, however, often combined. There is reason to believe that in true arteriosclerosis there is a marked excess of what occurs normally; there is splitting of the elastic lamina, on this occurs the newgrowth of connective tissue and degeneration takes place. There are strong reasons to support the view held by some that the fatty degeneration is primary, and not in the new tissue, the latter forming over this degenerated part. Another point of view that must be considered in a discussion of the pathology of arteriosclerosis is a very suggestive one advanced by certain clinicians, who ask if there is an affection of the arterial wall corresponding to and going parallel with affections of the wall of the heart. Some writers assert that there is a hypertrophy of the arterial wall in answer to excessive strain, just as in the heart, that as the condition in the heart is dangerous, so it is in the vessels, and that we may have in the artery the analogue of ruptured compensation in the heart. This view is coming to the front, but in the opinion of Welch does not yet rest upon a sound anatomic basis. Experimental work has not as yet shed much light on the pathology of arteriosclerosis; thickening can be produced, but it can hardly be called the disease in question. In general terms the most important cause of arteriosclerosis is functional strain, but this is only the exciting cause; in reality it depends on the condition of the vessel wall whether the strain will cause the lesion. Infections, toxemias, etc., may render the vessel wall incapable of bearing even physiologic, let alone pathologic strain. What are the effects of arteriosclerosis upon the circulatory system and the heart? There may be enormous changes in the aorta without inducing a rise of arterial pressure or hypertrophy of the heart. The most important general point now before us is to determine why in some cases we do and in others do not find these results. The question is still an open one. Another point to be determined is whether we have cases in which raised arterial pressure is primary. In this type there is hypertrophy of the heart. This should be investigated by the pathologic anatomist, who should analyze his cases of arteriosclerosis with reference to the type that causes hypertrophy of the heart. The teaching of the Leipsic school regarding the etiologic relation of sclerosis of the vessels controlled by the splanchnic system to hypertrophy of the heart should be carefully considered. As to the relation of arteriosclerosis to aneurysm, the latter is caused by syphilitic aortitis; this may be the only type. As to the kidney, a specimen now on exhibition seems to point very clearly to a sclerotic artery as the cause of a typical chronic interstitial nephritis.

Arteriosclerosis from Acute Infectious Diseases.—W. S. THAYER (Baltimore) said his attention was first attracted to this phase of the question by his recently reported studies in typhoid fever cases. These lead to the belief that typhoid plays a part in the production of arteriosclerosis and then to the inference that others might do the same. Other cases were then studied, the diagnosis of the lesion being based on the

presence of palpable radials. The latter do not necessarily mean that sclerotic arteries are present elsewhere in the body yet the fact that calcareous and tortuous radials are readily palpable makes it reasonably certain that similar conditions do obtain elsewhere. The certainty is great enough to make such a study of value. A study was made of 3,894 consecutive case histories regarding the decades in which arteriosclerosis appeared and as to its cause. The causes appeared in the following ascending scale of importance: No cause, diphtheria, pneumonia, malaria, syphilis, scarlet fever, typhoid fever, rheumatism, alcohol, heavy work. The following shows the incidence of arteriosclerosis among the cases of each type studied: No cause, 18.9%; infectious diseases, 28.6%; alcohol, 58.3%; heavy work, 62.2%. From this study it can be said that acute infectious diseases play a part in the production of arteriosclerosis but to a less degree than alcohol and work. Among the acute diseases, rheumatism is the most important in this respect and typhoid fever is second in importance.

Arteriosclerosis of Syphilitic Origin.—C. T. DRENNEN (Hot Springs, Ark.) said that the relationship between syphilis and arteriosclerosis is obscure, though it undoubtedly exists. The effect of the disease is probably exerted through the lymph channels of the bloodvessels. Considering the enormous quantities of mercury administered in the treatment of syphilis, it is strange that that drug is not looked upon as a factor in the causation of arteriosclerosis. Mercury is not conducive to normal cell production, yet in many cases it is essentially the only drug given. Drennen suggests a more rational treatment of the disease in question, so as to eliminate the possibility of the remedy as a factor in the result, which has so long been attributed to the affection.

Arteriosclerosis of Nephritic Origin.—GEORGE DOCK (Ann Arbor) discussed the views of various writers regarding the renal origin of arterial disease. If the view is correct, that chronic nephritis by the action of toxins or spasm of vessels causes arteriosclerosis, why not attribute the same result to acute nephritis? The edema of acute nephritis is now regarded as due to the action of circulating toxins on the vessel walls. The value of clinical study of these cases was emphasized as being of the utmost necessity in determining the true relation of the processes involved. The question of hypertension is another very important feature. To show how early this condition may come on, Dock cited the case of a boy of 15, who complained of a sore throat as the first manifestation of an infection. Later uremia developed, and two months later the boy died during a severe uremic attack. During the course of the disease the blood-pressure was high, averaging 190 mm. of mercury. There was no clinical evidence of enlargement of the heart. Many somewhat similar cases recover, and we must believe that they act as a cause of arteriosclerosis. The possibility of renal disease of all kinds as a cause of arteriosclerosis must be borne in mind by the clinician and more clinical investigations made to determine their true status.

Arteriosclerosis Due to Lead.—FRANK BILLINGS (Chicago) in stating his reasons for changing his title from metallic poisons to that of lead, stated that other metals must be considered, but lead is so commonly used it is by far the most prominent. Its presence is suspected less frequently than it should be in obscure cases. The mode of entrance is often mystifying. One case of typical poisoning revealed no source of infection until finally it was found that the patient was in the habit of carrying once a week a bundle of soldering lead a short distance, placing it across his bare arms. A woman contracted lead-poisoning from washing the clothes of her husband, who was a painter. The mode of production of arterial disease by lead is a question. Its effect may be primary on the cells of the vessel wall or secondary to chronic degeneration of the kidney and resulting fibroid change. In some cases there is evidence of direct cell action in that red blood cells are affected and degenerate in various degrees. The lesion is widespread, involving the lung and other organs, especially the abdominal viscera. In the kidney there is at first a parenchymatous nephritis; later or associated with it are changes in the vessel walls; finally there is proliferation of tissue and diffuse interstitial change. The last cannot be differentiated from chronic interstitial nephritis due to other causes. Billings believes that with our present knowledge it is impossible to say whether arteriosclerosis is due to lead directly or is secondary to lead nephritis. It is impossible to make the direct diagnosis unless no other cause be found.

Arteriosclerosis of Alcoholic Origin.—RICHARD CABOT (Boston) said that all standard textbooks were emphatic in the statement that alcohol is a cause of arteriosclerosis. In making a study of this question it was necessary to decide first what is arteriosclerosis and second what is alcoholism. As to the first point he decided to disregard all cases where the arteries were merely palpable without the addition of tortuosity, roughening or stiffening. This he did because in a series of cases of palpable arteries coming to autopsy a careful microscopic examination of the vessels by Wright showed no evidence of arteriosclerosis. Regarding the second point he examined 283 cases of the severest types of alcoholism that could be found in any institution for such classes; many had been drinking from one to two quarts of whisky daily for long periods of time. Cases over 50 years were excluded as were those of syphilis. Of those studied only 6% showed evidence of arteriosclerosis of the peripheral vessels or of the heart. If patients between 40 and

50 were excluded, only 1.4% were diseased. A study was then made to determine the proportion of premature cases of arteriosclerosis, those occurring before the age of 45, that can be attributed to alcohol. Of this type 45 cases were examined and only 13 gave any history of alcohol. Third, among 132 autopsies there were found 19 cases of arteriosclerosis under the age of 50. Of these, 2 were syphilitic and of the remaining 17 there was a history of alcoholism in only 2. One young man was under observation about town for a long time before death; he had consumed a quart of whisky daily for 10 years. Autopsy showed no evidence of arteriosclerosis in the heart or peripheral vessels. From the results of this study, Cabot reaches the conclusion that the time-honored association of alcohol and arteriosclerosis is a pure myth. At any rate he has not been able to ascertain, either by his investigations or his reading, the data on which such view is based. Either strain or syphilis may accompany alcoholism and be a cause of arterial disease.

Arteriosclerosis and Angina Pectoris.—WILLIAM OSLER said there were many things doubtful about angina pectoris, but there is no doubt that in many cases it is associated with arteriosclerosis, particularly of the coronary arteries. A point to be considered is the relation of arteriosclerosis to attacks of pain. Among the types of headache are those of migraine, severe recurrent headaches due to high tension, and those associated with embolism or thrombosis. In certain cases the pain is almost entirely abdominal, suggesting the name of angina abdominis rather than pectoris. Numbness and tingling of the lower extremities met with in old persons is in many instances due to arteriosclerosis. Another type of pain deserves the name of angina cruris instead of the name given—intermittent claudication. Erythromelalgia is still another form under which this condition manifests itself. Angina pectoris with respect to arteriosclerosis may be divided into four groups: 1. Angina that is definite and severe, occurring in the young and often neurotic, that terminates fatally and no sclerosis of the coronary arteries is found. 2. Angina pectoris in association with syphilitic arteriosclerosis of the coronary arteries or the root of the aorta or both. This occurs in young men, and is emphatic of a very definite type of syphilitic aortitis. 3. Presenile angina pectoris occurring in people between the ages of 40 and 60. In this type the coronaries are always involved. 4. Senile angina pectoris, the typical variety found in persons between 60 and 80, and above 80 in some instances.

THIRD SESSION.

Twine in Lieu of the Elastic Ligature for Performing Gastroenterostomy.—J. W. DRAPER MAURY (New York City) presented the results of experimental work done in the surgical laboratory of Columbia University, New York. Two innovations were practised: 1. The use of a triangular instead of a square stitch. 2. The utilization of twine instead of the elastic ligature. Findings at the laboratory have served to entirely corroborate McGraw's contention that if properly inserted, the elastic ligature will invariably cut out. The specimens demonstrating this were made with a square stitch, and were demonstrated before the American Society of Clinical Surgery in its recent meeting in New York. For the past three months twine has been used in place of the elastic ligature, and in 13 consecutive cases proved successful. The specimens belonging to this series were exhibited. One of the best specimens shown was an enteroenterostomy produced in a pig by the quadrangular elastic stitch. The advantage of the triangular stitch over the square lies in the fact that it gives the operator the ability to increase the size of the opening which he desires to make in two dimensions instead of one, as is the case with the McGraw stitch. If it be true that the twine will cut out as freely as the elastic, its advantages over the latter are manifest: 1. It is always at hand. 2. It does not deteriorate as does the elastic with age. Furthermore, the ease in passing it is such that it is unnecessary to have any special needle to facilitate its employment. Any large needle will carry twine. Twine cuts through in dogs if applied in this triangular fashion in less than three and a half days, or about the same rate as the elastic ligature. The technic of the insertion of the triangular stitch was shown in detail from a diagram made for Robert F. Weir. Like any similar technic, it requires a few moments of study in order to acquaint one's self with the details, but when these are once understood, they will not be readily forgotten. The twine triangular stitch can be put in place in less than 1½ minutes. Like every other device of similar nature, it should be encircled with a protecting layer of Lambert stitches.

Remarks on the Disadvantages of the Murphy Button.—ROBERT F. WEIR (New York City). While no one doubts the advantages which have come to abdominal surgery by the use of the Murphy button, it has some decided disadvantages. In recent years, Weir has seldom used this device without safety sutures, so that the time of operation is not so greatly reduced. The opening is more likely to remain patent than after other operations, but closure does occur in some cases. In inserting the button, the forceps suggested for use by Murphy sometimes flatten it, so that the halves do not fit together well. The button sometimes slips into the stomach, and to remedy

this, Weir devised a special flange, but did not find it of special advantage. When the button is lodged in the intestinal tract over 21 days, the corrosive action of the digestive juices is seen; occasionally the wire spring is loosened in this way, or the button partly comes apart and gives rise to trouble. Even if all goes well, the button sometimes remains lodged three months or more. Weir does not approve of oval anastomosis buttons. To prevent the button from falling back into the stomach, he has sometimes tied a gastroenterostomy button to the enteroenterostomy button, the peristaltic action of the lower button pulling the upper one down.

Excision of the Ulcer-bearing Area in Gastric Ulcer.—W. L. RODMAN (Philadelphia). While it would be rash to operate upon all cases of ulcer, or when operating, to excise all ulcers, Rodman believes that more radical procedures than are now in general use are frequently indicated. Gastroenterostomy has its limits; pyloroplasty is frequently of little value, and while Finney's operation has great advantages, it does not always turn the current of stomach contents past the ulcer. Gastric ulcers are frequently multiple, and when this is the case it is not practical to excise. Some of the reasons which make excision desirable in these cases are that malignant degeneration follows in not less than 6% of all cases. In 150 cases of cancer of the stomach, Mayo found a previous history of ulcer in 60%. The percentage of carcinoma and ulcer at the pylorus is about the same. Moynihan has never seen duodenal ulcer uncomplicated by gastric ulcer. Pylorotomy leaves the stomach in better condition than gastroenterostomy, and avoids the dangers of subsequent perforation, hemorrhage or malignant degeneration.

Discussion.—OCHSNER (Chicago) has been using the McGraw ligature for but a short time, his earliest case having been operated upon only one and a half years ago. In his personal experience recovery following this method has been better than by any other method. Out of 86 cases in which he has employed this method, 68 have been under careful observation in the hospital. He has used it frequently in performing gastroenterostomy to give drainage to the stomach and prolong life in cases of carcinomas. In 12 benign conditions in which this method was used, all recovered; in 33 cases of ulcer, 32 recovered, and one died at the end of 3 weeks from pulmonary thrombosis. Out of his series of cases, 5 died, 3 because of weakened condition from carcinoma, and 1 was accidental. In one case he excised the pylorus, closing the end of the stomach and anastomosing the intestine with the pouch of stomach left; by this method the patient making a good recovery. A great advantage of this method is that it avoids unnecessary manipulation, and in this way prevents shock. MAYO (Rochester, Minn.) doubts the desirability of using these methods of anastomosis in certain cases when it is possible to do the operation by suture in 30 minutes, and usually in from 12 to 15 minutes. He doubts if it is advisable to close up the stomach entirely, even for one day. Rodman's suggestion for operation is desirable, although it is too big an operation to advise in all cases. MURPHY (Chicago) has found all of the defects and faults with the button which Weir mentioned, and many others. In most cases the manufacturers try to make the buttons cheaply, in some cases even using a spring of steel. The tendency of closure of the opening made in gastroenterostomy he believes will make it desirable to close the pylorus or duodenum in all cases. Closure by suture takes too long, and we are in need of some other more satisfactory method. McARTHUR (Chicago) has for some time been working along the same lines as Maury, but he used a crushing forceps to reduce the vitality of the tissues; result, entire failure. He has also used circular sutures to cut off the nutrition of the tissues without success. DUDLEY (New York) mentioned a case of carcinoma of the uterus in which he performed hysterectomy. The operation was difficult, and because of rupture of the intestine, he was obliged to resect a loop. A fecal fistula resulted, and some time later he removed the button from the same incision in which he originally inserted it. McRAE (Atlanta) called attention to the fact that Gaston, of Atlanta, in the early 80's used the same general principles suggested by McGraw, but he has generally failed to receive credit for his invention. In closing, MAURY stated that in dogs, closing the stomach entirely and doing the ligature operation is accompanied by symptoms of tetany and death. If the ligature cuts through entirely in three and a half days, as he has found experimentally, it is probable that it begins to make an opening in very much less time than this.

Rupture of Mesenteric Glands during Typhoid Fever Simulating Intestinal Perforation: Report of a Case with Operation and Recovery.—ROBERT G. LECONTE (Philadelphia) in looking through the literature has found only one case reported in which rupture of mesenteric glands has given rise to trouble such as reported. Slight intestinal lesions may be accompanied by great glandular involvement. The condition is evidently a rare one, for this is the first case of the kind that he has observed in the Pennsylvania Hospital, where 1,958 cases have occurred in three years. In the case reported, the patient was admitted to the hospital on the eighth day of the disease. On the thirty-third day he was taken with severe, sudden abdominal pains with distention. There was also pain and distention the following day, with the other usual symptoms of intestinal perforation. At the operation an ileocolic gland was found to be broken down; it was curetted, packed with gauze, and

recovery followed. Two other cases of this kind were reported, one operated upon by H. Deaver, and the other by Munro, both of whom died.

Discussion.—McARTHUR (Chicago) reported an additional case of the kind described by LeConte. EISENDRATH (Chicago) also reported a case of this kind, in which at the postmortem it was expected that a perforation would be found, but nothing but a ruptured gland was discovered. THOMPSON (Scranton) mentioned an undoubted case of typhoid fever with abscess, which was evacuated under cocaine. He believes the cause of the trouble was the same reported by LeConte.

Excision of a Part of the Ileum, All of the Cecum and the Ascending Colon. Ileum and Transverse Colon United by a New Method.—J. SHELTON HORSLEY (Richmond, Va.) believes that in intestinal anastomosis, suture is usually preferable to the use of mechanical devices, and he briefly described a method which he had reported before the session previously. He reported the use of this method in the case of a patient with a syphilitic history, who came to operation because of severe abdominal pain, and on opening the abdomen, a tumor was found, the excision of which involved the removal of part of the ileum, all of the cecum and the ascending colon. The ileum and colon were united by the method described. The patient died four days after the operation, death occurring from local infection. Pathologic examination showed the growth to be a syphilitic gumma.

Discussion.—SMITH (Hartford, Conn.). At the present time, almost every man thinks he can operate for appendicitis, but frequently when the abdomen is opened, conditions are found necessitating some more extensive operation, and every man who enters the abdomen should be prepared to do an intestinal anastomosis as is shown clearly by the history of Horsley's case. OCHSNER (Chicago). In order to excise the cecum and a part of the ileum successfully, the operator should have planned his method of attack carefully. In such cases he prefers to close both ends of the intestines and do a lateral anastomosis with the Murphy button. With this method it makes no difference what is the caliber of the two ends of the intestine. HORSLEY, in closing, said that it would take more time to close both ends of the intestines by suture as suggested by Ochsner and use the Murphy button, than to do the entire operation by suture.

[To be continued.]

Section on Obstetrics and Diseases of Women.

SECOND SESSION.

Diagnosis and Treatment of Pelvic Deformity.—GEORGE BOYD (Philadelphia) discussed the relative merits of cesarean section, induction of labor, and the "expectant plan." Induction of labor before the fetus has attained to too large a size would be ideal if we could ascertain the exact time of conception and hence the exact length of time during which gestation has existed. This cannot be ascertained without the strong probability of a mistake to the extent of two or three weeks, and this would make much difference in the size and condition of the child. So he prefers, except in highly contracted pelvises, to wait and give nature a chance, for in these cases delivery often occurs when the obstetrician had thought it impossible. Of course, if the pelvis be highly contracted cesarean section is indicated. It is in instances of moderate contraction that the attendant is puzzled as to what to do. The pelvimeter is a valuable instrument, but deductions from its use are only approximately correct.

Discussion.—BACON thought induction of labor the best procedure in most cases. From the initiation of morning vomiting, and from a record of the first fetal movements we can form a safe approximation of the length of the period of gestation. WEISS favors giving nature a chance in almost all cases. CARY thinks in many cases we can form a safe estimate of the size of the fetal head by external palpation; he favors the expectant plan in most cases.

Heart Disease as an Obstetric Complication.—C. S. BACON recounted the various heart lesions which may occur during pregnancy. An existing cardiac disease is of course liable to become aggravated during pregnancy. During labor great strain is thrown upon the heart and at such time the use of oxygen is of the greatest importance. The kind of cardiac murmur is not so material as the condition of the pulse and the general condition of the patient. Abortion occurs in about a fourth of the instances in which a pregnant woman has a cardiac lesion. Such women should have very special care as to diet, hygiene, exercise, etc. Milk is the best food, and if an anesthetic is given during labor it should be ether. Rest in bed is the most important factor in treatment. Induction of labor may become necessary. Signs of abortion are to be combated by rest and the use of morphin and codein.

Discussion.—HOLMES said recent investigation has shown that the danger of heart disease to the pregnant woman is practically nil unless the lesion be a mitral stenosis. Morphin must not be given after signs of labor appear, as it acts dangerously on the life of the child. In the third stage of labor he would remove placenta manually to favor bleeding for relief of the engorged heart. HOTCHKISS would induce labor, especially in case of mitral disease, and in which there had previously been shortness of breath. Loss of a moderate amount of

blood in the third stage does good. CARY seriously objected to manual removal of the placenta to favor bleeding. HASTINGS asserted that morphin often relieves dyspnea.

Difficulties and Dangers of Accouchement Forcé: A New Method.—H. G. WETHERILL objected to the slow and unscientific methods of dilating the cervical canal when such procedure is necessary. The Bossi dilator and all of that class were severely condemned as unscientific and barbarous. Unless the supravaginal portion of the canal fails to dilate, which is rare, then a rapid method is far more satisfactory. He described a plan of procedure used by him in which the dilating instrument is the Sims speculum. The anterior lip of the cervix is caught and drawn gently forward when a narrow but rather long retractor is inserted into the os, then the Sims speculum is inserted and by an ironing process, the posterior lip and sides of the canal are pressed and gradually stretched and thus the canal is dilated until forceps can be applied high up, and the child delivered. The whole procedure requires but a relatively short length of time and the author has employed the method successfully. Different sizes of the speculums are employed to suit the amount of dilation present. Its advantages are its simplicity, rapidity, the few instruments required, and its safety.

Discussion.—CARSTEN objected to the method, claiming that when indicated the ordinary induction of labor is better, and in threatened eclampsia it is not applicable, for vaginal section and rapid delivery is the treatment. BACON favored dilation with the hand. HASTINGS said there is but one indication for rapid dilation when this method could be used, and in that, dilation by the hand is better. FREY said although Philander Harris was the originator of dilation by the hand, yet recently he had devised an instrument for this purpose.

Cesarean Section a Rational Method of Treatment in Placenta Prævia.—JOHN F. MORAN said in the ordinary treatment for placenta prævia the mortality for mothers had been greatly reduced, but that for the children it still remains excessively high. He has found reported 24 instances in which cesarean section was performed for placenta prævia. Among these there was a maternal mortality of five, three dying immediately and two some days after operation; and a child mortality of 22%. He believes with the employment of cesarean section in cases of placenta prævia the child mortality could be much reduced from the figures shown by delivery in the usual way. There is a limited field for such operation, however.

Primary, Intermediate and Secondary Repair of the Anterior Vaginal Wall after Labor.—BARTON COOKE HIRST (Philadelphia) laid particular stress on the necessity for examining every patient after delivery to determine whether there be a laceration of the soft parts bounding the birth canal. That part of his paper which called forth most criticism was his advocacy of repair, in many cases, several days after delivery. Of course the nature of the injury must be taken into consideration but a series of cases was reported in which the author operated for repair several days after delivery and his results had been almost uniformly good. He also gave consideration to the operative treatment of cystocele which has already developed.

Etiology and Pathology of Cystocele with a New Operation for its Relief.—J. RIDDLE GOFFE (New York City) gave somewhat in detail his views as to the cause and the pathology of this condition, and described at length an operation which he has devised for the relief of cystocele. The present operations as commonly practised merely lift up the floor of the bladder which has herniated, and by such tucking up, folds and pockets are formed in the floor of the bladder, in which urine collects, resulting in cystitis. Goffe's operation consists essentially in lifting the bladder bodily by suspending it by its upper wall, from the anterior surface of the uterus, by sutures. The bladder is dissected free from the uterus, the peritoneal cavity is entered between uterus and bladder, and this horizontal slit in the peritoneum is torn widely, and in addition to the upper surface of the bladder being sutured high up on the anterior surface of the uterus, it is drawn laterally to each side and its side wall sutured to the broad ligament. The anterior wall of the vagina, which has, of course, been opened, is now closed, and the bladder being suspended as above indicated, the cystocele is completely corrected. In several patients operated in this manner the results have been entirely satisfactory.

Discussion.—M. PRICE (Philadelphia) objected emphatically to Hirst's procedure of repairing pelvic lacerations within five to ten days after delivery. Not infrequently puerperal fever does not arise till two weeks or longer after delivery. If repair has preceded this, who can say that it is not the cause of the infection. Should a malpractice suit be instituted it would put the surgeon in a very unenviable position. Repair the pelvic floor at once, but if for any reason this cannot be done, wait until after the puerperium. SPONE had done work along the same lines as that reported by Goffe without being aware of the latter's work. BOVÉE thought Goffe's operation rather overdoing the matter—two much operation. It invades the peritoneal cavity unnecessarily.

Repair of Pelvic Floor Lacerations.—JAMES H. BURTON-SHAW (New York City) pointed out the advantages of immediate repair of pelvic tears. Failure in many of these cases to restore the normal condition, or nearly so, is due to imperfectly placed sutures. None of the modern late operations accom-

plish what their authors claim for them. Emmet's operation has the advantage of following the lines of cleavage, but there is only a superficial denudation, and the deeper tissues are not approximated so as to effect restoration; Hegar's is a better operation, and much more easily carried out. In most of the surgery done for repair of the pelvic floor the deep muscles, such as the levator ani are not exposed and properly approximated. Too many of these operations merely reduce the lumen of the canal, partially close the outlet, but do not restore the floor to normal.

Treatment of Complete Uterine and Vaginal Prolapse.—FREDERICK HOLME WIGGIN (New York City) dealt with the causes of this form of prolapse, and asserted that failure of many operators to properly correct the condition is due to their failure to recognize that the prolapse is a hernia and should be treated as such. He described the preliminary treatment before operation, and then the operative treatment. The latter consists essentially in doing a laparotomy, anchoring the prolapsing structures to the broad ligaments, and then doing whatever operation for repair of the pelvic floor that is deemed wise.

Discussion.—NOBLE has tried at length both the Emmet and the Hegar operations for repair of pelvic lacerations, and has decided that the former is decidedly the better. More denudation than is done in the Emmet is overdoing the operation, and results in unnecessary scar tissue. LONGYEAR was of opinion that only the flap-splitting operation is of value. CRAIG held that no one operation is suited to all cases—that in any case the operation best suited to the conditions should be selected. JOSEPH PRICE insisted on more care in effecting immediate repair. If this is done, and done properly, there will be no subsequent cystocele or rectocele. The Emmet operation is not understood by many who attempt it.

Multiple Abscesses of the Omentum following Grave Septic Peritonitis.—HUGO O. PANTZER (Indianapolis) called attention to the tendency of the omentum to adhere to other structures and form a rich anastomosis of bloodvessels. It will even wall off foreign bodies within the abdominal cavity, and try thus to dispose of them. He reported two instances in which operation showed many small walled-off abscesses in the omentum, following a severe attack of peritonitis. Both patients died a few days after the operation which revealed the condition.

[To be continued.]

Section on Diseases of Children.

SECOND SESSION.

How to Produce the Best Milk for Artificial Infant Feeding.—EDWARD F. BRUSH (Mt. Vernon, N. Y.) spoke of the many difficulties to be overcome in the production of uncontaminated milk and the importance of having the infant food dairy separate from the commercial dairy. He emphasized the importance of breeding in cattle, saying the cow considered best by dairymen was most harmful to the child. The baby is a good milk analyzer. If the child does not thrive on the milk employed, it is the dairyman who is responsible. No chemist can improve on good milk. The speaker dwelt on the importance of proper feeding and hygienic care of cows used for this purpose. The cows should be handled with gentleness, as the milk is affected by fright or nervousness.

The Initial Contamination of Dairy Milk.—RICHARD C. NEWTON (Montclair, N. J.) spoke of the various methods employed to prevent contamination of milk, and discussed in detail the varieties of milk pails and other contrivances used in the effort to procure aseptic milk. Much of the contamination is cow excrement, which gives milk its characteristic odor and greatly increases the bacterial count. He said good results were obtained from the simple method of milking through four layers of sterile cheesecloth and a layer of absorbent cotton. He advocated the use of covered milk pails, but did not believe in complicated apparatus. Minimize as far as possible the agitation of milk and its undue exposure to the atmosphere.

Discussion.—GRIFFITH (Philadelphia) discussed the efforts made in his city to produce pure milk, saying that many dairies have certificates from the milk commission that their product contains less than 10,000 bacteria per cubic centimeter. SMITH (Connecticut) discussed the harmful results on the child from the feeding of green corn, decaying apples, etc., to the cow. AGER (Brooklyn) said an effort was being made to have the milk bottled at the farm rather than at the creamery. He also mentioned the difficulty of overcoming the dishonest tactics of the milk dealers. SCHWARTZ (Indiana) discussed the evils of the various nursing bottles now in vogue, and suggested steps being taken to completely abolish the long rubber tubing frequently used on the nursing bottle. MORSE (Boston) emphasized the importance of modifying milk, and advocated the use of milk sugar. FISCHER (New York) commended the use of raw milk, saying the principles of sterilization should be practised on the cow, the pail, and the hands of the milker, rather than upon the milk itself.

Chronic Constipation in the Infant.—J. ROSS SNYDER (Birmingham, Ala.) defined constipation as a condition in which food products are retained within the intestine after all the nutrition is removed. He said the intestinal canal in the infant is relatively smaller than that of the adult, and also,

relatively longer. Peristaltic movements are slight, as the muscular wall is undeveloped. He dwelt at length on the etiology of this condition, assigning as the principal causes, dietetic and hygienic errors, among which are irregular feeding, overfeeding, too concentrated nourishment, deficiency of fats or too much proteid. The pernicious habit of bundling the infant, preventing exercise, is a causative factor. The effect of heat on the proteid material in sterilization of milk induces constipation. In treating this condition we must get at the cause and remove it, and not simply get movements by applying stimuli to bowel. Rational treatment denies routine. We must correct the dietetic or hygienic errors responsible for the condition. Avoid massage and the use of soap and glycerin suppositories in children. The baby should be carried, not dragged, through infancy, and placed on the threshold of childhood in a position to enjoy its existence.

Discussion.—I. A. ART (Chicago) thought the muscular contracture of the sphincters was often a factor in inducing constipation and relief could be afforded by simply introducing a syringe or thermometer. Too perfect assimilation of the food may result in constipation.

The Effect on the Nervous System of Children, of Uncorrected Refractive Errors and Muscular Imbalance.—J. H. CLAIBORNE (New York City) described the various refractive muscular errors resulting in eyestrain. He explained the effect of the myopic and hypertrophic eye showing how the blurred image induced mental confusion and annoyance. The unhygienic conditions in the school room and various muscular defects produce eyestrain inducing headache, loss of power of concentration, distaste for learning, etc. The facial expression is of the greatest importance in diagnosis. The face mirrors the impressions received from the outside world. The speaker did not believe that ocular errors were responsible for epilepsy and insanity. In summing up his paper he laid down the following: 1. Nervous symptoms of a variety of kind occur as a result of eyestrain. 2. Eyestrain is due to refractive errors, to imbalance of the external ocular muscular system or more frequently to a combination of the two. 3. Of these two the refractive errors are by far the most frequent cause. 4. Muscular imbalance alone may cause it. 5. Headache is by far the most common nervous symptom in children caused by eyestrain. 6. The headache is chronic or induced directly by near work and is usually in forehead or temples. 7. Migraine or hemicrania due to eyestrain is comparatively rare in children. 8. Any nervous symptom in children should arouse suspicion of ocular defects either as direct or contributing cause. 9. Correction should be made under atropin. 10. Muscular defects are secondary to the refractive errors and should be corrected only in certain cases.

Congenital Occlusion of the Lacrimal Canal and Acute Contagious Inflammations of the Conjunctiva in Children.—JOHN E. WEEKS (New York City) described the symptoms arising from such occlusion, and said that in correcting the condition it was advisable to employ remedial measures before resorting to operation. He recommended washing thoroughly, two or three times daily, with boracic acid, and the use of some mild ointment. He explained in detail his method of procedure in operating upon these cases. He described four forms of acute contagious conjunctivitis occurring in children, the result of infection by the gonococcus, Klebs-Löffler bacillus, pneumococcus, and bacillus of Eberth. He discussed the prevalence of gonorrheal ophthalmia in children, saying it could become epidemic only in institutions, such as founding asylums and hospitals. In such instances careful inspections of the urethral and vaginal secretions would usually reveal the source of infection. The conjunctivitis due to the gonococcus may be so mild as to be hardly noticed, but the danger of its becoming a center of contagion was great, as the most virulent forms may occur as the result of infection from these mild cases. He emphasized the necessity of early diagnosing the specific organisms, and recommended the free use of the microscope. In treating these cases he uses a 3% solution of boracic acid every hour, with vigorous employment of argyrol and cold applications. In treating cases due to diphtheria bacillus he uses antitoxin until symptoms ameliorate, and also treats the accompanying nasal diphtheria. Cold applications give great comfort to the patient, and were indicated especially in the early stages, but were of little value where the causative organisms thrive and develop below a temperature of 88° F.

Enuresis.—MAURICE OSTHEIMER (Philadelphia) reported a number of cases studied in dispensary practice, stating that in nearly every case there was found to be present a reduced tone of the musculature of the bladder. Enuresis is often seen as an accompaniment or result of measles, whoopingcough, diphtheria, etc. Diabetes and injury are also ascribed as probable causes. In treating such cases he employs, in the majority of instances, tincture of belladonna in ascending doses, combining strychnin with atropin in the intractable cases. In these latter cases he begins with atropin $\frac{1}{16}$ gr. and strychnin $\frac{1}{16}$ gr. to one drop of water, gradually increased until incontinence ceased. Continue the highest dose for from two to four weeks, and then gradually decrease, so that the entire treatment usually covers from six weeks to three or four months. Fluids were stopped after supper, the diet carefully regulated, bathing with use of friction, and electricity were also tried. He found that 75% recovered under these forms of treatment. The

speaker also discussed the value of epidural injections and other remedial measures. Circumcision was done in cases having phimosis, and all adhesions broken up.

Discussion.—E. E. GRAHAM (Philadelphia) emphasized the importance of continuous and systematic treatment. He thought the success of the treatment depended to a great extent on giving the belladonna in ascending doses for the first few weeks, and then gradually decreasing it. ART (Chicago) cited a case in which after giving atropin for about two months the child developed delirium which quickly disappeared on discontinuance of the atropin.

The Bacteriology of Summer Diarrhea.—WILLIAM H. PARK (New York) said the intestines of the newborn were free from bacteria, but organisms quickly enter by mouth and anus especially *Bacillus coli communis*. The gastric juice of the infant has poor bactericidal properties. The intestine of the infant always contains *Bacillus coli communis*, *Staphylococcus*, and *Streptococcus*. *Bacillus coli communis* presents a great variety of cultural peculiarities, some being harmless while others are pathogenic but vary in virulency. He said a more perfect technic had proved the presence of Shiga's bacillus all over the world. Many cases of summer diarrhea occur without the presence of the dysentery bacillus. If Shiga's bacilli are present there will be blood and mucus in stools. He spoke of the various methods used in the treatment and the use of serum with rather indifferent results.

A Summer's Experience with Infantile Dysentery.—J. H. MASON KNOX, JR. (Baltimore, Md.) reported a number of cases he had observed at Wilson's Sanatorium, near Baltimore. These were analyzed carefully in regard to age, food and hygienic surroundings, condition of the children before the attack, types of disease, complications and results of treatment. He thought the character of food used at home and its hygienic surroundings had much to do with the summer diarrhea, the water-supply being an important factor. Insects play a part in the spread of the disease as does also the atmospheric heat. The symptoms are due to (1) the absorption of toxins; (2) inflammatory changes in the bowel. Hemorrhage was present in very few cases. The disease begins in June, reaches its height in July, and declines in August. Sporadic cases occur during any period of the year. Children under 1 year are the most susceptible, breast-fed children being rarely affected; 5% of the cases treated with serum recovered.

The Bacillus Dysenteriae in Relation to the Diarrheal Diseases of Infants: A Clinical Study of 237 Cases.—L. EMMETT HOLT (New York) discussed the presence of the dysentery bacillus in cases of infantile diarrheas. He said dysentery is seen in breast-fed children, as well as in those artificially fed. It is often a terminal infection in marasmic children. It is not a disease of any special locality, but is observed in all the larger cities, and in children under the best hygienic conditions. The mode of entrance into the body is not known, but is thought to be by ingestion, probably in water, which is given to all infants. The most characteristic type is the acute febrile form, with mucus and blood in the stools. He suggested the term infantile dysentery as the most proper one. The digestive disturbance in many cases is of greater import than the toxemia. The disease probably spreads by improper care of the stools. He said the serum treatment is disappointing, but that, owing to the complex conditions in the intestines, we cannot expect to get the results obtained in the use of the antitoxin of diphtheria. The serum should be used early before nutrition is interfered with, and, on the strength of clinical diagnosis, the indications for its use being the presence of fever with blood and mucus in the stools.

A Study of 28 Cases of Diarrhea in Children.—JOHN C. COOK (Chicago) gave a detailed report of 29 cases of diarrhea in children, in which a careful study had been made of the principal symptoms, duration, and course of the disease and the bacteriologic findings. He described the manner of feeding and quality and quantity of food used in each case.

The Management of Summer Diarrhea.—THOMAS S. SOUTHWORTH (New York City) said in managing these cases a careful prophylaxis should be instituted long before summer appears. The child should be given plenty of outdoor exercise, sleep in well-ventilated rooms and kept under the best hygienic conditions. The milk fed to the child during the summer months should be sterilized or pasteurized as it lessens the liability to disease. Much of the intestinal disturbance prevailing during this period is the result of dietetic errors or of inferior milk. The danger is chiefly in proportion to artificial feeding. We should have a clear appreciation of the conditions existing in the digestive tract that require treatment. The diarrhea and vomiting are but the efforts on the part of the digestive tract to rid itself of effete material and we should assist nature. Three factors of prime importance in the treatment of these cases are: (1) Discontinue the milk and substitute a bland diet; (2) clean out the alimentary tract; (3) check secretion and arrest peristalsis. When vomiting is severe, gastric lavage should be employed. Careful and thorough irrigation of the colon with salt solution, 1 dr. to the pint could be used, with the addition of tannic acid if congestion be great. The internal medication is given for four reasons: (1) To relieve irritation; (2) to restore normal digestion; (3) to disinfect the bowel; (4) to control peristalsis. Boating and seaside and country trips are great life savers. The speaker thought the

term cholera infantum was often misused, it being a decidedly rare condition where the intoxication was unusually severe.

Discussion.—J. P. C. GRIFFITH (Chicago) opened the discussion by stating that milk should be early removed. He spoke of the method of treatment used by the French pediatricians of giving only water in the early stages. He thought opium should not be used too early nor kept away too long. J. L. MORSE (Boston) believes in the employment of an initial purge, followed by a starving period. He favors the French treatment of giving nothing but water early. KILMER (New York) insisted on complete sterilization and care of nursing bottles. GILBERT (Louisville, Ky.) agreed with the speaker on treatment, but objected to the use of opium, preferring chloral if any anodyne were employed. ROSA ENGLEMAN (Chicago) discussed the importance of insects, especially cockroaches, as infection carriers. She spoke of discoveries made along this line in carrying out some investigations in her native city. WATSON (Baltimore) thought nursing bottles need not be boiled an hour or two, claiming sterilization could be effected by bringing to the boiling point. He advocated the feeding of raw milk if it could be gotten pure, and mothers were intelligent. STOWELL (New York) favored the use of raw milk and gravity cream. In summing up, PARK said great care should be exercised in determining the causative organism.

Landry's Paralysis in Children, with Report of a Case.—HENRY E. TULEY (Louisville, Ky.), defined the disease and described the pathology and characteristic symptoms, discussing its relation to acute anterior poliomyelitis or infantile paralysis. He cited a case he had observed in a child two years and three months old, in which there was inability to walk following an injury. There was slight elevation of temperature and little or no sphincter involvement. He described in detail the symptomatology and course of the disease which ended fatally in this case. He said in treating the condition, elimination should be gotten by all the emunctories.

[To be continued.]

Section on Ophthalmology.

FIRST SESSION (CONTINUED.)

CASEY A. WOOD (Chicago) announced that he would, on instruction from the section, present a resolution to the house of delegates in reference to the placing of methyl alcohol among the poisons. He was accordingly instructed.

Tumors of the Orbit.—H. V. WÜRDEMAN (Milwaukee) read a paper on this subject, giving a new classification of these growths in accordance with the demands of modern pathology. He considered them as neoplasms (1) inflammatory swellings; (2) primary and secondary; and (3) as anomalies. Among the neoplasms he directed attention briefly to those beginning in the eyeball (1) and primary orbital neoplasm (2) including those primary to the mesodermal tissues, those primary to the bony walls of the orbit and pia, those primary to the optic nerve and sheaths, those primary to the lacrimal gland, those extending from the skin, conjunctiva, and sinuses; those of metastatic origin, teratoid tumors, cysts, angiomas, and pulsating exophthalmos. Among orbital inflammations he mentioned the primary and secondary varieties and orbital protrusions from inflammation in neighboring sinuses. The various orbital anomalies were described. The paper was well illustrated by 200 or more photographs, drawings, and wet specimens. A feature of this paper was the use of the Hoy opaque projector with which the photographs, specimens, etc., were placed behind a very intense illumination and projected through a powerful lens on a screen much in the same manner in which an image is focused on the ground glass plate of a camera. Color details were retained. A watch in motion was projected by this apparatus.

Discussion was opened by C. S. BULL (New York City), who stated that he concluded that if the orbital tumors develop in the orbital tissue proper, sheath of the nerve, or periosteum and are encapsulated the prognosis is good, but if not encapsulated, independent of the origin of the growth, the prognosis is bad and each succeeding operation serves only to hasten the return of the growth and to shorten life of patient. He always gives a frank prognosis and lets the patient decide about the operation. He has observed improvement from use of röntgen ray in three cases and feels justified in using it in all cases as it undoubtedly relieves pain in every case. E. C. ELLETT (Memphis, Tenn.) cited cases of orbital growths. L. W. FOX (Philadelphia) referred to a case of orbital sarcoma in which the röntgen ray had effected a cure after operation had been rejected. He stated that he believed in the so-called inoperable cases, it was useless to perform any operation as it served to make them worse and to exaggerate any tendency to metastasis. He thought the röntgen ray prevented development of tissue and should be employed in all cases. KLINEDENST (York, Pa.) gave the history of a case of sarcoma of the orbit with the usual symptoms. J. O. McREYNOLDS (Dallas, Texas) asked if any success had been obtained in glioma with the röntgen ray. Personally he had not. In closing the discussion, WÜRDEMAN stated that benign neoplasms may be removed without the loss of the eye but usually with some loss of function; that all tumors when small should be operated on and later röntgen rayed; that benign tumors should be extirpated; that röntgen

ray was often of benefit without operation as in Fox's case, and that the röntgen ray seems to retard the growth of glioma.

A Case of Pulsating Exophthalmos: Successful Ligation of Both Common Carotids; Death.—HOWARD A. HANSELL (Philadelphia) read this paper, giving the history of a case with left-sided pulsating exophthalmos three weeks after injury to the opposite side of the face; venous congestion of the lids and ball, partial immobility of the globe, diplopia and deep-seated pain. In spite of prolonged rest in bed and medicinal treatment, the symptoms slowly increased in severity. Ligation of the left common carotid was followed by amelioration of all symptoms and recession of the globe. Relapse in four weeks, attended with retinal hemorrhages. Ligation of the right common carotid, with edema of face and brain, convulsions, and death five days later.

Intermittent Exophthalmos, with the Report of a Case.—WM. CAMPBELL POSEY (Philadelphia) gave a detailed account of this case and illustrated the paper by means of photographs projected by the Hoy apparatus. Both eyes were usually normal, but under violent muscular strain the left eye slowly protruded and by this and other signs showed venous engorgement of orbit. Symptoms rapidly disappeared on cessation of cause. There was an absence of bruit or pulsation in orbit, or of any visible or palpable tumor. No ophthalmoscopic changes. History of intermittent exophthalmos. Its great rarity; 46 cases in all literature. Symptomatology: Limitation to one eye. Ophthalmoscopic appearance negative in most cases. Diagnosis easily made from other angioma of orbit by absence of bruit and pulsation and the transient character of exophthalmos. Etiology obscure. No autopsies, and hence no pathologic anatomy. Most authorities believe cause is dilation of orbital veins from individual predisposition to weakness in walls of vessels and by relaxation of orbital fascia. Disease often congenital, but has followed blows. Prognosis rather favorable. In a few cases vision affected by retinal hemorrhage or by atrophy of optic nerve consecutive to hemorrhage into orbit, but vision usually remains good. Fellow-eye does not become affected. Degree of proptosis does not increase greatly with time. Treatment unsatisfactory. Electrolysis may be essayed or excision of varix with the knife if the tumor be accessible. Complete bibliography was appended to the article.

Discussion was opened by C. R. HOLMES (Cincinnati) with the report of a somewhat similar case which he also believed to be due to some pathologic condition of the orbital veins. The one-sided character he believes argues in favor of a local cause. He stated that sometimes it bore a relation to menstruation. L. J. BORSECH (Philadelphia) expressed surprise at the great rarity of this affection and stated he had observed several of these cases and employed tincture of gelsemium for six or eight months in them with success. LEAMAN (Milwaukee) referred to four cases in which ligation of the carotids had been performed with varying results. W. H. WILDER (Chicago) stated that he had observed several cases having similar symptoms which proved to be syphilitic in origin. G. C. SAVAGE (Nashville, Tenn.) seemed to think that these cases were all due to angioneurotic edema and mentioned several such cases of his own. W. L. PYLE (Philadelphia) related the history of a case of intermittent exophthalmos secondary to angioneurotic edema in which death ultimately resulted from edema of the glottis. R. A. RANDOLPH (Baltimore) made reference to a case of exophthalmos in which death followed within 24 hours after operation and believed that operation was contraindicated in persons over 60 years of age. In closing the discussion POSEY emphatically stated that his cases were not due to angioneurotic edema.

Diaphoresis and Diaphoretics in Ophthalmic Therapeutics.—HIRAM WOODS (Baltimore) and T. A. WOODRUFF (Chicago) read separate papers on this subject. Briefly stated, these papers consisted of the following deductions from physiology of diaphoresis and action of diaphoretics, regarding the class of ocular lesions to which such treatment should be applicable: 1. Congestive. 2. Exudative lesions of such structures as are intimately connected with bloodvessels. 3. To promote elimination of toxic products. Ocular disorders in which they are thus indicated are: 1. Uveitis, especially certain forms of choroiditis. 2. Iridic congestion or iritis. Effect, so far as observed by the writers, is not marked after formation of synechiae. 3. Retinal detachment dependent on choroidal exudate rather than that accompanied by degenerative or cicatricial changes, as in myopia. 4. Certain forms of exudative retinitis. 5. Possibly hemorrhagic orbital lesions. Narration of an observation in which it seemed to have a marked effect. 6. Toxic amblyopia. Difficulty in estimating value of such agents, when improvement follows withdrawal of toxic agent. Treatment by this method often disappointing when one would expect, *a priori*, good results. Method of application. Dosage of diaphoretic agents. Good results seen with small doses.

Discussion opened by W. B. MARPLE (New York City) stating that he believed in the use of diaphoretics, but that the patient's disinclination to inconvenience often influenced the physician in prescribing them. He advises with KIPP (Newark) the use of the Turkish bath, the indications being the same. It is especially valuable in acute uveitis. He also employs the salicylates and aspirin. These he states are less efficient than pilocarpin and the bath, but are certainly of value. In toxic

amblyopia he believes withdrawal of the poison is essential, after which diaphoresis may be of benefit. W. L. PYLE (Philadelphia) protested against the routine hypodermic injection of pilocarpin for sweating purposes, and related a fatal case following such a procedure. He prefers hot water, heat, Turkish bath, hot alcoholic drinks, and Dover's powder to produce diaphoresis in iritis and similar inflammations. He thought salicylates were less efficient and that large doses were unsafe. He employs warm atropin solutions in these cases. TIMBERMAN (Columbus, O.) agreed with the essayist, and quoted a confirmatory case. W. REBER (Philadelphia) said he relied greatly on pilocarpin when there were no evidences of organic disease. He thought there was no danger if the drug was used carefully. He employs it in iritis. S. C. AYERS (Cincinnati) believed the Turkish baths given in portable cabinets to be preferable to the use of pilocarpin. L. CONNOR (Detroit) spoke favorably of hydrotherapy, particularly the use of hot water and vapor baths as a means of producing diaphoresis. E. E. HOLT (Portland, Me.) rose to voice the sentiments of the essayists in regard to the use of diaphoresis and the means of inducing it. J. L. BORSCH (Philadelphia) stated that he employed pilocarpin, and in one instance observed alarming symptoms follow its use. F. BULLER (Montreal, Canada) believed pilocarpin to be of value, but also defended the use of the salicylates in all inflammatory and other conditions of the uveal tract, and cited several cases in which they were of value. THOMPSON (Indianapolis) questioned the accuracy of one of the cases cited, in which there was reattachment of a detached retina. He also asked regarding the use of gelsemium. WOODS, in closing the discussion, agreed with Pyle as to the danger of pilocarpin, but said that some risk always had to be assumed to bring about definite results. He acknowledged a susceptibility in some cases and in others a marked tolerance for pilocarpin. He advised great care in its use. Age should be considered, patient should be kept in bed, and small doses should be used at first. He then cited the conditions in which diaphoresis was of greatest value. WOODRUFF, in his closing remarks, said he had seen no bad effects from the hypodermic injection of gr. $\frac{1}{10}$ to $\frac{1}{4}$ of pilocarpin. He also stated that he had found the hot bath at home to be unsatisfactory.

[To be continued.]

Section on Nervous and Mental Diseases.

FOURTH SESSION.

Facial Paralysis, Bilateral with Marked Sensory and Reflex Defects, Possibly Due to La Grippe.—F. W. LANGDON (Cincinnati) described a case in a man of 51 who, after an attack of grip, suffered from severe occipital headache, and later, after a journey of 50 miles, had right lagophthalmos. Three days later he was unable to close the left eye, and suffered from disturbance of speech and swallowing. Examination showed that both facial nerves were paralyzed. There was distinct disturbance of taste on both sides. There was slight quantitative change to faradism and galvanism, but no reactions of degeneration.

A Clinicopathologic Study of Hemiplegia, with a Microscopic Examination in Eleven Cases.—T. H. WEISENBURG (Philadelphia) reported a statistical study of 150 cases of hemiplegia, in which the following phenomena were observed: Hereditary influences, prehemiplegic and posthemiplegic pain, atrophy of the muscles of the paralyzed side, the respiratory movements, and trophic disturbances of the paralyzed side.

Two Cases of Congenital Deformity, Possibly Due to Intrauterine Disease of the Spinal Cord.—C. W. BURR (Philadelphia) stated that he was unable to add any important data to the pathology of these cases reported. He displayed a number of photographs, illustrating, beside the unusual deformities, among other peculiarities, an absence of calcium salts in the bones. He believes the disease was muscular and skeletal and not a result of spinal cord disease. (Discussed by SKELLY and HERDMAN.)

A Case of Spastic Diplegia Occurring During an Attack of Pertussis, with Autopsy.—JOHN H. W. RHEIN (Philadelphia). During an attack of whoopingcough a child of 20 months lost the power of walking, and later developed spasticity of the legs and arms, nystagmus, petit mal attacks, and finally just before death, general convulsions. At the autopsy important microscopic changes were observed. The perivascular spaces were distended and there was a round-cell infiltration around the vessels. Surrounding the perivascular spaces, in the paracentral region, were found numerous fatty granular cells. There were, in places throughout the cortex, pons, and cerebellum, multiple small hemorrhages. In the cord there was degeneration of the crossed and direct pyramidal tracts.

A Promising Case of Locomotor Ataxia.—GUY HINSDALE described a case of this disease in which, under treatment, the patient gained 46 pounds in a short space of time.

The Surgical Treatment of Poliomyelitis.—W. G. SPILLER and CHARLES FRAZIER (Philadelphia) contributed the results of their experiments in the surgical treatment of this disease. In one case there was some improvement, but the conditions were unfavorable; and in the second case only fair results were obtained. In this case the musculocutaneous nerve was grafted into the anterior tibial nerve. They conclude that in these cases surgical intervention may help. The operation can not be done until after six months has elapsed from the begin-

ning of the disease. (Discussed by SINKLER, STERNE, WOLFSTEIN, and HERDMAN, and others.)

A Dynamometer for Measuring Perspiration.—H. E. WETHERILL demonstrated his instrument and made a brief report of the possible advantages.

Minor or Border-line Psychoses of Alcoholism.—F. P. NORRERY (Jacksonville, Ill.), reported cases which seemed to justify the conclusion that such cases are rare in acute alcoholism, but may appear in adolescents of neurotic types; that they are more frequent in adolescence, and up to 40 or 50 years of age; that they occur both in continuous and periodic drunkards; that the prognosis depends upon the inheritance; that the prevention of major psychoses calls for early treatment which may be said to be successful in the majority of cases.

Psychic Force.—B. F. BEEBE (Cincinnati) read a paper on this subject in which he discussed the influence of mind upon mind and mind upon body. He referred to the advantages of suggestion in therapeutics, and offered a plea for greater knowledge and employment of psychic influence by physicians, not only in their treatment of disease, but in their intercourse with mankind.

Have Drug Habits a Pathologic Basis?—A. STERNE discussed the hereditary influences bearing upon this subject, and believes that acidity occurs and exists as a true pathology, and probably is the basis for some cellular change, which change he however was unable to define.

A Case of Locomotor Ataxia with a Tremor resembling Paralysis Agitans.—JOHN H. W. RHEIN (Philadelphia) reported a case occurring in a man of 55 who developed, together with the usual symptoms of locomotor ataxia, a tremor resembling that of paralysis agitans. The autopsy revealed the characteristic lesions of locomotor ataxia, and failed to show any pathologic change which could be said to account for the presence of the tremor. The case was probably one of locomotor ataxia complicated by paralysis agitans.

Some Unusual Forms of Multiple Neuritis.—WHARTON SINKLER (Philadelphia) described some interesting cases of neuritis illustrating some unusual manifestations of this disease. Among these were multiple neuritis following the administration of arsenic and lead, and cases of septic multiple neuritis occurring after miscarriage and labor. (Discussed by RHEIN and others.)

Hysterical Delirium, Report of Four Cases.—THEODORE DILLER (Pittsburg) believes that insanity as an expression of hysteria may be unrecognized by those of experience either within or without an asylum.

A Brain Tumor with Progressive Blindness as its Most Prominent Feature, with Microscopic Report.—W. C. KENDIG and D. I. WOLFSTEIN (Cincinnati) described a case in which the autopsy showed the presence of a spindle-cell sarcoma.

A Clinical and Pathologic Study of a Number of Cases of Epilepsy.—ONUF (Sonyea, N. Y.), reported a case of this character in which he showed that in a certain number of cases there was distinct pathologic change in the brain. The true significance of this change, however, could not be determined.

[To be continued.]

Section on Pathology and Physiology.

SECOND SESSION.

Uncinariasis in the South, with Special Reference to Mode of Infection.—CLAUDE A. SMITH (Atlanta) called attention to the mild cases, in which no general symptoms appear. Cases are to be found in all the Southern States. Positive diagnosis is only possible by finding the larvae or the eggs in the stools. Wherever a severe case is found a large number of mild cases will be present, and the physician must find and treat them. Thymol should be used with caution because of the toxic effect of the drug. The eggs can be hatched by mixing feces with soil; the larvae live for three or four months. Infection occurs by the penetration of the larvae into lesions of the skin, especially in "ground-itch," a disease to which barefooted children are subject. A patient was experimentally inoculated by binding soil containing larvae upon the uninjured skin of the wrist. The success of the inoculation seems to depend upon the presence of particles of soil which offer the larvae a certain counterresistance, thus enabling them to work their way into the epidermis.

The Nature and Significance of Leukocytosis.—A. MANSFIELD HOLMES (Denver) detailed a number of theories and fallacies pertaining to leukocytosis and the causal and antagonistic factors in production. He then dwelt on the source and destiny of the cell recruits in leukocytosis and the nature and significance of the differential blood count in abnormal blood states. A differential blood count is indispensable to a correct interpretation of leukocytosis but there are additional factors to be considered. Leukocytosis was then studied in its relation to pyogenic infection: (a) The degree of virulence of the infection vs. (b) the degree of the resisting power of the organism. The range of usefulness of a leukocyte and differential count in clinical study is perhaps wider than that of a simple blood count.

Further Observations on Leukocytotoxins.—HENRY A. CHRISTIAN and THOMAS F. LEEN (Boston) considered the effect on the amoeboid motion of leukocytes of serums produced

by the injection of somatic cells (spleen, liver, kidney, heart), the effect of bacterial toxins (*Staphylococcus pyogenes aureus*, *Bacillus diphtheriae*); he made a comparison of the action of the two. The paper forms a further contribution on the subject, detailing the results of work done since the previous report before the American Association of Pathologists and Bacteriologists. More or less specific leukocytotoxins can be produced by injecting somatic cells. Natural leukocytotoxins are rare.

Studies on Antistreptococcus Serum.—D. H. BERGEY (Philadelphia) stated that studies of antistreptococcus serums have shown great variability in the powers of different serums. Practically all investigators agree in the demonstration of agglutinating powers in antistreptococcus serums, the property varying with the degree of virulence of the organism, etc. No bactericidal powers in antistreptococcus serums have been thus far demonstrated, the general opinion being that favorable influence of serum is due to stimulation of phagocytic action. The author had immunized goats and rabbits with different races of streptococci to throw additional light on the character of immunity produced in treated animals, as well as on nature of substances in serums of such animals. Serums of goats and rabbits immunized with streptococci isolated from cases of scarlatinal angina and from cow's milk showed definite agglutinating powers for homologous and for heterologous cultures. No evidence of bactericidal property was demonstrated in serums of different animals immunized with streptococci, neither could any marked evidence of stimulation of phagocytosis be determined. Preventive inoculations of the different serums into white mice, followed 24 hours later by fatal doses of streptococci, did not always protect the animals from death, though they usually served to prolong life.

A Bacteriologic and Clinical Investigation of a Curative Serum for Typhoid Fever.—WILLIAM R. STOKES and JOHN S. FULTON (Baltimore). The authors quoted the description published in September, 1901, of curative typhoid fever serum, produced by injecting hogs with typhoid cultures. This serum protected guineapigs against seven times the minimum fatal dose of bacilli. Five cases treated, three showed satisfactory drop of temperature. The present paper reports continuation of this work, and the results correspond to former tests. A long series of tests was also made to test bacteriolytic properties. The serum destroys large numbers of typhoid bacilli in dilutions of 1 to 10, while dilutions of even 1 to 1,000 showed some bacteriolytic effect. The serum was used in the treatment of 23 human cases; if used before the end of first week, results seemed favorable in most cases. The most striking effect consisted in premature fall of temperature, and improvement in general symptoms. In cases treated later, improvement was not so marked, or even not noted. This might be accounted for by gradual exhaustion of the complement by the disease. The authors pointed out that there was danger of using excessive amount of intermediary body in treatment and spoke of the inability to furnish an artificial complement at present. An elaborate review was made of experimental work of Ainley Walker in curing rabbits of laboratory typhoid infection and results from treatment of human beings by Professor Tavel, of Berne.

Bone Cysts: A Consideration of the Benign and Adamantine Denterogenous Cysts of the Jaw and Benign Cysts of the Long Pipe Bones.—(With lantern slide demonstration.) JOSEPH C. BLOODGOOD (Baltimore) stated that in his opinion the early metastasis of the tumors of bones makes it inadvisable to attempt more than a palliative operation for malignant growths, while the less malignant forms can be cured by operations which are not so mutilating as many which have been in use. He exhibited three röntgen ray photographs of rare cases of bone cysts, due to the inclusion of islands of cartilage which later break down.

A Hitherto Undescribed Intestinal Parasite of Man.—ALLEN J. SMITH (Philadelphia) states that the worm is found to be an ordinary earthworm, one of an unusual species, probably due to some error of collection. Smith substitutes another case, in which he has found a new genus of ascaris. The paper is a detailed description of the worm.

[To be continued.]

Section on Laryngology and Otology.

FIRST SESSION (CONTINUED).

The Relation of the Chemistry of the Saliva (Stalosomeiology) and Nasal Secretions to Diseases of the Mucous Membrane of the Mouth and Upper Respiratory Tract, with Special Reference to Hay-fever.—D. BRADEN KYLE (Philadelphia) reported further investigations along the line, which he has been carrying out for several years, regarding the import of salivary and nasal secretions, with practical application with reference to hay-fever. In the chemic study of the secretions three main classifications were made: 1. Secretions, nonirritating *per se* which, on exposure (when coming to the surface), undergo some chemic changes, producing an irritant. This may be noted in either an acid or an alkaline secretion. An exceedingly alkaline secretion is decidedly more irritating and productive of a more destructive pathologic process than even a strongly acid secretion. 2. Secretions which are irritating *per se* when poured out on the surface. 3. Secretions which come to the surface in a nonirritating

form, but on coming in contact with extraneous material are rendered irritant. Two principles demonstrated are: 1. In highly alkaline conditions there is an exaggerated oxidation, and the chemic change takes place in the secretion after it is poured out. 2. In highly acid conditions oxidation is incomplete, causing a great tendency to precipitate material within the tissues—an infiltration process. If hay-fever is distinctly a neurosis, why should the patient, as a rule, improve in a high, dry climate, when such altitudes are decidedly irritating to a nervous individual? Why is it that an individual, after having had hay-fever for several years, will miss one season or even two, without any treatment at all? He thinks the answer lies in the individual, at least in a majority of cases, and that the secretions of such persons having changed under certain conditions were nonirritating. Treatment, directed toward rectifying the pathologic condition of the secretions, is advised several weeks before the usual time for the hay-fever attack to come on in individuals who have been chronically susceptible, and in acute attacks the same line is carried out, though more vigorously, the secretions being rapidly shifted from acid to alkaline, or vice versa. KYLE reports 80% to 90% of cures in patients treated on this basis.

Discussion.—DALAND (Philadelphia). This is a very important and seldom recognized cause of nasal and oropharyngeal disease, and it is obvious from this paper that the same cause plays an important role in certain cases of hay-fever. The observations are interesting from a practical as well as a scientific standpoint because a proper appreciation of the chemic causes of these affections indicates a plan of treatment which has given brilliant results. It is not at all improbable that certain spasmodic bronchial affections, that are usually considered under the name of "nervous asthma," may have a like cause, and a study of this disease from this standpoint may yield similar therapeutic results. The profession has been gradually recognizing the importance of hyperacid conditions of the upper respiratory tract and mouth, but KYLE is to be complimented upon drawing attention to direct poisoning influences of the sulfo cyanids and of the marked local irritating effects of hypoaoid conditions which are frequently found in association with ammonia compounds, and at times, free ammonia. These observations are of importance to the general practitioner because of their prejudicial influences upon the general health, and there can be little doubt that certain cases of general toxemia may be due to the sulfo cyanids. On the other hand, he is inclined to believe that there are cases of toxemia of intestinal origin, usually fecal, that play an etiologic role in the production of morbid chemic states of the nasal secretions and the saliva. When we remember that in a few moments after the taking of lithium it can be discovered spectroscopically in the saliva, and that normally within eight minutes after the swallowing of one of the iodid salts, iodine can be detected in this same secretion, we realize how rapidly is the diffusion of these soluble substances, and how promptly the salivary glands excrete these substances, which here have the peculiarity of again being swallowed to be again absorbed into the circulation. KIRK (Philadelphia) stated that his observations from a dental standpoint coincided with those of Kyle, there being numerous cases in which the irritations seen about the mouth, gums, and alveolar structures are undoubtedly due to a pathologic condition of the salivary secretions. INGALLS (Chicago) expressed interest in the investigations of Kyle for two or three years, and believed there will develop many points of practical interest.

SECOND SESSION.

Lithemic Nasopharyngitis Due to Systemic Disturbances.—J. A. STUCKY (Lexington, Ky.) defined the term lithemic nasopharyngitis as that type of disease having close etiologic relationship to rheumatism or the so-called lithemic diathesis, having its origin in autointoxication caused by absorption of biproducts from the intestinal tract, or in the faulty metabolism occurring in the liver. He laid stress upon the fact that elimination is the function of prime importance, that it is not so much a matter of regulation in diet as it is the regulation of the intestinal tract, that the fact that the patient has one or two bowel movements daily is not an indication that there will be no fecal retention. He emphasized the importance of indican in the urine as a factor in diagnosis. In a series of a hundred cases in which indican was present in this class of patients, the symptoms were relieved as soon as the indican disappeared from the urine. He exhibited an apparatus consisting of a nursing bottle to which is attached at one end a rubber compression bulb and at the other opening a rubber tube with a cut-off similar to that used with a fountain syringe. This is used for making high rectal injections of soap-suds followed by olive oil, the tube being used in connection with a high rectal tube and the fluid forced in by means of the bulb.

Discussion.—CLINE (Indianapolis) believed that in our attention to surgical procedures and in collecting new instruments for operative work, we are apt to overlook the importance of systemic treatment as referred to in the paper read, which procedures may often relieve the condition without resorting to radical operations. HOLINGER (Chicago) did not altogether approve of the rectal treatment because of the danger of developing a neurotic condition in which the patient might rely on the tube for the alleviation of all ills. To this Stucky

replied, in his closing remarks, that he has never had such a result, since as soon as the acute condition is corrected the patients are encouraged to indulge in outdoor exercise and the observance of such hygienic measures as would tend to the establishing of normal physiologic functions. MYLES (New York) expressed approval of the oil treatment, having used it for some time. SMITH (Philadelphia) in addition to the rectal use of the oil advises its internal administration as well.

Reversional Vestiges in the Human Pharynx as Sources of Irritation.—NORVAL PIERCE (Chicago) stated that the title was somewhat erroneous, in that his paper has to do simply with one reversional vestige, namely, the styloid process. Though this subject has been treated by several foreign authors, and while cases have been reported on this side, yet, so far as he has been able to discover, this is the first time the subject has been treated in American literature from the standpoint of comparative anatomy. He took up in the beginning the aboriginal skull, the connections between the base of the skull and the hyoid bones in the lower animals, the appearance of the styloid and the stylohyoid ligaments. He referred to instances of bony connection between the styloid process and the hyoid bone in man, and brought out the point that a long styloid process and projection upward from the hyoid bone are reversions to the lower animal types of connection, referring to cases in which these anomalies have occurred. The paper showed thorough research, and brought out many interesting applications, which may be made practical in diagnosis and treatment of apparent anomalous conditions in man. In the treatment of these conditions Pierce made the point that we should be conservative in the removal of these bony projections.

Discussion.—MYLES (New York) agrees with Pierce that the removal of these bony projections are in most cases unnecessary. He referred to his having observed a case in which the styloid process approached the anterior pillar of the fauces. ROY (Atlanta) referred to two cases reported at Atlanta at a previous meeting, in which "bones in the tonsils" were found to be extensions of the hyoid bones. HOLINGER (Chicago) stated that these suggestions may be of value in the diagnosis of bony growths encountered in adenoid operations. CASSEBERRY (Chicago) suggested that calculi and cartilaginous formations may be mistaken for the styloid process. TURNER (Edinburgh) stated that the paper is especially valuable from the standpoint of comparative anatomy and may throw light on many conditions observed in the human being. He thinks that Holinger is likely mistaken in his supposition that the styloid may be encountered in removing adenoids, that it may more likely be found to be a prominent first cervical vertebra. HOLMES (Cincinnati) reported a case operated upon in which a projection into the tonsil was removed with forceps and scissors.

Section on Materia Medica.

SECOND SESSION.

Relation of Internal Secretions to Epilepsy, Puerperal Eclampsia and Kindred Convulsive Disorders.—CHARLES E. DEM. SAJOUS (Philadelphia) bases his paper largely upon the experiments of others and says he does not lay so much stress upon his own investigations if they do not coincide with the results of investigators whose experiences are of 20 or 30 years' standing. He believes, however, that the pituitary body, thyroid gland and adrenal are physiologically allied, and that the secretions of the adrenal are concerned in raising the blood-pressure. Experimenters, he says, have shown that blood taken from the vein of the adrenals and injected into an animal possessed the property of increasing blood-pressure the same as adrenal extract. The splanchnic plexus regulates the amount of blood going to the adrenals and in that way regulates the function of these organs. Stimulation of splanchnics failed to show the least evidence to vasomotor constriction or dilation in the adrenals. Pavy, he maintains, showed that division of the nerve from the superior ganglion to the cord in the spinal canal produced diabetes mellitus. Removal of the ganglion produced the same effect. The administration of adrenal extract has been found to give rise to glycosuria. In discussing the part played by the pituitary body, he says, there is an intimate relationship between this organ and the adrenal for by stimulating the pituitary body there is an increase in the cardiac power, an increase in the arterial tension and an increase in the cerebral pressure, practically the same phenomena obtained by the administration of adrenal extract.

Discussion.—STERN (New York City) believes that the physiologic investigation must be corroborated by other observation. In regard to the production of glycosuria he says there are many other extracts that produce glycosuria beside adrenal extract.

The Indications for and the Nature of the Various Hypnotic Drugs in Mental Diseases.—ALFRED R. DIFENDORF (Conn.) classifies the insomnias he purposes to deal with into two groups: 1. The insomnia which precedes or is found in the early stages of the mental derangements; these he regards as the prodromal insomnias. 2. Those insomnias that come on after the mental conditions are well established. Of the first group he enumerated a few of the characteristic symptoms,

such as various peculiar sensations in the head, a fullness of the head, irritability, malaise, fear, suicidal attempts or tendencies, loss of weight, alteration in the sexual functions, at times loss of the sexual desire, other times an increase. If the treatment of these conditions and the insomnia be appropriate it may do much in preventing the mental derangement. In speaking of the treatment he lays particular stress upon the removal of such conditions that may or do give rise to anxiety, fear, or irritating effect. These conditions do much to produce not only the insomnia, but also the mental disturbances. He particularly emphasizes that hypnotic drugs should be resorted to only when everything else fails. He urges that hot drinks, hot broths, and exercise should be given to relieve the insomnia of these conditions. When these measures fail he advises the use of bromin salts in small doses which he believes are the best hypnotics for this form of sleeplessness. Trional, he says, is better than sulfonal because it does not tend to accumulate, and is not so liable to produce untoward effects. It must be given in hot water, and can be given for a period of two weeks when its employment should be stopped because it also produces accumulating effects in time. The insomnias of the second group depend upon the psychoses themselves, and he says, the hypnotics are necessary to the treatment of these conditions in many instances. But even in these conditions prolonged baths should be first tried. These baths can be continued for long periods of time without producing any deleterious effect; the patients may remain in them for two hours at a time. It, says Diefendorf, may be necessary at first to give the patients small doses of hyoscin hydrobromate to quiet them while in the bath. When baths, massage and electricity fail, he combines chloral hydrate with the bromids, except in cases of fatty degeneration of the heart, other lesion of the heart and diseases of the bloodvessels and kidneys. If hyoscin fails, scopolamin may be given; paraldehyd may also be tried. For the insomnias of hallucinations and dementia præcox (Diefendorf) give the deodorized tincture of opium and cannabis indica if the patients are of an asthenic type and have albuminuria. For the insomnias of the depression of dementia præcox and dementia paralytica he first tries hot and cold packs. And for the insomnia of senile dementia, paraldehyd. He spoke of many new drugs which were supposed to act as hypnotics but which have not stood the test. There are two new hypnotic drugs which he believes are of value, although they have as yet not stood the test of time. The first of these is somnos, which should be given in doses of one-half to one ounce. He says there are no after-effects. The second is veronal, which is given in from three to fifteen grains. This last named drug is very expensive.

Discussion.—LOW (Philadelphia) says, because the physician neglects to direct the sulfonal to be dissolved in hot solution before it is given the desired effect is not produced until five or six hours after the administration. ROBINSON (New York City) says no hypnotic drug is without danger, and he does not believe that a drug can be produced that will be absolutely dangerless. FOSS (Arizona) maintains that hypnotics should not be used. WESTCOTT (Atlantic City) thinks the copy of the prescription upon the box or bottle is responsible for the use of hypnotics by the laity. WALL (Chicago) calls attention to the fact that digitalin sometimes relieves insomnia when other drugs fail. STERN (New York City) maintains that sulfonal is destructive to the hemoglobin and gives rise to hematuria. OSBORN says the blood-pressure has much to do with relieving of insomnia. At time the pressure is too high, then nitroglycerin will do; when it is too low, digitalis will do much to relieve the insomnia. In closing the discussion, DIFENDORF says that all means should be exhausted to relieve the insomnia before drugs are resorted to. He corroborated the view expressed by the chairman in reference to blood-pressure as a factor in producing sleep.

Chronic Arterial Hypertension.—HENRY W. COOK (Richmond, Va.) asserts that the adage "one is as old as his arteries," is no longer to be regarded as true. To illustrate this he cites the condition of the arteries of individuals in asylums and the condition of the active business man's arteries as seen at autopsy; the first are extremely atheromatous and calcareous while the latter show possible only slight evidence of atheromatous changes, yet these men are most liable to apoplexy while those individuals of asylums rarely died of apoplexy. Longevity is an inverse proportion to the hyperarterial tension. Hyperarterial tension may be due to cardiac hypertrophy, alcoholism, toxins, and it may be idiopathic. Heredity plays a part in the idiopathic hypertension. In speaking of the treatment he says amyl nitrite is of use only for instant and transitory effects. He believes that sodium nitrite is a more valuable drug than nitroglycerin. Its effects last about four hours and when given after meals even longer.

Discussion.—BARNES (Washington) alluded to the mental effect of dilating the bloodvessels; if the mind is concentrated upon a particular part the vessels of that part dilate. Posture and exercise also lower blood-pressure. Thyroid extract is of value in some cases. He agrees with Cook in the statement that sodium nitrite is a very valuable drug. SAJOUS (Philadelphia) refers to the rise in blood-pressure due to pituitary body. WALL (Chicago) maintains that nitrites are for temporary use only, but that veratrum may be administered for long periods of time. H. C. WOOD, JR. (Philadelphia) does not approve of Cook's idiopathic form of hypertension; he thinks

there must be a lesion somewhere. The use of the nitrites does not in any way effect the lesion but is merely symptomatic. He asserts that potassium nitrate has a more lasting effect than the sodium nitrite. ROBINSON (New York City) thinks veratrum viride will lower blood-pressure for weeks at a time. To lower blood-pressure the crude potassium nitrate must be used and this in all probability produces the effect as a result of the minute quantities of potassium nitrite it contains. TOMPKINS (West Virginia) relates a case in which the effects of amyl nitrite were apparent for eight or nine days. OSBORN (chairman) thinks the iodids stimulate the thyroid gland whose secretions produce a lowering of the blood-pressure. In closing the discussion, Cook says he has seen the pressure fall 40 mm. of mercury and remain 80 for three hours by the use of sodium nitrite. He does not recommend the use of aconite and veratrum viride because of the effect upon the heart.

The Control of Internal Hemorrhage by Drugs.—T. L. COLEY (Philadelphia) begins his paper by saying there is no specific treatment for internal hemorrhage. At its onset hemorrhage needs no treatment; the treatment may do harm at this time. Astringents, he says, are of value only where they can be applied locally; they are valueless when administered internally. This is true both of vegetable and mineral astringents. Adrenalin should be used locally only, since a rise in blood-pressure results from its internal administration. Ergot, for the same reason, can be used only in uterine hemorrhages. Digitalis produces in many instances harm by raising the blood-pressure. Opium does good by quieting the patient. Coley does not believe hydrastis, ipecac, calcium chlorid and gelatin are of much value in internal hemorrhages. He opposes the use of strychnin because it excites the patient, except when the hemorrhage is in the splanchnic area, then strychnin and hydrastis may be of value. Hot salt solution is undoubtedly of value. ROBINSON, in opening the discussion, says upon the whole he agrees with the author of the paper, but he prefers to combine atropin with the morphin. Large doses of bismuth, $\frac{1}{2}$ oz. to 1 oz., are useful in gastric hemorrhages. He is also favorably impressed with aromatic sulfuric acid in gastric and pulmonary hemorrhage. To control epistaxis he uses a combination of fluid extract of hydrastis and fluid extract of witch hazel. This, he says, prevents the recurrence of these hemorrhages. Gelatin, in his opinion, is of value in stopping hemorrhages. WALL (Chicago) advocates the use of atropin, especially in pulmonary hemorrhage; hydrastis is entirely too slow in its action. ABBOT (Chicago) maintains that morphin quiets the patient, while atropin dilates the peripheral vessels, especially the cutaneous, and in that way draws the blood from the bleeding area. The dose of atropin should be large and morphin correspondingly small. H. C. WOOD, JR., (Philadelphia) upon theoretic grounds maintains that atropin is contraindicated in hemorrhage since it elevates the internal blood-pressure. He believes gelatin to be of great value. COOK (Va.) says stimulation in hemorrhage is dangerous. Strychnin and adrenalin both raise arterial pressure and therefore should not be used in internal hemorrhages. Vasomotor dilators are also dangerous. ROBINSON (New York) calls attention to the fact that gelatin increases the coagulability of the blood, and that by heating the gelatin too high destroys its coagulability. Sajous points out that atropin causes a contraction of the arterioles and that the capillaries are composed of endothelial cells only and are not affected by the atropin. Coley, in closing the discussion says bismuth and ferric chlorid and antipyrin might be of value if they could reach the bleeding point. Atropin is dangerous because it raises blood-pressure. He believes theoretic evidence should be greater than clinical.

[To be continued.]

Section on Cutaneous Medicine and Surgery.

FIRST SESSION (CONTINUED).

RAVOGLI read a paper on false or cicatricial keloids, in which he differentiated between a false and a true keloid. He described a case in which there are multiple keloids of a painful character. The difference between true and false keloids was demonstrated by photographs; in these it is shown that the papillas are visible only in the true and not in the false variety. Ravogli detailed the most important etiologic factors in the formation of keloids. In considering the treatment, he said complete removal of the tissue is the best. Röntgen ray treatment has been quite satisfactory.

Discussion.—GOTTHEIL (New York) holds that every case of keloid is cicatricial in character. BAUM (Cincinnati) described a case of keloid following lupus vulgaris. MONTGOMERY (San Francisco) saw a case of symmetric keloids; they were removed by excision.

C. B. COOPER (Hawaii) was introduced. He gave an interesting talk upon leprosy in Hawaii and spoke of the destitute condition of the treasury of the Board of Health in Hawaii. In describing the possibility of contagion, he says that the only reliable procedure is in absolute segregation, although in the Caucasian race the disease is extremely mild.

Discussion.—SCHAMBERG (Philadelphia) believes in segregation of lepers. CORLETT says that lepers of Paris are allowed to live in the same hospital with other patients.

Psorospermose Cutanée Vegetante Folliculaire.—

DAVID LIEBERTHAL (Chicago) enumerated previous cases and reported a case which came under his observation in a boy aged 12, who presented very painful symptoms. The histopathologic condition present was entered into. The theory of Darier was emphasized. The macroscopic features were beautifully shown with lantern slides. He has found that the hair follicles contain most of the psorospermose plug. The etiology of this affection is said to be unknown. The face was treated with röntgen rays; the rest of the body with resorcin or ichthyol ointment and the like. At times complete excision of nodules has proved efficacious. LEUTGALT believes that the condition is caused by coecydia.

Larva Migrans.—STELWAGON (Philadelphia) reported a second case, involving the regions of the foot and ankle. The patient was a male adult, who had the eruption for 10 days. There was but one parasite found. Attempts to secure it were futile. The treatment instituted was the cataphoretic application of mercuric chlorid; this seemed to be of no value. Nitric acid was substituted, with the result that the patient recovered in a very short time. In the majority of cases the disease developed in those who had just returned from the seashore.

Discussion.—SCHAMBERG had seen a case. LORD (Baltimore) had a patient in which the site of the parasite was excised, the result being complete recovery.

Acne Keratosa.—GOTTHEIL (N. Y.) says he found but 11 cases in literature, though the condition is not rare. The lesions are acuminate inflammatory papules, but not containing pus, they are seen at all ages, but found especially in the young. The condition recovers spontaneously. He reports several cases, all of which seem to elect exposed parts for the disease. Some of the lesions were quite large—as large as a half inch. He shows microphotographs of the histology of the disease. The disease, the etiology of which is unknown, is distinctly a true hyperkeratosis.

Cover-glass Cultures and Their Possibilities in Studying the Epidermic Fungi.—J. F. WALLIS (Philadelphia) read this paper describing the tube and plate cultures in solid and liquid media. The advantages of his method are many, but the greatest is the ability of the observer to study the growth of the microorganisms through the various stages. He describes Unna's method for studying living microorganisms microscopically, and showed photographs demonstrating living fungi found in the skin and plates.

Discussion.—SCHAMBERG has seen hairs prepared in this manner, and has found that the method is most admirable. WALLIS states that he is enabled by his method to preserve his specimens.

Prurigo (Hebra) as Observed in the United States.—CORLETT (Cleveland, Ohio) said that it has been said that the Austrian prurigo does not appear in this country. He reported several cases. The first in a child, normal in every respect, in which the entire body was covered with a papulopustular eruption. The skin appeared to be dry and thickened. The lower extremities were more affected than the upper. Treatment consisted of tonics internally and local applications; the result is as yet unsatisfactory. The disease seems to be worse in the winter and spring, though it does not disappear in the summer. Corlett believes the disease more common than usually thought.

Discussion.—RAVOGLI (Cincinnati) sees on an average of from 12 to 15 cases of prurigo every year. STELWAGON says that Philadelphia furnishes no cases of prurigo.

[To be continued.]

Section on Hygiene and Sanitary Science.

SECOND SESSION.

Dairy Hygiene; with Special Reference to Tuberculosis.—RICHARD COLE NEWTON (Montclair, N. J.) described the fallacies inseparable from the diagnosis of tuberculosis in dairy cattle by means of the tuberculin test, and the futility of the restrictive measures now in use. He advocated extensive reforms in the management of dairy herds, a minimum of 1,200 cubic feet of air space for each animal, sunlight in abundance, daily exercise in all mothers, a shortened period of lactation, and the conversion of dairy cattle into beef after two or three pregnancies.

GRESSY L. WILBUR, Chief of Division of Vital Statistics of the Michigan Department of State, and Expert Special Agent of the United States Census Bureau, read a paper entitled **What the Census Bureau is Doing to Improve the Registration of Vital Statistics in the United States.** Wilbur displayed by means of a map the disgracefully small part of the United States which in 1900 constituted the "registration area," that is, the area in which returns of death are collected under local laws to 90% or more of completeness. This area included no more than nine States—the six New England States, New York, New Jersey and Michigan. The accessions to this number since 1900 are Indiana and Maryland. The establishment of the Census Bureau on a permanent footing has awakened an interest in the subject of registration in this country. Colorado has now an effective plan of registering deaths at the time and place of their occurrence. Illinois and Iowa have undertaken the work of registration, but have not as yet shown practical results. In Pennsylvania, Ohio, Florida, Louisiana and California the subject is now in active agitation. Wilbur

pointed out the essential features of effective laws and ordinances and emphasized the importance in undertaking such work of avoiding the errors which have appeared in the history of registration in the various States, and of proceeding at once upon a plan conforming as closely as possible with the standards arrived at through the combined experience of older registration States.

Is Pneumonia Increasing?—JOHN S. FULTON (Baltimore) said that for 58.5% of the population of the United States, and for 66.5% of the urban population this question can be answered in the negative, for pneumonia is definitely diminishing between the ages of 15 and 60. There remain to be considered those parts of the population above 60 and under 15. The proportion of population above 60 is at present about 6.6% of the total population. The pneumonia mortality charged against this age period has apparently increased in 10 years from 21.9% of the total pneumonia mortality to 22.6%, but the proportional part of the population in this period has risen from 6.2% in the same time. The proportion of urban population above 60 has grown only from 5.25% to 5.27% in 10 years, while the pneumonia mortality has grown from 16.1% to 19.5% of the total mortality charged to that cause. Meanwhile there have been added to the group of pneumonias a number of pathologic conditions not formerly recognized and not properly counted under a statistical head supposed to include the true pneumonias. In the last 20 years the deaths classified under the head of senile debility have materially diminished notwithstanding the inclusion from time to time of several indefinite causes of death formerly supposed to merit separate classification, and notwithstanding the increasing proportion of population in ages above 60. These considerations fully explain the apparent rise of the pneumonia account for this period, and leave the assumption of an increased incidence or fatality of pneumonia without support. For the proportion of population below 15, that found below 5 alone contributes to the apparently increasing pneumonia mortality. For this period of life only about 5% of pneumonias autopsied are found to be true lobar pneumonias. Of the remaining 95% nearly all are secondary or complicating bronchopneumonias and notwithstanding the accessory relation of the pneumococcus to a considerable number of these bronchopneumonias, they should not be so treated in statistics as to confuse our knowledge of the more definite massive pneumonias due to that organism. The secondary bronchopneumonias should be referred in the statistics to their efficient cause, whenever that is known. The apparent rise of pneumonia under the age of 5 can be shown to have consisted up to 1890 of a steady unloading of indefinite mortality accounts into the pneumonia column. The diseases of the nervous system of infants have been discharging for 30 years into the pneumonia accounts. Since 1890 a new contributor to infantile pneumonia has appeared. This, Fulton believes, is influenza, and should be charged to influenza. The relation of the influenza organism to fatal bronchopneumonias of children is strongly suggested by the statistics, and invites careful clinical and pathologic study. Speaking of the statistics of cities, Fulton attacked especially the statistics of Chicago, which he said showed pneumonia in relations quite inconsistent with their claimed general mortality, the known age distribution of the population, and the published mortality from other diseases of childhood. For instance, he said, then the claimed proportionate mortality of 26% for ages under 5 would, upon their published ratio of mortality from pneumonia, require that 400 or more of any 1,000 deaths under 5 should be charged to pneumonia, and then every conceivable method of adjusting their published pneumonia mortality to their population would result in a relation just as monstrous.

[To be continued.]

AMERICAN ACADEMY OF MEDICINE.

Twenty-ninth Annual Session, Atlantic City, N. J., June 4 and 6, 1904.

[Specially reported for *American Medicine*.]

[Continued from page 980.]

The Relations of Dentistry and Medicine.—EDWARD C. KIRK (Philadelphia) stated that dentistry has had a dual origin; its problems in pathology have kept it in relation with medicine, and the requirements for skill in relation with the artisan. He traced the development of dentistry as a separate profession, the establishment of dental colleges, societies, and literature. The relationship between medicine and dentistry is the expansion of dentistry to include the fundamental portion of medical training. The dentist lacks the educational training that leads to the medical degree, and in a technical sense he is not a physician, but he does not lack medical training, as in the professional training of dentists today the requirements for the first two years are the same as in medicine. The dental course is now four years, and to acquire the degree of medicine and dentistry would involve time and money undesirable and unnecessary. The issues which the dentist is called upon to treat are rarely those of life and death, but they are problems

which are intimately associated with bodily health and personal comfort. More rational understanding of the interdependence of pathologic phenomena of the faulty nutrition in even so local a condition as dental caries, has come to be viewed as a diathetic fault or error of metabolism in the buccal secretions, charged with waste products, or as a pabulum of fungi. The constant presence of specific pathologic bacteria in many locally healthy mouths, causes inquiry into the question of immunity, the chemistry of abnormal metabolism, as factors to disease predisposition. For these reasons the dentist and the practitioner will in future be brought closer and closer together. It may also be possible in future to discover evidence of disease by studying the oral secretions when no other evidence of its presence exists, or when the patient is not aware of such disease.

The Relations of Physicians to Dentists.—JOHN S. MARSHALL (read by the assistant secretary) stated that there is still a question in the minds of a good many medical men as to whether or not the dentist is entitled to be classed as a medical specialist, and to be consulted on the same professional and ethical grounds as other specialists, and quoted definitions of the words "physician" and "dentist" by various authorities. "Dentist" no longer indicates the narrow field of the dental region, and the term stomatologist has been suggested as a substitute to define more clearly the sphere of dental surgery. Stomatology would include that department of medicine and surgery relating to the study of diseases and injuries and irregularities of teeth, their treatment, preservation, replacement of lost teeth by artificial substitutes and the treatment of diseases, injuries, and deformities of the oral cavity, the jaws and accessory sinuses. He outlines the course and term of study of the dental student, together with the subjects covered in his curriculum, and concludes that the dental surgeon is entitled to be classed as a specialist in medicine. He cites the relationship of dentistry to medicine, and asks why pregnancy sometimes causes toothache or produces pyorrhea alveolaris, and extraction in a pregnant woman may produce abortion. Why it is never wise to cap an exposed pulp in a malarious region, why an impacted third molar causes deafness or reflex neuroses in various parts of the body? Alveolar abscesses as causes of septicemia or chronic abscess cause pyemia, and disorders of the mouth cause intestinal disorders. Uterine irritations or displacement may cause gingivitis. No plea is made for the recognition of the dentist as a specialist, as he has already achieved this position, dentists having been invited to appear before the American Medical Association and the International Medical Congress, and the mere fact that the dentist does not hold the M.D. degree should not debar him from his just rights to fellowship to the medical profession. Dentistry was the first to organize special schools and to confer special degrees and the younger specialties like ophthalmology, rhinology, etc., have since been organized in all the large colleges. Dentistry itself has developed to such an extent that it also has been subdivided into separate specialties, such as orthodontia, oral surgery, operative dentistry, etc.

[To be continued.]

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-ninth Annual Meeting, Held in Boston, Mass., May 24, 25, and 26, 1904.

[Specially reported for *American Medicine*.]

[Continued from page 980.]

The Value of Nonoperative Local Treatment in Pelvic Disorders.—WALTER P. MANTON (Detroit, Mich.) said that there were three factors which, among others, were largely responsible for the neglect of medical gynecology: 1. The average physician's lack of knowledge in the accurate diagnosis and local treatment of pelvic disease. 2. The allurements and fascinations of surgery. 3. Competition in the field of practice. In the best of hands the results from local treatment in pelvic diseases were frequently slow in manifesting themselves, and discouragements were often met with, but in suitable cases persistent effort would ultimately attain the desired end. The objects of local treatment were the relief of pain and irritation, often of a reflex nature; the allaying of congestion and inflammation; the absorption of the products of inflammation, and the reposition of displaced organs. In the regulation of the uterine functions, in congestions and mild inflammations of that organ and surrounding parts, and in displacements of the uterus, with and without adhesions, the application of proper local treatment was of signal value; while in prolapse of the tubes and ovaries, even in the presence of extensive adhesions, but without ascertainable morbid changes in the organs themselves, vaginal tamponade offered the simplest and most efficient means of reposition and cure.

Treatment Preparatory to Operation.—HENRY C. COE (New York) introduced his remarks with the statement that while his early training had led him to believe that such treatment was practically indispensable in cases of so-called "cellulitis," subsequent experience had convinced him that this notion was not in accordance with pathology or common sense. He had expressed scepticism in this subject as long ago as 1886,

when he read a paper of the "Exaggerated Importance of Minor Pelvic Inflammation," and subsequent experience had only served to confirm his opinion that old pelvic exudates and adhesions were not *per se* a contraindication to operations on the uterus. Modern aseptic technic was a sufficient safeguard against danger from this source. The reader contrasted the old practice of keeping the patient in a hospital for several months, with the preparatory treatment between each minor operation, with the present plan of performing combined operation at one seance, and sending out in three or four weeks. He questioned the actual value of the hot vaginal douche, local applications to the vaginal fornix, treatment of the ectopic cervix, etc., previous to trachelorrhaphy, since the diseased tissue would all be removed at once by amputation. At the same time, he admitted the remarkable results often observed as regards the absorption of extensive pelvic exudates. Acute and subacute inflammations in and around the adnexa formed the real contraindication to operation, and doubtless surgeons were not always as careful as those of the former more conservative generation in selecting their cases. Competition and the rush of modern life were responsible for some ill-advised operations, minor as well as major. In major operations the author thought that (excluding pus cases) general preparatory treatment of the patient was rather more important than local. He believed, however, that the admirable results obtained by the pioneers in the treatment of vesicovaginal fistulas were due to careful preparatory treatment, such as the division of cicatrices, stretching of the vagina, etc. Fortunately we were seldom called upon to handle such complicated cases as those described by Sims, Emmet, and Bozeman. With all our improvements in technic we have not yet outgrown all the wisdom of our old teachers.

The Value of Postoperative Local Treatment.—J. RIDDLE GOFFE (New York) said the experience of all observers was that local treatment relieved congestion, pain and discomfort, inaugurated, hastened, and accomplished the absorption of edema, plastic exudate, adhesions, and pseudohypertrophy. If it would relieve these conditions, how much more certainly would it prevent them? It had been found serviceable in preventing the deposit of plastic exudate and the reformation of adhesions in cases in which these were present at the time of operation. It was especially valuable in cases subjected to vaginal section for the relief of sterility. The author reported several instructive cases to substantiate the points made in his paper.

The Implantation of the Human Ovum in the Uterus.—CHAS. SEDGWICK MINOT (Boston) discussed this subject, by request. He said that the human ovum produced upon its exterior during its earliest stages of development a thick layer of cells, the trophoblast. The function of the trophoblast was to corrode away a portion of the mucous membrane of the uterus, making a cavity in which the ovum lodged itself. The trophoblast thereupon underwent a hypertrophic degeneration, such as to produce a series of irregular spaces, which persisted and became the intervillous spaces of the placenta. Papillary outgrowths of the chorionic mesoderm meanwhile penetrated the trophoblast, initiating the formation of the chorionic villi. The trophoblastic cells over each mesodermic outgrowth persisted in two layers, the inner cellular, and the outer syncytial. These two layers represented the first stage of the villous ectoderm. Similar observations had been made upon primates, and were compared with those upon the human subject. He compared briefly the method of implantation in man with that in other animals, to show that the trophoblast was of general occurrence, and that by destroying uterine tissues it inaugurated the formation of the true chorionic placenta.

[To be continued.]

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY.

Tenth Annual Meeting, Held in Chicago, Ill., May 30, 31, and June 1, 1904.

[Specially reported for *American Medicine*.]

Officers.—The following officers were elected: President, F. C. Cobb, Boston, Mass.; vice-president of the Southern Section, Wm. Cheatham, Louisville, Ky.; vice-president, Middle Section, Thomas Hubbard, Toledo, O.; vice-president, Eastern Section, S. MacCuen Smith, Philadelphia; vice-president, Western Section, W. B. Shields, St. Louis, Mo.; secretary, Wendell C. Phillips, New York, N. Y.; treasurer, Ewing W. Day, Pittsburg, Pa. Boston, Mass., was selected as the place for holding the next annual meeting.

An Address of Welcome was delivered by FRANK BILINGS (Chicago).

President's Address.—NORVAL H. PIERCE, in his address, pointed out the great changes that have been wrought in the special domain of laryngology, rhinology, and otology during the life of the society. Ten years ago it was hardly more than a matter of sprays and spurs, of snares and syringes. The members no longer confined themselves to intralaryngeal, intranasal and intracranial operations, but by most radical external surgical procedures it was the aim to cure the most extensive diseases

of the nose and accessory sinuses, the larynx, the pharynx, the ear, and neighboring parts within the cranial cavity. This change has taken place gradually. It took years of endeavor to set the bounds of laryngoscopy, rhinoscopy, and otoscopy. Latterly, by the work of Killian, Jensen, and of many of the fellows, the advance has been made more rapidly, so that at the present time the well-rounded and successful specialist must not only possess that special skill and dexterity which enable him to examine successfully the larynx, the nose, with the orifices of the several accessory sinuses; the ear, both by otoscopy and by means of complex functional tests, but he must combine with [this a broad surgical knowledge equal to that of the general surgeon, and an ever-accessible knowledge of regional anatomy superior thereto. Thus do they prove the right to exist as specialists and members of the surgical department of the great science and art of medicine; but he expressed the fear that the pendulum might swing too far in the direction toward radicalism. With the technic of external operations firmly within grasp, were not the members liable to resort to them prematurely—to forget that much might be done by more conservative local measures, etc.?

Some Points in the Pathology of Bone Cysts in the Accessory Sinuses of the Nose.—A. LOGAN TURNER (Edinburgh, Scotland), by invitation, read a paper on this subject. An analysis of the various published cases illustrating this condition revealed the interesting fact that in some the bony cavity merely contained air, in others the contents were of a mucoid character, while in a third group of cases pus or mucopus was found.

Purulent Otitis Media Complicating Typhoid Fever.—EWING W. DAY (Pittsburg, Pa.) read an exhaustive paper on this subject in which he considered deafness, otitis externa, disorder of the perceptive apparatus, acute catarrhal otitis media, myringitis, and acute purulent otitis media as complications of typhoid fever.

Chronic Otitis Media.—JAMES F. MCKERNON (New York City) reported a case of chronic otitis media, complicated by chronic mastoiditis and jugular bulb thrombosis, with operation and death. The patient, a boy of five, had scarlatina seven months previously, with a discharge from both ears. One ear ceased running after six weeks; the other continued to discharge intermittently. During the periods of intermission the child was peevish, drowsy, and constipated; the tongue coated; the breath foul. There were headache and earache. While the ear discharged the patient's condition was approximately normal. Three weeks after the ears became affected there was pain behind both ears, worse on the right side, for ten days. On examination the right canal was found red, excoriated, and filled with foul, thick discharge. The drum was perforated over the Eustachian orifice, and in the posterior superior quadrant granulations and dead bone were discovered. The left drum had healed. A diagnosis of intratympanic caries was made and operation advised, but refused, although the dangers of delay were pointed out. Under the usual palliative treatment the discharge stopped for a time, but recurred. About two months later the condition within the ear was found somewhat better. Operation was again urged, but was declined as before. Three months later the discharge increased again, and operation was agreed to. Examination at this time failed to reveal any signs of mastoid trouble, but the general physical condition was not so good. Temperature, 99° F. When the mastoid was opened the cortex was dark; the antrum, tip, zygomatic root, and several medullary spaces behind the sigmoid groove contained thick creamy pus. The bone was necrotic between the canal and sigmoid groove, down to the bulb. The posterior canal wall was removed and the typical Schwartze-Stacke operation done. A skin graft was placed over the entire middle-ear cavity and antrum. All went well until the eighth day, when the patient complained of headache and photophobia and became restless. The temperature rose to 104°, preceded by vomiting. The condition gradually improved for a week, with no marked variations in temperature. Several consultations were held, and irregular typhoid, central pneumonia, and meningitis were suggested. On the eighth day the child became drowsy and irritable, complained of posterior headache, and refused nourishment. After some delay in obtaining permission, an exploratory operation was performed, the writer suspecting an intracranial condition, resulting from the previous long suppuration. The child's physical condition at this time was poor. The bone over the sinus being removed, an incision was made an inch long, gelatinous clot removed from the torcular end, establishing a blood current from this direction. The bulb was then curetted and some firmer clot removed without, however, establishing a flow of blood. The jugular vein was therefore resected, together with several enlarged glands. The patient's condition was good at the end of the operation, but he never regained consciousness, and died 20 hours afterward. No autopsy. The author had since had two other cases with a similar history, in which early operation resulted favorably. He was unable to say whether or not any other intracranial condition existed in the case detailed, but if so, it was obscure. There were no chills or chilly sensations to suggest sinus involvement. In conclusion, the writer sounded a note of warning in atypical cases against delaying too long a search for the cause in the original focus of infection, when the patient did not progress well.

[To be continued.]

SOME REMARKS ON THE TREATMENT AND AFTER-TREATMENT OF CONGENITAL DISLOCATIONS OF THE HIP.

BY

ADOLF LORENZ, M.D.,

of Vienna.

Ever since my first communication, concerning the treatment of congenital hip-dislocations by the bloodless method, I have followed with great interest the experiences and reports of other physicians with reference to the subject, having been always prepared, from whatever source it might have arisen, to adopt that which was better. In spite of this consummate purpose to better my method, by judging and trying various suggestions, this method has nevertheless remained completely unchanged in its entirety, during a trial of 10 years, and I have nothing more of importance to add to what I have already described in my book¹:

As to the technic of the reposition, I have nothing more to add; but I may say that it makes very little difference, by what method the reposition is brought about, whether by the lever maneuvers of abduction, or whether by extension. Instrumental aids (machine contrivances—extension tables) are in neither case necessary. It is best to emancipate oneself from machine assistance. In the case of children under the age limit, the manual reduction is, as it were, playfully easy, and attained without exertion, so that the use of any such machine appliances ("Boston Machine") seems to me superfluous, to say the least. But when I add that by mechanical methods the intimate contact between operator and working object is lost completely; that he no longer can judge the resistance offered by the soft parts; that he no longer can palpate the fundus of the acetabulum and its borders, using the head of the femur as a probe; that he can no longer picture to himself the relations about the acetabulum—then I must designate the application of a reduction machine as a disadvantage.

Moreover, the complicated extension appliances are superfluous, and are indeed under certain circumstances harmful in effect. Rhythmic manual traction overcomes every resistance, without carrying with it the danger of permanent traction. A method is not characterized by the art and manner of *reposition alone*, but it is characterized by the after-treatment, especially by the retention methods.

The most important rule in the retention is the temporary fixation of the thigh in *right-angled abduction*. It is important to note that this right-angled abduction does not follow indifferent or common extension (ordinary extension of the standing position) but from right-angled flexion. When a thigh flexed to a right angle is abducted to a right angle, it comes to lie between the sagittal, in the frontal plane. A child lying upon the back, whose thigh has been thus carried from right-angled flexion into right-angled abduction, shows therefore the following peculiarities in the way it manages its lower legs; the extended leg on the sound side lies with the posterior side and heel in contact with the underlying surface; the affected leg, on the other side, has its entire outer surface, as well as that of the foot, in contact with the table; the thigh forms a right angle with the side of the trunk; the knee-joint is bent to a right angle. If turning the thigh inward upon its longitudinal axis, is designated inward rotation, and turning it outward, outward rotation, then the position described entirely is distinct from such rotation, that is, the limb is turned neither inward nor outward. In this position, which we call the "*primärstellung*," or primary position, the reduced hip is fixed for from six to seven months on the

average, by a plaster to the knee, leaving that free. If one observes the gait of such a child, one sees that the lower leg, on the operated side, owing to its dead (intrinsic) weight, is directed somewhat behind the frontal plane, so that the foot is stepped upon with its inner edge, wherefore it is indicated to raise the outer border of the shoe about 1 cm. This placing of the right-angled flexed lower leg behind the frontal plane results from the turning of the right-angled abducted thigh inward; while the leg is in function, the right-angled abduction of the thigh is associated with a slight inward rotation. This, however, is so slight, even in the functioning leg, that one may speak of the rotation in the primary position as an indifferent one. So long as this *primärstellung* is maintained, the femoral head remains in slight or extensive (surface) contact with the acetabulum, according to whether it is shallow or deep, assuming of course, that the reduction has been properly carried out.

From this, the principle is deduced, that this *primärstellung* is to be preserved as long as possible. In the *primärstellung*, a "*relaxation nach hinten*" (posterior relaxation) (which would mean a complete failure) is as good as (completely) ruled out. And just as impossible is a relaxation upward (anterior upward relaxation, or subspinal position).

The only relaxation possibility exists in the inward direction, that is, medianward from the acetabulum. Should this condition occur remedy may be effected at a later period. Such a relaxation position, as well as a relaxation upon the edge of the horizontal ramus of the pubic bone, I have observed, when, for purposes of security, retention of right-angled abduction had been combined with overstretching or hyperextension (the right-angled abducted thigh being pushed behind the frontal plane). I therefore no longer apply hyperextension, but content myself with right-angled abduction.

In cases of very bad stability of the *primärstellung*, the right-angled abduction may be exaggerated so that the angle, which the trunk and thigh make with each other, becomes acute (negative abduction). But, as a rule, this means is also superfluous. For the primary position the simple right-angled abduction, as a rule, is sufficient. On account of the fixation in this position during a period of several (5 or 6) months, there results an artificial right-angled abduction contracture, because certain *pelvitrochanteric* muscles undergo shortening, due to the fact that their insertions are brought closer together continuously for a considerable space of time. This acquired shortening of *pelvitrochanteric* muscles is of the greatest importance in the after-treatment. With the gradual diminution of right-angled abduction, the shortened *pelvitrochanteric* muscles are rendered highly tense and this tension acts as a retention factor, because, by this means, the femoral head is pressed against the rudimentary acetabulum.

During late years I have carried out the after-treatment in the following manner: After the primary position of right-angled abduction has been maintained for five or six months (in cases of bad stability even longer), the plaster is removed and as a rule no subsequent one is applied.

In unilateral cases the right-angled abduction is corrected by gymnastic means *only so far* as to permit the child to walk easier. A high sole of 3 cm. or 4 cm., worn under the healthy foot, serves to maintain a considerable abduction angle. If the abduction contracture is very rigid, a simple bandage is applied, which draws the leg somewhat medianward. This bandage consists of a pelvic girdle, and a leather gaiter, about the breadth of a hand, which is applied to the knee of the crippled leg. This pelvic girdle and gaiter are bound together before and behind by a strap or straps, which may be shortened, in this manner bringing about adduction. Wearing this leather bandage, children are able to walk very well. *The correction into normal (indifferent) exten-*

¹ Heilung der angeborenen Hüftverrenkung durch unblutige Einrennung und funktionelle Belastung.—Toepfliz & Deuticke, Wien, 1900.

sion must take place very slowly, occupying a period of many months or indeed a year. I hold firmly to the principle that, during the after-treatment, the facility, active and passive, of easily and unresistingly attaining the "primärstellung" (right-angled abduction) is more important than the correction of the primärstellung into the normal extension. Active and passive leg exercises, therefore, should have for their purpose, not merely to correct, but must also fulfil the important task of securing the facility of easily attaining the primärstellung.

To this end the child is laid in a plaster-bed at night. This is made by laying the child prone upon its front and modelling it with the reduced thigh placed in right-angled abduction. Such an abduction appliance, which is, so to speak, nothing more nor less than the posterior half of a fixation plaster, is accordingly well padded. In this manner we secure the exact maintenance of the primärstellung by night, whereas by day a gradually diminishing abduction is admissible. To attain right-angled abduction, the most important active exercise is that in which the child lies upon its well side and brings the crippled leg gradually to the perpendicular against light manual resistance. This sort of after-treatment is of especial importance in such cases in which the acquired abduction contracture is of lesser rigidity and the joint more or less "wobbly." In case of very rigid abduction contracture, it may at times be necessary to correct the same to an easier walking attitude, by bringing it forcibly down under light narcosis. In such cases, there is no danger of relaxation, and the facility of again obtaining the primärstellung is of no concern under these circumstances.

The further correction, from the primärstellung into ordinary extension advances the more noticeably as the limb assumes an attitude of outward rotation, because the head of the femur does not plunge properly into a socket which is too flat. If this outward rotation disturbs one, it may be combated by methodic inward rotation. A certain degree of outward rotation remains persistently, and I can see absolutely no disadvantage therein. Forcibly rotating the thigh inward may lead to posterior relaxation of the head, and so to complete loss of the result sought for.

Moreover, after attaining the normal extension attitude of the leg, a high sole of about 1 cm. to 2 cm. retained under the foot of the well side is advisable in order to secure a habitual abduction in the reduced joint. Soles of equal height, in which any residual shortening is eventually compensated, are only admissible after the stability of the position permits it.

Mutatis mutandis, the same laws hold in the after-treatment of double luxations. Here, too, I have departed from overstretching (hyperextension), as this tends in the same way to bring about relaxation upon the horizontal ramus of the pubic bone, and I content myself with right-angled abduction, which, only in very unfavorable cases is increased to negative abduction. The primärstellung is held fixed for five or six months by means of plaster. If at the end of that time the joint is still wobbling, then the primärstellung is held fixed anew for another two or three months. As a rule, however, a second plaster is not applied.

If the primärstellung is found strongly contracted, a correction of the same into the walking position (*i. e.*, in abduction lessened only so far that it is possible to walk) is undertaken, under light narcosis. This correcting plaster remains only a very short time—perhaps eight days—after which gymnastic treatment begins. In cases of lesser rigidity of the primärstellung, no second plaster is applied, and gymnastic after-treatment begins immediately after the removal of the fixation plaster.

The lessening of right-angled abduction is brought about in a gymnastic way by active and passive exercises promoting abduction, and at first only carried so far

as to acquire a pretty fair degree of abduction, by which walking may be possible. In order to secure this position and to prevent the undue abduction of the legs, a small leather bandage is applied. This consists of a stocking fastened about the knee-joint on each leg, and the two connected before and behind by a narrow strap. Correction to the normal standing position of extension of both legs must be allowed to take place very slowly and carefully during a period of many months.

Here again I hold to the principle that the facility of easily gaining the primärstellung is more important than the correction. So long as it is possible to attain the primärstellung actively and passively, easily and without pain, so long may we be sure of retaining the femoral head, at least, in that best possible position, which we were able to gain at the time of the reposition. Action of the adductor muscles is lastingly eliminated. Children who have been treated in this fashion, are able, without any trouble, to assume the so-called "trick position" or "split attitude," which is the ability to sit upon the perineum with the legs thrust apart at right angles. After gymnastic treatment has fulfilled its purpose of correcting the primärstellung into the normal extension attitude, then the only remaining problem consists in retaining the easily attainable primärstellung. This is done by using a plaster-bed at night. This is modelled over the pelvis and thighs of the pronated child, the hips being in the primärstellung, and thus, after it is padded, represents a mould, which corresponds in a manner to the posterior half of the original fixation plaster. The outward rotation which accompanies diminution of the primärstellung, and which is somewhat more frequent in double cases, is treated gymnastically, yet nevertheless corrects itself spontaneously to a certain degree, after a long time, so that, indeed, it becomes of no concern whatever. The foregoing method of treatment is so simple that it may be carried out at home by the mother without the least trouble.

As to the results, they are entirely satisfactory, at least as regards function.

If head and socket are fairly well developed, then we may succeed in fixing the femoral head in the acetabulum and in arriving at a faultless result, at least as regards function. Absolutely normal anatomic relations can naturally seldom be attained, and the expert will recognize a reduced joint as such, as well in the röntgen picture as by clinical examination; in many cases, however, such a complete restitution *ad integrum* is reached that one may speak of a cure in its strictest sense. But even an imperfect anatomic result is compatible with a satisfying and even good functional result, providing that the head has found a bony support upon the os ileum.

Very often, in bringing down the leg, the femoral head shifts its position upward and fastens itself in the region of the anterior inferior spine. In such a case one refers to it as *forward transposition*. I believe this expression is poorly chosen, because a faultless retention of the head in the acetabulum is brought about also by a *transposition* of the luxated head forward. I refer to such a case as a *relaxation forward and upward*, or an *anterior superior relaxation*, or as a *subspinal position*. Such a position is very easy to recognize clinically, because the pulse of the femoral artery beats no longer upon the rotating head, but interior to it. The head of the bone is therefore located somewhat too far external and somewhat too high, but still always below and inside of the anterior superior spine. The slight residual shortening that remains does not interfere essentially with the functional result, but in these frequent cases, the pelvitrochanteric muscles must be nursed and maintained with especial care. Posterior relaxations (which represent complete failure) fortunately occur very seldom. Only in three cases (so far) have I had to repeat the reduction on account of posterior relaxation, and in this second reduction, which was made about two years

after the first operation, I have every time been surprised to find a better primary position than at the time of the initial reposition.

In several cases I have met a position of the head which represents, so to speak, an intermediate position between anterior superior relaxation and posterior relaxation. I have called this position "lateral apposition." Such cases represent anatomic results to the slightest degree, or are perhaps complete anatomic failures; the head hardly touches the acetabular surface at all. The upper end of the femur is closely applied to the side of the ileum in a practically sagittal direction (lateral apposition), the trochanter being behind; the head is found at the outer end of the inguinal sulcus and located somewhat below and *outside* of the anterior superior spine. It would be an error to refer to this position of the head as posterior luxation, as the anterior pole of the head still extends to the inguinal sulcus and may indeed perhaps cause a perceptible prominence there. Motion at the joint is essentially limited, especially the inward rotation, which is almost impossible, and every attempt in that direction calls forth energetic muscular resistance, manifested in the patient by a decided movement of defense. But even this evident anatomically bad result is in reality not synonymous with a functionally bad result. Indeed such children walk surprisingly well after compensation of the residual shortening, although, of course, the limp remains noticeable. But other complaints disappear and as regards the endurance of such children, it satisfies all reasonable demands. One need feel no fear whatever that lateral apposition represents a step to posterior relaxation and thus to a complete loss in the result. I have seen on the contrary that this lateral apposition has remained unchanged for many years. It is very probable, that the striking frequency with which relaxation occurs forward or superiorly forward, is caused by the pathologic anteversion of the femoral neck.

In order to remedy this difficulty, it was proposed by Schede, as is well known, to select abduction and inward rotation as the primärstellung, to fix in this position for several months, and finally to correct the excessive inward rotation by osteotomy in the lower third of the femur, while at the same time the upper part of the bone is held in its position of inward rotation by means of a golden nail driven through trochanter head and neck. From a theoretic standpoint, there is nothing to bring forward against this proposal. Indeed, I had myself pointed to the possibility of doing away with artificially gained rotation positions by means of osteotomy (with subsequent *diolatio ad periferiam*), before the osteotomy was proposed by Schede for this purpose. With marked anteversion of the neck, we must as a matter of fact, point to the primary position of inward rotation, followed by osteotomy of the femur, as the only means of preventing anterior superior relaxation or lateral apposition. In spite of which, I have never as yet carried out osteotomy, but have contented myself with those functional results which, in cases of strong anteversion, are attainable by a bloodless way. In several cases, which had been treated by primary inward rotation and subsequent osteotomy I have seen very bad results from the treatment owing to posterior relaxation.

This danger of posterior relaxation is occasioned by the excessive rotation inward; it requires strong hyperextension of the joint to lessen this danger. Added to this it is to be noted that in cases in which the neck of the femur is anteverted to a marked degree, the acetabulum is also usually underdeveloped, and is therefore able to offer little support to a femoral head, even if it is normally directed. In such relaxations, I have arrived at quite satisfactory functional results by the bloodless treatment carried out subsequently.

If on the one hand, I concede that one is fully authorized in using a primary position of inward rotation followed by osteotomy, in cases of marked anteversion, I

must state on the other hand, that all my patients have been so satisfied with the bloodless treatment, that I have as yet, not found occasion to complicate my method, which was conceived as a bloodless one, with any supplementary bloody operation.

It is by no means seldom, that patients will not agree to a transition from a bloodless to a bloody treatment, and therefore interrupt the treatment to their own detriment. In one very interesting case of this kind—it was a case of double dislocation—the hips were fixed in the primary inward rotation position on account of unfavorable anatomic relations, for a very long time (over a year) and were next to be corrected by bilateral osteotomy. The parents refused consent and stopped treatment, which was therefore continued further by the bloodless method. It was found possible to diminish the inward rotation by methodic gymnastics without the feared luxation taking place. Proof therefore was offered, that the proposed osteotomies were unnecessary.

If one concedes that the procedure of Schede may be of use in some cases of marked anteversion of the neck, on the other hand it is firmly established that it is unnecessary to do osteotomies in more than half the cases, as was practised by Schede. Till now I have not in a single case had recourse to such a means, and, although I have not always satisfied myself, I have nevertheless been rewarded with the satisfaction of my patients by using a bloodless method.

According to approximate statistics of end-results of such cases, in which a period of at least two to three years has elapsed since the reduction, the relation between anatomically good, and anatomically imperfect results is brought out by the following:

Out of 364 cases of unilateral dislocation 218 gave anatomically good results while 127 showed subspinal positions (anterior relaxation, upward and outward) and 19 showed lateral appositions.

Out of 158 cases of bilateral dislocations, 70 showed good anatomic results on both sides, 19 resulted in subspinal positions on both sides, 7 showed lateral apposition on both sides, 49 resulted in anatomically good results on one side, while the other side became subspinal; in 4 cases one side became anatomically replaced, while the other side showed lateral apposition; in 9 cases one side was subspinal, the other lateral apposition. Taking all the hips together ($364 + \text{twice } 158 = 680$), 358 of these show good anatomic results, i. e., 52.6%—a good half of the cases.

Further, I wish to be permitted a word upon the age limits for bloodless reduction. I believe that the endeavors to increase the upper age limit are not justified by the results obtained by forcible reduction of old luxations, and that these results do not make up for the great danger which goes hand in hand with forcible redressment. Putting aside exceptional cases, I still believe that the age of 9 years to 10 years should be the limit for reducible unilateral cases, and 7 years to 8 years for the bilateral. In individual cases beyond the age limit, reduction has been effected after repeated sittings. I do not favor reducing by degrees in this manner. As we approach the upper age limit, the reduced joints tend to a stiffening which often simulates a functional ankylosis.

If reduction is impossible in cases beyond the age limit, using a reasonable amount of force, there is still a thankful object to be gained by bloodless therapy. In such cases, in both unilateral and bilateral luxations, I employ the so-called "inversion" of the joint, that is, reversing the existing position of the joint into an opposite "habitual" position. Under all conditions, such old dislocations manifest adduction contractures, combined with more or less flexion. We have, therefore, to deal with the task of changing an existing flexion adduction position into one of habitual abduction hyperextension. This "inversion" is executed in exactly the same way as an intended reposition.

First, one does away with the resistance of the adductors by subcutaneous, bloodless myorrhexis, and obtains a considerable abduction. Then the subspinal soft parts are severed by subcutaneous myotomy, and hyperextension of the joint is attempted. The procedure, according to the principle of modelling "redressment," is continued till a considerable abduction hyperextension attitude is possible without undue tension of soft parts. This attitude, which is quite compatible with the walking posture, is sustained for two months or three months by means of a plaster, allowing the knee-joint to be free. We concern ourselves here not with a reduction, but with forcing the head against the upper outer end of the fossa inguinalis. This driving the head forward takes place owing to the ever-stretching hyperextension. By stretching the adductors, we try to gain a sinking of the corresponding half of the pelvis, and therewith an apparent compensation for the shortening.

The acquired habitual inversion of the pelvis on the corresponding side (by the habitual abduction position of the joint) also creates, on account of the accompanying apparent lengthening of the leg, *much better mechanical conditions for the weight-bearing function* of the head of the bone. Under the previously existing adduction, the head finds no support on the steep external surface of the ileum; the entire weight of the upper half of the body is borne by the stretching of the pelvitrochanteric soft parts, from which arises the painful exhaustion, after the use of the leg for a short time. After establishing the habitual abduction attitude, the relations become far more favorable, because the more horizontally placed center of the ileum offers a better bony support, and acts in a manner as an improvised acetabular roof. After-treatment consists in active and passive abduction and hyperextension gymnastics, with attention to the pelvitrochanteric muscles.

The result of such palliative treatment by the "inversion" of the luxated joint, lies, in the case of unilateral luxation, in the noticeable apparent lengthening, in the disappearance of the pain, in the marked improvement in the limp, and above all, in the acquirement of a very satisfactory power of endurance in walking.

In bilateral dislocations the thing to be aimed at, above all, is the improvement of the attitude of the trunk by lessening the significant lordosis; the necessary hyperextensibility of the joints must be maintained, by daily applications of heavy weights upon the buttocks, with the knees firmly supported. Long-continued attention to the pelvitrochanteric muscles (in which the exercise of alternately standing on one leg, at the same time holding the pelvis as horizontal as possible, plays an important role) becomes an essential step in the after-treatment. Such patients, when provided with good supporting corsets, display at times quite unexpectedly good functional results, as apparent in the appearance and power of endurance in walking, as in the shape of the trunk. In any case, it is firmly established that such results are attainable in a simpler and easier way than by subtrochanteric osteotomies, without at the same time sharing the disadvantage of the shortening which is a necessary accompaniment of the operation.

With reference to the lower age limit of bloodless redressment, I take the stand that it should not be lowered too much, for practical reasons. As a rule, the dislocation is not discovered till the child begins to walk. This holds especially in the double cases, in which there is no inequality in the lengths of the legs and therefore no indication for an examination. But even in unilateral cases, if the existence of a subluxation or even a complete dislocation is discovered, the child being as yet still unable to walk, and the evident disturbance in function has occasioned an examination, I hold that it is not opportune to begin treatment at once, because it means a never-ending torture to the delicate

child as well as to the parents. Before beginning treatment, I wait not merely till the discrepancy in the gait declares itself beyond any question, but till the child is able to keep itself clean. Then, for reasons which are easily deduced, the treatment is so much simplified that I am accustomed to wait till the expiration of the second year before attempting reduction. It pleases me most, if the children come to me for treatment after the expiration of the third year. By this time the unclean accompaniments following reduction are done away with; and on the other hand there is the important advantage that the greater tone of the soft parts materially enhances the stability of the primary position after the reposition is brought about, and so increases the chances for permanent retention.

In conclusion, as to the practical value of the röntgen images in judging prognosis and the results arrived at, I must say, first of all, that to question the scientific value of the investigation of cases by such means (radioscopy) is farthest from my intention, as goes without saying, but I must warn against basing judgment as to prognosis, upon the röntgen picture *alone*, and underrating or perhaps overlooking entirely the clinical aspect. On the contrary, the clinical examination as regards prognosis seems to me far more valuable than the röntgen picture. Interpretation of such an image with reference to the direction of the neck of the femur is unreliable, if the rotation position of the leg during the exposure is not well understood or not carefully taken into calculation. On the other hand, a single grasp of the trained hand (with the transverse knee axis placed in the frontal plane) is sufficient to convince one, not only as to the anteversion (if more than slight), the size and the development of the head, but also as regards the length of the neck.

Again, in forming judgment as to the condition of the rudimentary acetabulum, the röntgen picture is liable to mislead, for it may induce one to believe an acetabulum to be well preserved and of sufficient depth, whereas its dimensions may be altogether imperfect on account of the thickening of the cartilaginous cover. Of course, even the clinical examination with reference to acetabular relations may be unable to lead to correct conclusions. But with regard to this point, I should like to communicate my experience, that in cases in which the head and neck have been well developed and well directed, I have found, with extraordinary frequency when it came to reduction, that I was dealing with a proportionately well-preserved acetabulum, so that, if I have a good femoral neck, I conclude that I have a good acetabulum, and herein I have seldom been wrong. The most unmistakable conclusions as to the acetabulum are to be drawn from the clinical aspect after the reduction is completed, the great test being the primary stability of reposition. In the act one may use the head as a probe, and picture to oneself with great exactness the edges and the depth of the socket.

A further advantage of the clinical examination in establishing the prognosis is still to be mentioned, namely, that by this means one can form a good judgment with regards to the elasticity of the soft parts. I regard a röntgen picture merely as supplementary evidence in the investigation, with reference to prognosis, and lay greatest stress upon the aspect brought about by clinical examination. He who reasons in the opposite way will err much oftener.

Also in judging the anatomic results secured, does the clinical examination give sufficient evidence; from the points of evidence shown above, it is certainly not difficult to distinguish a normal position of the head, from a relaxation upward and forward, or even from a lateral apposition. The röntgen picture gives absolutely reliable information in judging correctly the position of the head as regards its height in the vertical sense, but it throws no light upon the question as to whether

the head is further forward or behind in the sagittal direction. The stereoscopic röntgen image alone displays complete clearness of the relations, and is of the greatest value.

However, it would be an error, and would lead to an absolute undervaluation of the practical worth of the method, if we formed our judgment of the functional results of the bloodless reposition from evidence drawn from radioscopy alone. We should come to the unjustified as well as false conclusion, that the method is valueless in nearly half of the cases, which conclusion is entirely inconsistent with everyday experience. If the functional—that is to say, the practical result is satisfactory, I do not lay too much stress upon the röntgen picture. *Nil perfectum sub sole!*

SURGERY OF HYDROCEPHALUS.*

A Historic Review.

BY

BENJAMIN MERRILL RICKETTS, PH.D., M.D.,
of Cincinnati, Ohio.

CHAPTER I.

Aspiration.—This method has been most universally employed. There is some difference of opinion as to where the trocar should be made to enter the place from which the fluid is to escape. The principal caution to be observed is injury to bloodvessels and sinuses. When possible the opening should be made in the fontanels. When the ventricles are involved the site of tapping is at the lateral angle of the anterior or posterior fontanel because of the absence in this locality of vessels and sinuses.

An opening in the basilar arachnoid cavity is sometimes best, and the arachnoid cavity should be opened before the cyst of spina bifida is punctured when this is an associated condition. When such exists the canula may be inserted above the spina bifida for temporary drainage until the incision in the spina bifida sac has become united.

Dr. Stevens proposed trephining the cranium of Dean Swift in 1745; this is the first recorded suggestion for this operation. Dionis' suggests draining the arachnoid cavity through the various sutures and fontanels.

Le Cat, October 23, 1744, punctured for hydrocephalus.

Remmet, of Plymouth, 1778, used the trocar in removing 80 ounces of fluid from a patient with hydrocephalus.

One of the earlier reports on surgical operations for hydrocephalus was by Odier, 1785.

Vose, 1818, successfully treated hydrocephalus by a surgical operation in which he removed the fluid.

Textor, 1821, no doubt prompted by the brilliant results obtained by Vose, succeeded in benefiting an extreme hydrocephalus by aspiration.

During the year 1821, Lizars, Freckleton and Delafield each operated for this condition, with more or less benefit.

Michaelis, 1822, employed paracentesis for hydrocephalus.

Fenoglio, 1823, punctured the subdural space for the accumulation of fluid resulting from injury.

Ruppius, 1823, removed the fluid by trocar in a case of hydrocephalus.

Gray, 1825, records a case of hydrocephalus in a child 9 months old, in which the head was tapped three times.

Sym, 1826, and McComb, 1831, each report repeated puncture in a case of chronic hydrocephalus.

Dubruell, 1837, mentions a case of the voluminous

formation of fluid in the meningeal cavities relieved by puncture through the occiput.

Conquest, 1837, mentions tapping the head in 19 cases of hydrocephalus, once successfully.

Kilgour, 1840, records two such cases, in which operation was done by puncture.

Petit, Huster, Boerhaave, De la Motte, Pare, Portal, Richter, Golis, Breschet, Bayer, Dupuytren, and Physick, each condemned the trocar.

Battersby² also condemned its use for hydrocephalus.

West, 1842, before the days of aseptic surgery, collected 55 cases of tapping for hydrocephalus, with 40

12,584, U. S. Museum.—Hydrocephalus. Plaster cast of head of adult male, showing hydrocephalus. Measures 21.5 inches sagittally from nasal point toinion; 21 inches coronally between tips of ears; and 25 inches horizontally on level of glabella.

deaths and 15 cures. Fifteen appeared at birth; 36 before 6 months of age, and 4 not given.

Dickinson reported 26 cases; 4 began at birth, 16 before 6 months, and 6 near 2 years.

Edward, 1846, cured a patient with hydrocephalus by puncture and drainage, as did also Kilsell in 1849.

Battersby, 1850, reports three cases of congenital hydrocephalus, in which he employed puncture with the evacuation of sanguineous fluid.

Malgaigne only aspirated under four months of age, and in older patients when life was threatened.

Langenbeck, 1850, operated by puncturing the cranial cavity through the orbit, entering the anterior horn of the lateral ventricle, passing the trocar under the lower lid.

Geo. C. Blackman, 1854, records 69 operations, from which the following deductions are made: There were 24 males, 20 females, and in 15 cases sex was not stated; 32 patients were under 1 year, 2 of these being under 1 month; 6 patients were from 1 to 2 years, one 2 years old, and the ages of 17 were not given. Sixteen recovered, and 53 died. Ages in patients that recovered were 12 years; 2, 4 months; 1, 3 months; and 1, 20 months. The ages of 8 are not given. In the patients that recovered, congenital enlargement occurred in 1, and in the others from a few days to 14 months after birth. There were 8 females, 5 males, and in 3 sex was not given.

In the patient 12 years old, the head was a third larger than was natural; 6 pounds of fluid was drained away in 20 days. Patients were heard from, 90 days to 8 years afterward. Health and intellect were good in all

*Read before the Western Surgical and Gynecological Association, Denver, Colo., December 28-29, 1903.

of them. In those that died, death occurred from 1 to 115 days afterward.

Autopsy showed dilation of the ventricles, atrophy of the pineal gland, and very little trace of choroid plexuses. The cavity of the brain was filled with clear water, brain was atrophied; dura mater thickened, pia mater inflamed.

Gibson, 1857, records a case of spina bifida with post-natal hydrocephalus in which paracentesis capitis was performed 17 times.

Thompson, 1864, cured a patient with hydrocephalus by paracentesis capitis.

A case of chronic hydrocephalus in which the patient was successfully operated upon, is reported in the *Glasgow Medical Journal*, 1866-67, 1, 162.

Kidd, 1866, records a cure following paracentesis for chronic hydrocephalus.

Palmer, 1884, cured a patient with chronic hydrocephalus by tapping.

Morris, 1887, speaks of a case of hydrocephalus in which the patient responded to surgical treatment.

From U. S. College Veterinary Surgeons, Washington, D. C. Skull of hydrocephalic calf two days old.

A. D. Stapleford, Cincinnati, February, 1904, reports the following:

In the case of congenital hydrocephalus, 1887, I performed paracentesis of the cranium by the use of a small trocar, one-eighth inch in diameter. Selected site for puncture at a point one and a half inches to right of median line on a line corresponding to union of frontal with parietal bone. Withdrew four ounces of clear straw-colored fluid at first sitting. The anticipated collapse did not occur. There were no difficulties experienced. Four ounces was removed each succeeding day, closing the opening each time with pad of iodoform gauze held firmly in place with strip of surgeons' rubber adhesive plaster. At times I felt that I could remove any quantity with impunity, and would often allow double the usual quantity to drain away. The total amount removed, (about 13 pints), did not all exist at the same time, as the cavity was observed to refill during the intervals of removal. The residual fluid which I was unable to withdraw amounted to between one and two pints. The enormous growth of bone on the left side was not discovered before the operation, it was thin and had not interfered with the translucency of the cranium. Its presence made it impossible to empty the cavity completely, and would have rendered nil any good effect of the operation had the child continued to live.

Ewart and Dickenson, 1891, report two cases of chronic hydrocephalus in infants in which treatment consisted of tapping and the introduction of air in the place of the fluid.

Mauny, 1893, trephined and drained in hydrocephalus.

Roswell Park, 1893, "operated at the base posteriorly, gouging away the bone one inch below the superior curved line of the occiput, and a half inch to the right of the median line, incising the dura mater, and with a probe opening up the subarachnoid space."

Moseley, 1894, aspirated the lateral ventricles for hydrocephalus.

Glynn and Thomas, 1895, record a case in which they trephined and opened the fourth ventricle with recovery of the patient.

Bilhaut, 1895, made a circular craniectomy to drain in hydrocephalus.

Gordon, 1897, mentions the treatment in a case of adult hydrocephalus by supratentorial and subtentorial operation.

Good, 1897, cured by operation a patient with hydrocephalus and Jacksonian epilepsy.

Bruce and Stiles, 1897, drained through the fourth ventricle in a case of acquired hydrocephalus due to chronic nontuberculous basal meningitis.

Stewart, 1897, reports a case of unilateral hydrocephalus, epileptiform convulsions, and hemianopsia, treated by drainage of lateral ventricle.

Deelen, 1898, punctured and drained the lateral ventricle in hydrocephalus.

Grosz, 1899; Keen, 1899; and Dehler, 1899, each resorted to ventricular drainage for hydrocephalus.

Davis, 1900, made a craniotomy and drained in a case of hydrocephalus.

Ricketts reports three cases, viz., (1) rupture of lateral ventricle; (2) operation; (3) operation.

Cumston³ reports a case of spina bifida in a child of 11 months. Family history of syphilis, a brother or sister of the child had hare-lip. Fourth and fifth thoracic vertebrae. Operation, cyst connected with cord. Dissection, sac cut away. Death on fifth day. Anterior fontanel became tense. Autopsy, ventricles distended with fluid. Internal and external hydrocephalus present.

CHAPTER II.

Lumbar puncture to drain hydrocephalic fluid has not as yet resulted in a cure. In a few cases, slight improvement and considerable comfort have ensued. Repeated punctures at intervals varying in length have been practised aseptically, but the cerebral fluid cannot be removed by a lumbar puncture in all cases.

However, this method might prove successful if continuous aseptic drainage could be maintained from the onset of the disease.

Quincke, 1891, resorted to lumbar puncture for the relief and cure of hydrocephalus.

Koster, 1892, succeeded in removing the cerebral fluid, but without any permanent beneficial results.

Parkin, 1893, made basal drainage in hydrocephalus.

Raczynski, 1898, resorted to lumbar puncture in a case of hydrocephalus.

Maisch, 1897, made repeated lumbar punctures for the relief of hydrocephalus, with resulting great improvement and comfort.

Bauermeister, 1898; Pozzolo, 1901; and Varavssilis, 1901, each resorted to lumbar puncture in cases of hydrocephalus.

Tyler and Williamson, 1903, discovered hydatid cyst in the spinal canal by aspiration.

CHAPTER III.

Subcutaneous Drainage.—Feiss suggested subcutaneous drainage, and it was practised by Türck, 1885 to 1890, but without avail.

Senn⁴ attempted to drain subcutaneously in a case of internal hydrocephalus, the object being to avoid infection. The patient died somewhat unaccountably. No autopsy was permitted, though marked improvement seemed to follow the operation.

He says, "the case indicated that subcutaneous drainage is preferable to open drainage, and proves conclusively that the cerebrospinal fluid is quickly absorbed by the connective-tissue elements as soon as it escapes from the ventricles."—(*Journal American Medical Association*.)

CHAPTER IV.

Compression of the cranium for hydrocephalus has been frequently practised with more or less benefit, for almost a century.

Muslin bandages have been firmly adjusted and readjusted daily, and kept moistened with water to contract them.

Adhesive plaster has also been applied after the scalp has been divested of its hair. Straps of this material do not require readjustment as often as muslin.

Rubber bandages are probably the most desirable for bandaging the head in treatment of hydrocephalus as the pressure is greater, more uniform and constant, less objectionable than plaster and can remain longer than muslin without readjustment.

Blanc, 1821, mentioned compression as a most efficacious means of effecting a cure in certain cases of hydrocephalus.

Girdlestone and Costerton, 1822, employed compression with most satisfactory results in certain cases of hydrocephalus.

Barnard, 1825, successfully treated a patient with chronic hydrocephalus, by compression.

Compression is mentioned in the *London Lancet*, 1838, 1839, i, 376, as a most useful method in dealing with hydrocephalus.

Trousseau, 1843, resorted to compression with gratifying results in a case of chronic hydrocephalus.

Baader, 1848, employed compression, and the application of turpentine in the early stages of chronic hydrocephalus, with beneficial results.

Phillips, 1857, resorted to elastic pressure in a case of hydrocephalus.

Didion, 1858, combined compression with drainage in a case of hydrocephalus with marked improvement.

Roux, 1859, employed this treatment in a case of hydrocephalus, benefiting the patient materially.

Lowenhardt, 1888, compressed in hydrocephalus, greatly lessening the size of the head for a considerable time.

CHAPTER V.

The seton has been employed for many years in the treatment of hydrocephalus. It is especially adapted to the arachnoid type, and in the early stage of the disease.

It is efficacious, as it permits of constant drainage indefinitely or until the desired end is accomplished, whether it is partial or complete obliteration of the arachnoid cavity or otherwise.

The seton can be used in any form of hydrocephalus, gauze probably being the most desirable material to be employed.

It should be passed through the anterior fontanel, its exit to be the posterior fontanel on each side of the median line, and it should be reapplied daily with aseptic precautions.

History.—Chater, 1845, treated a patient with hydrocephalus by instituting drainage and seton; death followed.

Grantham, 1854, reported a case of hydrocephalus in which he made repeated punctures and employed the seton.

Demeaux, 1854, drained and introduced a seton in a case of hydrocephalus.

Kennedy, 1867, records his observations on hydro-

cephalus, and its treatment particularly by the use of setons.

A case of hydrocephalus is reported in the *Irish Hospital Gazette*, 1873, i, 134, in which cure followed the use of the seton.

Haven, 1882, resorted to puncture and "antiseptic" drainage in hydrocephalus.

CHAPTER VI.

Cranial injection is one of the most dangerous, irrational, and ineffectual of all the methods employed for the cure of hydrocephalus.

Various kinds of astringents and irritating solutions have been used with but little if any good effect. They have been injected into the cyst both before and after the removal of its contents. Some operators have increased the strength of the medicament, at the same time removing more or less of the contents at intervals of days, weeks, or even months.

Injection of Iodin.—Boinet, 1856, after removing the

6,410, U. S. Museum.—Skeleton of a dwarf Chippewa Indian squaw, aged 85. The brain of this subject constitutes specimen "1,031 b" of the Anatomical Section. The dura mater and scalp constitute specimen "1,031 C" of the Anatomical Section.

fluid in a case of congenital hydrocephalus, injected tincture of iodine.

Hayden resorted to the same treatment during this year.

Brainard, 1859, made multiple injections of tincture of iodine into a hydrocephalic tumor.

Racis, 1865, made repeated injections of iodine in a case of chronic hydrocephalus.

Lauder, 1881, employed iodine injections in cases of hydrocephalus.

CHAPTER VII.

Internal Treatment.—Greatwood⁵ claimed to have effected a cure in a case of hydrocephalus by the internal administration of potassium hydriodate.

CHAPTER VIII.

Topical Treatment.—Hannay,⁶ 1843, applied a liniment combined with ipecacuanha to the scalp in hydrocephalic cases.

Electricity.—Brenner and Januszkewitsch, 1870, employed galvanopuncture in a case of hydrocephalus.

CONCLUSIONS.

1. Excessive secretion of the cerebral meninges may occur in any form of animal life.
2. The various forms of vegetable life are subject to excessive local or general secretion to a fatal degree.
3. Hydrocephalus, ventricular or meningeal, may develop in utero or at any time throughout infant or adult life.
4. The cases of spontaneous recovery are probably numerous, especially in infant life, in which the arachnoid is alone involved.
5. All cavities may unite, with or without external rupture; when so, it is usually fatal, not necessarily instantly so.
6. Spontaneous rupture may occur externally or subcutaneously, with an occasional recovery.

Hydrocephalus and spina bifida, 7 months.
(From personal collection.)

7. The effusion may be into the lateral third or fifth ventricle, or it may be in the arachnoid or subarachnoid cavity, one or all.

8. A clot in the arachnoid cavity may cause a cyst which will enlarge, with all its consequences.

9. Syphilis, tuberculosis, and rickets have been assigned as causes of hydrocephalus, but such have never been proved; the cause is yet unknown.

10. Sometimes zones of new osseous material are scattered here and there in the meninges, and sometimes upon or in the brain substance.

11. The septum lucidum is invariably thickened, as are the cerebral meninges in general.

12. Probably the greater number of cases of early hydrocephalus, whether of the third, fourth, fifth, or lateral ventricle, or of the

arachnoid variety, can be cured by some form of drainage.

13. Continuous drainage by seton or the repeated use of the trocar has given the best results in the way of benefit or cure.

14. Spinal drainage has been practised in a very limited degree, and its value is as yet undetermined.

15. Subcutaneous drainage has not resulted in a cure, but there seem to be many possibilities for this method.

16. Trephining for drainage is only resorted to in cases in which the fontanels have been closed by bony union.

17. Results from drainage are more favorable if done when the presence of fluid is first detected.

18. It is sometimes necessary to drain both hemi-

spheres, together with the right and left cerebellar cavity.

19. The secret of curing arachnoid hydrocephalus by drainage probably lies in obliterating the arachnoid cavity. However, this can be done with hydrocephalus of the third, fourth, and fifth ventricular variety.

20. The cardinal principle in this, as in all operations upon the brain, is asepsis.

CHAPTER IX.

Pathology.—The word hydrocephalus should be applied to noninflammatory cerebral exudation. It is found alike in both animals and man and is due to the same causes, although they are not definitely understood.

Breschet gives five varieties: (1) Between dura mater and brain; (2) between dura and parietal arachnoid; (3) in cavity of arachnoid; (4) ventricles (most common); (5) between arachnoid and brain.

It is thought that the children of cretinous parents, and those suffering from myxedema, are especially subject to hydrocephalus. No explanation being given, Dickenson believes rickets to be a cause.

Syphilis, both hereditary and acquired, has been accredited as being a cause, while tuberculosis has been more frequently so. Embolisms and neoplasms varying in type have no doubt been properly classed as exciting causes.

Arachnoid engorgement from any cause, such as rheumatism, gout, and the infectious diseases, are supposed to be a causative factor.

Rokitansky⁷ believed the seat of hydrocephalus to be in the lateral ventricles, while Rilliet and Barthez⁸ thought that hemorrhage from the arachnoid membrane is the cause of fluid in the arachnoid cavity, for in this variety the fluid generally contains blood.

The disease may originate in the third, fourth or lateral ventricles, or anywhere in the arachnoid cavity. It, however, is supposed to occur rarely in the arachnoid sac.

A blood clot in this sac may cause excessive and serous effusion.

The development of the disease may be unilateral or bilateral, and remain so, or when in one ventricle it may rupture into the other or into the arachnoid cavity, one or both, and thus become general in character.

Nélaton thought that spontaneous recovery would result from diarrhea, copious perspiration and cutaneous eruptions.

Hubbell⁹ reports a recovery following cutaneous eruption upon the head.

In either event there may be spontaneous rupture externally with or without recovery. If rupture does not occur externally and the fluid is not removed artificially, hypertrophy or atrophy of the brain may ensue, with all its consequences.

Zones of new osseous material are now and then found scattered here and there in the meninges, and sometimes upon or in the brain substance.

It is not known whether or not they are a cause or a consequence of the disease.

The cranial bones separate in the young before union of the sutures as they never separate after that time, consequently hydrocephalus is confined to infancy. The disease may not manifest itself until a time when the sutures should be united, but the formation of the fluid begins before the sutures unite, and is the means of preventing their union.

Blackman says: "In the majority of cases the fluid is confined to the ventricles; rarely in the arachnoid cavity."

However, this statement is very much questioned as there seems to be no special age for hydrocephalus.

J. Lewis Smith thinks congenital hydrocephalus is due to syphilis alone.

Spina bifida is sometimes associated with hydrocephalus.

Destruction of bloodvessels, laceration or pressure has in a few instances resulted in gangrene of the brain substance, and in certain other cases of continued severe pressure the septum lucidum has been found very much thickened.

Retzius, of Stockholm, has a collection of large hydrocephali.

A full bibliography to this article will be appended in the reprints.

CONCERNING THE EMBRYOLOGY OF KIDNEY ANOMALIES.

BY

A. G. POHLMAN, M.D.,

of Baltimore, Md.

Johns Hopkins University, Department of Anatomy.

The reports on cases of faulty development are of little assistance to the laboratory investigator of embryologic processes, partly because such reports are made in the light of a curiosity, and partly because the writer is not well enough informed in the particular embryology of the case to know what facts are essential in making his observation useful. The majority of cases—say of unilateral kidney—are described in greatest detail as to the relations of the usually quite normal kidney, when the real interest lies in the one which is absent and, as will be mentioned in a later paper, in the condition of the sex gland and the genital tract, particularly on the affected side.

It seems to me that a plea for the cooperation of the surgeon and gynecologist is not out of place at this point. The demand for material is very great, and strong efforts to make the physician realize how important the embryos that come into their hands are to the anatomists, have been made notably by Professor Mall, of Johns Hopkins, and by Professor Minot, of Harvard. Personally, as a specialist in the anatomy of the urogenital system, I wish to illustrate how important the clinical side of embryology is, by mentioning one case in which a process, although constant, is extremely obscure. I refer to the descent of the testicle. And while the reasons for the male sex gland assuming its position in the inguinal region may never be known, there is great probability that the actual mechanics will be worked out, provided the investigators are furnished with sufficient—unlimited—material.

It is important to come into close relation with the pathologist as well, for many things which are developmentally abnormal are first discovered on the post-mortem table, perhaps because they give no pathologic manifestations during life and because some are impossible to diagnose, at least as yet. Reference is made later to cases of double ureter, and I will state that only two cases were found in over 60 embryos. I know of no cases reported in the literature. The two embryos were luckily of an age to be of most service in placing the embryology of the double ureter on a sound basis. The exceptional fetus that may throw light on the wandering of the sex gland, may be one in five hundred.

The short tabulation I offer on the anomalies of the kidney is of course imperfect and incomplete. It will require years of work and an intimate knowledge of the enormous literature before a system such as this will be so perfect that but few cases will not conform. However, should these brief articles merit the attention of the profession, they will surely be the means of placing

more material in the hands of embryologists. This will certainly be a stimulus to the anatomist to keep in touch with the application of the facts bearing on the clinical side of his subject, and an inducement to the physician to keep his laboratory colleague supplied with what he needs most—embryos.

The trouble in preserving and sending embryos is not great. Formalin 10% is a simple and effective preservative, and if there is any doubt as to the strength of the solution, the stronger the better. Mutilation of the embryos should be avoided, and they should be handled as little as possible. All embryos are acceptable, and no selection should be made whatever. In sending, the bottle should be filled completely with fluid to prevent injury in transportation, and such history as may be obtained, forwarded with the specimen. Any anatomic laboratory where research is going on, will be only too delighted to receive such contributions.

Anomalies in general may be divided into two main classes: those which may be said to have a definite embryologic origin and those which are beyond such an explanation. In the former class are such abnormalities as Meckel's diverticulum, cleft palate, canal of Nuck, imperforate anus, etc.; while in the latter class may be grouped, acephalic monsters, multiple extremities, etc. I will confine myself to those anomalies which may be explained from a developmental standpoint; will establish a scheme from the probabilities of faulty development and will compare it with actual cases. To understand the abnormal it is necessary to review the normal, and the article will therefore be divided into three parts:

(a) The general embryology of the kidney and ureter.

(b) The probabilities of faulty development.

(c) Actual cases corresponding with the foregoing.

In defense of the words, "probabilities of faulty development," I would say that practically all the possibilities mentioned were worked out from a knowledge of the normal processes, before any reference to the literature was made. That there may be more, goes without saying.

A. *The General Embryology of the Kidney and Ureter.*—The Wolffian duct is of mesodermic origin. It is connected with the Wolffian body (mesonephros) above; grows down toward the tail and finally comes to empty into the cloaca. (The cloaca divides later into a ventral segment forming the bladder and the urogenital sinus and a dorsal segment entering into the formation of the rectum.) The duct reaches the cloaca in human embryos of about 4.0 mm. greatest length, and at a trifle older stage (5.0 mm.) each duct gives off a bud dorsally—the renal bud—at a short distance from the cloacal wall. The renal bud grows into the surrounding, and as yet undifferentiated mesoderm and specializes it about its blind end. This specialized tissue stains darker and has a different arrangement from the surrounding tissue and is called the renal mesenchyme. The two buds lie so closely together that the two masses of mesenchyme almost touch in the median line. They are placed just in front of the second sacral vertebra.

Before a stage of 10 mm. is reached, the two buds sprout at the blind end—an upper and lower sprout—representing the future upper and lower pelves of the adult kidney. A subdivision of the developing tract may now be made; that portion of the bud that lies between the Wolffian duct and the point of sprouting, is the ureter; the place of division, the future pelvis of the kidney and all that lies distal, capped by renal mesenchyme, is the kidney proper. The kidney has assumed the distinct "bean shape" and its upper border is at the brim of the pelvis.

The two kidneys lie parallel to each other and grow progressively upward until the upper end of the kidney is in the mid-lumbar region (14 mm.) when each undergoes an axial rotation bringing the hilum, that up to this time has been directed ventrally, toward the

median line. The kidney reaches its normal height in embryos of 25 mm. to 30 mm. length or at about the end of the second month. It is after this period that vascularization is effected as may be inferred from the fact that the renal artery is given off at a right angle to the aorta. The increase in size of the kidney is proportionate to the body size, at least in all the stages investigated (up to the fifth month).

The ureter, it will be remembered, extended dorsally from the Wolffian duct at a short distance from the cloaca. The segment of the duct lying between the cloaca and the bud disappears, and at the same time the ureter loses its dorsal position and comes to lie laterally to the duct. This occurs at about the same time that the kidney undergoes rotation. Finally at a trifle older stage, the ureter opens laterally to the duct and in the further growth, due perhaps to a down-growing of the genital ducts and to an increase in size of the bladder segment above, loses its relation to the duct completely and is found opening higher and more laterally, as is normal in the adult.

Personally, I attribute the change in relation entirely to the development of the upper part of the ventral segment of the cloaca into the urinary bladder and do not believe there is any ground to assume that the male genital duct (Wolffian) grows down the urogenital sinus just because this is the case in the female (Müllerian duct). This point will be considered in greater detail later.

To summarize the development as described we find the following facts:

I. That the renal bud arises dorsally on the Wolffian duct after the duct has reached the cloaca, and at a short distance from its entrance.

II. That the buds grow dorsally and that they lie closely together, each being capped by a specialized mesodermic tissue, the renal mesenchyme.

III. That each bud divides into an upper and lower sprout at some distance from the Wolffian duct.

IV. That the kidney wanders upward from a position in front of the second sacral vertebra, rotates at the mid-lumbar region and finally reaches its normal height at about the end of the second month.

V. That the kidney becomes vascularized after it reaches its normal height.

VI. That the ureter changes its position on the Wolffian duct from dorsal to lateral, and finally comes to empty distinct from it.

VII. That the ureter loses its relation to the Wolffian duct entirely and comes to empty higher and more laterally.

It is quite impossible to consider the development of the urinary organs in any detail and only the grosser changes in position have been mentioned. Those developmental faults which may be explained by this review will be considered and are therefore those occurring before the third month.

B. The Probabilities of Faulty Development.—Each heading of the review will be taken and considered from a standpoint of possible developmental fault. In the report on the cases, the headings and subheadings will be referred to by number and letter.

I. That the renal bud arises dorsally on the Wolffian duct after the duct has reached the cloaca and at a short distance from its entrance.

(a) *The Wolffian duct might not reach the cloaca.* This is inferred on the ground that such faults are sometimes found in the development of the Müllerian duct, which is of similar origin and has a similar growth. Should the duct not reach the cloaca, there is no reason to suspect that the renal bud would develop; (1) because the stimulus to the growth of the bud is probably due to the cloaca, and (2) the direct pathology of the duct not reaching the cloaca is sufficient to admit of a doubt that normal structures will arise from it. We would expect the kidney absent and the sex gland affected, particularly in the male. All the genital tract developed from the Wolffian duct would be atrophic or missing.

(b) *The renal bud might not be given off after the duct has*

reached the cloaca. In this case it will be clear from the embryology that there would be absence of the kidney. The kidney present would naturally be hypertrophied to compensate, but not necessarily affected otherwise. The fact that the bud is not given off, points to further abnormalities in the Wolffian system, which we will not consider.

(c) *One bud might be given off some time after the other.* It is quite natural to infer from our knowledge of the rapid growth of the kidney that one kidney may be placed lower than the other, and this may account to some extent for congenital low positions of one kidney, or even both, if both buds are belated.

(d) *The renal bud might be given off at the cloaca.* This was formerly thought to be the case. It is unlikely that any abnormality would result.

(e) *The bud might be given off at a greater distance from the cloaca than normal.* In this case it would probably take a longer time for the ureter to assume its position lateral to the Wolffian duct (see later VI), and delay its growth into the bladder.

(f) *The bud might arise other than dorsally.* A species of ectopia would probably result. Would be extremely uncommon and difficult to surmise.

II. That the buds grow dorsally, and that they lie closely together, each being capped by specialized renal mesenchyme.

(a) *The buds might not grow dorsally.* Would result in ectopia renalis of a very unusual form. (See I f.)

(b) *The two buds might come to lie too closely together and the masses of mesenchyme fuse.* The growing together would, of course, be a permanent one. It would result in any form of horseshoe kidney, depending on the amount of fusion. This form of anomaly would be more probable if one kidney were in advance of the other, and if this were the case, there would be likelihood of the upper kidney in its attempted rotation dragging the lower kidney across the midline. (See IV d.)

(c) *The two buds might be surrounded by one mass of renal mesenchyme.* Would result in a form of horseshoe kidney, which would be difficult to separate from the former variety. There would probably be no rotation whatever and no distinctness as to the two kidneys. Would be one diffused mass, with no marked subdivision, having two ureters.

(d) *The sprouts of the buds might each be surrounded by an independent mass of mesenchyme.* This would result in two distinct kidneys on one side and would account for the rare cases of supernumerary kidney.

(e) *The renal mesenchyme might not develop.* Would be very difficult to tell from I b. Theoretically, there would not be any disturbance of the male genitals as an accompaniment. That one might find traces of a ureter is unlikely.

III. That each bud divides into an upper and lower sprout at some distance from the Wolffian duct.

(a) *Might not divide into major sprouts.* The ureter must divide or there would be kidney deficiency, but the main budding might be suppressed and there would be one major pelvis. This might also result in the later stages of the development of the kidney.

(b) *There might be more than two major sprouts.* Would result in more than two major pelves, and even be exaggerated into ureter faults. (See III, c.)

(c) *The sprouting might be too near the Wolffian duct.* This would result in incomplete double ureter. There being but one orifice in the bladder, and any form of reduplication depending on the proximity of the division from an exaggerated pelvis to almost complete double ureter.

(d) *The sprouting might be directly at the duct.* Would result in complete double ureter. Two orifices in the bladder. For further account see report of original case.

IV. That the kidney wanders upward from a position in front of the second sacral vertebra, rotates in the mid-lumbar region and finally reaches its normal height about the end of the second month.

(a) *The kidney might remain in any position from the second sacral vertebra to the normal.* Cause would be doubtful. (See IV, c and I, e.)

(b) *Might reach normal height early—no abnormalities.*

(c) *Might not reach normal height before the vascularity was effected.* This would be a distinct cause for low positions. (See V, b.)

(d) *The kidney might not rotate, or undergo a false rotation.* In case the kidney is fixed below the midlumbar region, it would be found to lie, hilum ventrally, because at this stage no rotation has occurred. The false rotation has already been alluded to under II, b and c. The lower kidney would be the crossed one.

V. That the kidney becomes vascularized after it reaches its normal height. A stage after 25 mm. to 30 mm.

(a) *The vascularization might be belated.* Probably no effect.

(b) *Vascularity might wander into the renal substance too early.* Might be a cause of low fixation taken in connection with a belated renal bud. In case the vessels entered before the kidney was rotated they might come from any adjoining artery and enter at any point on the surface of the organ, even posteriorly. The lower the fixation, the more the probability of abnormal arteries, because of the splitting of the aorta into the iliaes and the still lower division of the iliaes. The more adjoining arterial trunks, the more numerous the vessels.

VI. The ureter changes its position on the Wolffian duct from dorsal to lateral, and finally comes to empty distinct from it.

(a) *The ureter might remain attached to the Wolffian duct,* and would naturally open in common with it or into parts developed from its lower end.

(b) *The ureter might open laterally to the Wolffian duct and on a level with it.* Opening in this case would be found in the prostatic urethra.

VII. The ureter loses its relation to the Wolffian duct and comes to empty higher and more laterally.

(a) *The ureter might have an orifice anywhere from the entrance of the Wolffian duct to its normal position.* To be spoken of later under case VII, a.

In referring to the embryology I would mention the admirable article by Keibel on the origin of the bud and its earlier development.

I would like to acknowledge the kindness of Professor Mall in placing his collection of human embryos at my disposal, and also to thank Professor Keibel for the loan of embryo Piper, one of the abnormal ones reported. I am indebted to Mr. Max Brödel for valuable suggestions as to material collected on the embryology of the tract, which I find he has worked upon with a similar object in view as that of this paper.

C. Reports on some cases.

I—(a) Case reported by Ballowitz:

Left kidney and ureter missing in an adult male; no trace of renal vessels. There were many defects in the genital apparatus. Left vas deferens absent and only a mass of connective tissue found in place of the left vesicula seminalis. No opening in the prostatic urethra on the left of the colliculus. The testicle was descended, but atrophic. Right kidney and right inner genital tract normal.

Mention is made that some Wolffian remains were found in the rudimentary epididymis, and there is, of course, no proof that the Wolffian duct did not reach the cloaca and then atrophy. However, it seems fair to suppose, as the individual was entirely normal on the right side, that a mechanical interference with the descent of the left Wolffian duct would explain the matter very satisfactorily.

Cases have been reported with congenital absence of the kidneys on both sides. These monsters are, of course, not viable, and therefore have no clinical significance.

I—(b) Case reported by Menzies:

Similar to the foregoing; the left kidney was missing, but there was no implication in the genitals whatever. Both testicles and cords were normal. A similar case is also reported by Tweedy in the female. The proportion of single kidney, according to Tweedy, is four to one in the males.

I—(c) Case reported by Howden.

Left kidney normal. Right kidney found below the bifurcation of the aorta with its upper end between the fourth and fifth lumbar vertebrae. The hilum pointed to the front. Ureter opened into the bladder normally. Arteries entered irregularly—some posteriorly. Arteries derived from aorta, sacra media, and the right internal iliac. The testicle was small and atrophied. Epididymis was rudimentary. Vas deferens but a fibrous cord, and vesicula seminalis absent on affected side. Testicle retained.

According to our tabulation the Wolffian duct must have reached the cloaca and atrophied later. It is interesting to note the opening of the ureter on the affected side was normal. Microscopic examination might have shown traces of the Wolffian duct in the prostatic region.

II—(d) Report of M'Murich with excellent account of the literature of crossed dystopia. The kidney may be fused in almost any fashion. Horseshoe kidneys are usually low; I am almost tempted to say always. The ureters are usually to the front because the rotation is interfered with, and if one kidney is rotated, it is the higher one, and lies above the mid-lumbar region.

In an as yet unpublished case, Brödel finds a kidney joined to its fellow at the upper pole and lying back of the aorta. The case, so far as I know, is unique, and if I may be allowed to suggest its causation, was due to a fusion of the renal mesenchyme, and owing to a faulty development of the sacra media artery, the kidney mass was allowed to slip behind the well-developed hypogastric arteries, and once under the aorta, kept

that relation to that vessel. The hila were to the front. The report on this case will be of great interest.

III—(a) To quote Brödel:

"Such cases are extremely uncommon, and when found are usually the first indications of hydronephrosis which, by the dilation of the pelvis obliterates the division into the upper and lower segment."

At a later stage than is discussed in this paper, the division into an upper and lower pelvis is lost temporarily, and a single large pelvis might be a result of a persistence of this condition.

III—(b) Case reported by Richmond.

There were four ureters coming from the hilum of each kidney, and at a distance of four inches from the kidney they formed a pelvis from which a ureter proper arose. There were also signs of abnormality in the genital tract.

It may be perhaps inferred from this case that the ureter sprout undergoes a second major division which is as yet unknown to us or the case may be quite unique in this respect.

The case showed bilateral symmetry which corresponds with what Brödel maintains—that anomalies of the pelvis are always bilateral.

III—(c) Incomplete double ureters are so common that they scarcely need reporting here. They should always be considered incomplete unless each of the double ureters has a separate orifice in the bladder. The relation of the two incomplete ureters is similar to the double one and will be described further on.

III—(d) I take pleasure in presenting two cases in embryos.

Embryo Mall 175 (13 mm.)

Two ureters arise from the left kidney. The one from the upper part of the kidney lies ventrally and is somewhat smaller than the one from the lower part of the kidney. As the two ureters approach the urogenital sinus they curve around the Wolffian duct, the one ventral coming to lie close to the duct and the one dorsal lying more laterally. The three openings are at the same level and are arranged from the mid-line laterally; Wolffian duct, ureter from the upper part of the kidney and then the ureter from the lower part.

Embryo Piper-Keibel (24 mm.)

In this the relation of the ureters is the same excepting at the sinus. Owing to the development of the bladder the more lateral ureter has been carried higher than the more median one. This corresponds to the findings in the adult—that the ureter from the upper part of the kidney opens into the bladder somewhere between the opening of the usually normal orifice of the posterior ureter (from the lower part of the kidney) and the orifice of the vas deferens, and is due to the swinging laterally of the ureter on the duct and the development of the bladder. Reasons more completely dealt with under VII, a and b.

IV—(a) Case reported by Farquharson. (See also Howden.) Right kidney normal. Left kidney lay in front of the bodies of the fourth and fifth lumbar and first sacral vertebrae and only slightly to the left of the middle line. The blood-supply was naturally abnormal. The kidney was not rotated and the ureter came directly from its ventral surface.

IV—(d) Already referred to in the cases of horseshoe kidney (see II b and also above IV a.)

V—(b) The normal blood-supply to the kidney has been most admirably worked out by Brödel. Abnormal arteries seem to come directly from the neighboring trunks and in nonrotated kidneys may even enter posteriorly. The more numerous the adjoining arterial trunks, the more numerous the bloodvessels entering the kidney. (See accounts of low-placed and horseshoe kidneys.)

VI—(a and b) Find reference to these cases in a general way in article by Arneil in the "Reference Handbook."

VI—(c) The case of the Mall embryo. Know of no such case in the adult, but it is fair to assume that such a condition might persist.

VII—(a) Cases talked over with Brödel. May occur in single orifices, but more evident in double ureter. (See below.)

VII—(b) A hint has already been made that the reason for the position of the ureter lateral and above the genital duct was due to the development of the bladder. I have measured the path of the ureter from the time it loses its relation to the Wolffian duct to a time when it is relatively in its normal position and find that it grows proportionately upward and outward. This is verified by the findings in abnormally placed ureters in that they are always in the path of what might be considered their normal development. In double ureters the more lateral one has the same course as the usual normal and the more mesial one is placed in a position of disadvantage and lies, always the case, somewhere between the Wolffian duct and the normally placed orifice.

It may sound a little like heresy to say that the bladder is developed entirely from the cloaca, but such is the interpretation I place on my findings and believe that the double ureter has a decided bearing on this point.

How much clinical importance these developmental facts may possess is a very difficult matter to say. Cases of unilateral kidney are extremely uncommon, although two cases of direct clinical bearing have been mentioned: The one of Polk, in which a single kidney was removed,

and the case reported by Taylor of fatal injury to a unilateral kidney.

In the male the misplaced kidney would not be any element of danger. A case, however, has been reported in a pregnant female in which a tumor was discovered at the brim of the pelvis which occluded the inlet, and abortion was induced. It was not until a second abortion with fatal termination that the obstruction was found to be a horseshoe kidney. Just so in any developmental aberration, the importance clinically is entirely a matter of personal equation. Such direct anatomic facts as the proper placing of sutures in the kidney or where the incision should be made into a kidney from an intimate knowledge of the bloodvessels, always find a place in practical surgery. It only remains to be seen how much may be accomplished by the combined effort of the practising physician and the laboratory investigator.

TWO CASES OF FATAL POISONING (CRIMINAL) BY STRYCHNIN, WITH A REPORT OF THE TOXICOLOGIC EXAMINATION OF SOME OF THE ORGANS.

BY

JOHN MARSHALL, M.D.,

of Philadelphia.

Professor of Chemistry and Toxicology, University of Pennsylvania.

On Wednesday, October 1, 1902, about 12.30 p.m., John Coffin, aged 11 years 8 months, and Price Jennings, aged 14 years, schoolboys residing in Camden, N. J., left home presumably to spend the afternoon in usual boyish amusements. Their failure to return in the evening alarmed their parents, and the police were notified of their disappearance. On Friday afternoon, October 3, the body of one of the boys, Price Jennings, was discovered by boys in an unused field at Haddon Heights, a few miles below Camden. The boys, however, were in such a condition of fright that they neglected to notify the authorities at once. About 7.30 p.m. of the same day two men, residents of the locality, found the body lying under an old chestnut tree. They described the position of the body as lying on its back, right arm drawn up toward the body, the left arm extended in a straight line from the body; head turned to the side, the mouth partly open, with a frothy discharge on the lips. The coroner was at once notified by telephone, and he immediately proceeded to the place described by the men, but on account of the darkness and the locality being unfrequented, he failed to find the body. The following morning he again visited the locality and succeeded in finding the body, but it was not

until 11.30 a.m. of that day, October 4, that the body reached the morgue in Camden. During the morning of the same day (October 4) the body of the smaller boy, John Coffin, was found in the same field, about 40 paces distant from the place where Jennings' body had been found. The body when discovered was lying on its back, with the head to one side, one arm drawn up toward the body, the other extended in a direct line from the body, the hands half closed, the legs somewhat spread apart and slightly drawn up; the eyes partly open, the lips apart, and a frothy discharge on the lips. This body was brought to the morgue shortly after noon of October 4, and the autopsies of the bodies were made the afternoon of the same day, by Professor W. L. M. Coplin, with the cooperation of Dr. W. S. Jones, county physician. The autopsy disclosed marked decomposition of the body, maggots having been already developed on the eyelids and lips. There was no undue rigidity. The lungs exhibited a settling of blood in some portions, but no organic lesions were anywhere observed. While the autopsy excluded death by violence, no evidence of the cause of death was discoverable.

The atmospheric conditions prevailing at the time of the disappearance of the boys were such as would favor putrefaction and would readily account for the marked evidences of decomposition observed in the bodies, and the absence of rigor and opisthotonos.

On the night of September 30, according to the records of the government weather-observer for Camden, there was a heavy rain, which continued until 6.45 a.m. of the morning of October 1, during which time the rainfall amounted to 1.81 inches. On October 1, light rains occurred from 8.05 a.m. to 11.28 a.m., the temperature varying from a minimum of 62° F. (16.6°C.) to a maximum of 72° F. (22.2°C.), the humidity at 8 a.m. being 95%, and at 8 p.m. 75%. On October 2 and 3 there was no rainfall and the temperature varied from a minimum of 54° F. (12.2°C.) to a maximum of 72° F. (22.2°C.). The humidity at 8 a.m. on October 2 was 78% and at 8 p.m. 74%, and at 8 a.m. on October 3, 75% and at 8 p.m. 45%. There was cloudiness during the night of October 3, and during the night of October 4 there were light rains at various intervals of time. From this information it is obvious that the soil must have been saturated with moisture. The temperature during the period averaged about 65° F. (18.3°C.) and the humidity of the air was quite high.

At the autopsy of the body of Price Jennings there were removed for toxicologic examination, the stomach and its contents, one kidney, the brain, a portion of the intestines, and a portion of the liver. By inadvertence the portion of liver was placed on top of the portion of intestines contained in a glass jar, and consequently any fluid which may have exuded from it prior to the analysis would be included in the analysis of the portion of intestines. Each of the other organs, however, was placed in a separate glass jar. About 250 cc. of urine was removed from the bladder.

At the autopsy of the body of John Coffin there were removed for toxicologic examination, the stomach and its contents, one kidney, and a portion of the liver.

In the toxicologic examination I was associated with George M. Beringer, A.M., Ph.M., of Camden, who examined the stomach and its contents, one kidney, portion of intestines, portion of liver, and 150 cc. of the 250 cc. of urine, all from the body of Price Jennings, and I examined the brain and the remaining 100 cc. of urine from the Jennings body, and also the stomach and its contents, one kidney, and a portion of the liver, all from the body of John Coffin.

As the authorities suspected that the boys had died as a result of the administration of "knock-out drops" (chloral hydrate), the toxicologic examination was first directed toward the detection of that substance. The examinations were made by us, independently of each other, in our respective laboratories. The material first examined

by each of us was the urine of Price Jennings, but the examinations failed to determine the presence of chloral or its product, trichlorethylglycuronic acid (urochloralic acid.) Likewise, examination for morphin and metallic poisons failed to determine their presence. The urine was highly albuminous, and after having coagulated the albumin by means of heat and subsequent filtration, the filtrate was evaporated nearly to dryness on a water-bath and the residue was repeatedly extracted with alcohol. The alcoholic extract was then evaporated to dryness and the residue treated with water, and this final solution was rendered slightly alkaline with ammonium hydroxid and extracted in a separatory bulb with chloroform. The chloroform extract was intensely bitter, and on testing residues obtained by evaporating small volumes of the chloroform extract to dryness, with the potassium dichromate-sulfuric acid test, the peculiar succession of colorations attributed to strychnin promptly appeared. In the examination made by each of us there was not obtained from the urine a weighable quantity of the alkaloid. One of us (Marshall), injected a few drops of the small quantity of aqueous solution hypodermically in the lumbar region of a small frog with the production of tetanic convulsions in the animal.

These tests having satisfied both of us that the toxic substance for which search should be made was strychnin, independent examinations for that alkaloid were made by us of the various tissues, in which examination each of us used an identical method.

In brief, the method adopted was as follows:

The solid organs were cut into very small pieces by means of a scissors, and the mass covered with distilled water, to which a small quantity of alcohol had been added, and the mixture was acidulated with acetic acid. This was warmed at a temperature of about 80°C. on a water-bath for about an hour, with occasional stirring and testing with litmus paper to determine the reaction of the mixture, and the addition of more acetic acid to keep the liquid acid in character, when found necessary. The mixture was then strained through washed cheese-cloth placed over washed muslin; the mass on the cloth was washed with water acidulated with acetic acid, and the washings were added to the filtrate. The liquid (filtrate and washings) was concentrated to a small volume on a water-bath, allowed to cool, and treated with an excess of strong alcohol to precipitate albuminous and other interfering substances. The precipitated substances were removed by filtration, the precipitate was washed with strong alcohol and the filtrate, to which the washings had been added, was evaporated on a water-bath to a syrup-like consistency and then diluted with water and rendered distinctly alkaline with ammonium hydroxid. This liquid was placed in a separatory bulb, chloroform added, and the contents vigorously agitated to extract the strychnin. Extraction of the alkaline aqueous liquid with chloroform was made twice after the first extraction and the three chloroform extracts were combined, evaporated to dryness spontaneously at ordinary room-temperature, the residue was treated with a small quantity of water, rendered distinctly acid with acetic acid, and placed in a separatory bulb and extracted twice by agitation with chloroform. The chloroform extracts were discarded, and the acid aqueous liquid was then rendered alkaline with ammonium hydroxid, placed in a separatory funnel and extracted with three separate portions of chloroform. The chloroform extract was allowed to evaporate spontaneously, and the resulting residue, after repeated purification by extracting in turn its acid and alkaline solutions in the manner just described, was finally obtained in a colorless condition.

EXAMINATIONS OF TISSUES MADE BY MR. BERINGER.

Stomach and its contents of Price Jennings.—The stomach had been cut open in the course of the autopsy. It was in a somewhat decomposed condition and emitted a putrid odor; the walls showed no evidences of irritation or inflammation. It contained only a small amount of food and mucus; a small quantity of the contents had passed through the cut into the glass jar in which the stomach had been placed. Portions of raisin skins were detected by the naked eye in the mass of food, and by means of the microscope powdered cinnamon and starchy material were detected. Examination was made for chloral hydrate, chloroform, morphin and metallic poisons with negative results. The amount of strychnin recovered from the stomach and its contents was 0.0014 gm. equivalent to 0.001794 gm. of strychnin sulfate.

Liver of Price Jennings.—The portion of liver examined weighed 865 gm. and exhibited strong evidences of decomposition. The amount of strychnin recovered was 0.003 gm., equivalent to 0.003844 gm. of strychnin sulfate.

Another portion of the liver was examined for volatile

poisons, cyanids, chloral hydrate, and metallic poisons with negative results.

Kidney of Price Jennings.—The one kidney examined weighed 120 gm.; 90 gm. were employed for the examination for strychnin and from this quantity of tissue 0.005 gm. of strychnin, equivalent to 0.0064 gm. of strychnin sulfate was recovered.

The remaining 30 gm. of kidney were used in an examination for chloral hydrate, metallic and other poisons with negative results.

Intestines of Price Jennings.—Decomposition to a marked degree had occurred in the tissue of the intestines which at places was yellow and green, and emitted a foul odor; 620 gm. of intestine and contents were examined for strychnin, from which 0.007 gm. of strychnin, equivalent to 0.00897 gm. of strychnin sulfate was recovered.

From the above portions of tissue Mr. Beringer recovered a total of 0.0056 gm. strychnin; equivalent to 0.007175 gm. of strychnin sulfate.

EXAMINATIONS OF TISSUES MADE BY DR. MARSHALL.

Stomach and its Contents of John Coffin.—The inner walls were slightly pink. No odor resulting from decomposition was observed. Contents were salmon-colored and semifluid. Volume of contents 150 cc. Weight of the stomach without its contents 186 gm. The material from the stomach contained starch granules in masses about the size of a mustard seed, skin and fragments of the interior substance of raisins, seeds resembling raisin seeds. The starchy masses on examination under the microscope were found to be exactly like the columnar structure of the periphery of a chestnut kernel. The strained liquid from the contents of the stomach measured 75 cc. Of this liquid 25 cc. were used in an examination for chloral hydrate, hydrocyanic acid, morphin and metallic poisons, with negative results. The remaining 50 cc. were added to the stomach tissue and small amount of solid stomach contents.

From the 186 gm. of stomach tissue, 50 cc. of liquid contents and possibly 6 gm. of solid contents 0.0038 gm. of strychnin, equivalent to 0.00486 gm. of strychnin sulfate was recovered.

Portion of Liver of John Coffin.—The weight of liver with accompanying bloody fluid was 837 gm. The tissue showed only very slight evidences of decomposition. It was not disintegrated nor to any extent softened. The tissue was very dark and emitted a disagreeable odor.

From the 837 gm. of material 0.0027 gm. of strychnin, equivalent to 0.00345 gm. of strychnin sulfate was recovered.

One Kidney of John Coffin.—The weight of the kidney with the bloody fluid which accompanied it was 105 gm. (75 gm. kidney, 30 gm. fluid).

The tissue was in well-preserved condition. The interior was slightly red and had a fresh appearance.

From the 105 gm. of material employed, 0.0007 gm. of strychnin, equivalent to 0.00088 gm. of strychnin sulfate was recovered.

Brain of Price Jennings.—The brain with the fluid accompanying it weighed 1,650 gm. The tissue had softened to a very considerable extent.

From the 1,650 gm. of material 0.0005 gm. of strychnin, equivalent to 0.00062 gm. of strychnin sulfate was recovered.

The total quantity of strychnin recovered from the amount of tissue of John Coffin was 0.0072 gm., equivalent to 0.00919 gm. strychnin sulfate.

The strychnin recovered by each of us responded promptly and highly satisfactorily to the potassium dichromate-sulfuric acid test and to the physiologic test on frogs. Furthermore, the various residues obtained by one of us (Marshall) from the tissues of John Coffin were aggregated and a portion was employed for a melting point determination and it was found that it melted sharply at 268° C., corresponding to the melting point of strychnin.

It was ascertained that Paul Woodward, a young man aged about 26, a resident of Camden, had been with the boys on the afternoon of October 1, when they left their homes. Suspicion was cast upon him of having poisoned the boys with the object of robbing them. He was arrested on October 5, and placed on trial on November 12, before Judge C. G. Garrison, the prosecution being conducted by Prosecutor of the Pleas Frank T. Lloyd, Esq., assisted by the assistant prosecutor, F. Morse Archer, Esq. At the trial it was shown, that Woodward had planned to have the boys obtain money from their homes and run away with him. His movements on October 1, the day of the disappearance of the boys, were traced, and he was identified as having purchased cinnamon buns at a wayside booth on the road leading to Haddon Heights, and that the two boys were with him at the time. This probably accounts for the presence of powdered cinnamon as detected by Mr.

Beringer in the stomach contents of one of the boys, and for the skins of raisins found by Mr. Beringer and by me in the separate stomachs. He was also identified as having been engaged with two boys in obtaining chestnuts from a tree near the road adjacent to the field in which the bodies of the boys were discovered. This accounts for the presence of small particles of raw chestnut kernels detected by me in the stomach of young Coffin. Woodward admitted having accompanied them to within a mile or two of the place where the bodies were found. Up to almost the last day of the time taken by the prosecution in the progress of the trial, the authorities were unable to locate the place where Woodward had purchased the strychnin. By accident, however, the Prosecutor of the Pleas learned that he had purchased strychnin at a certain apothecary's in Camden, but the clerks were unable to identify the accused. By good fortune it was ascertained that possibly the strychnin had been purchased from a clerk who had been connected with the establishment during the summer, but who had resigned to take a position in a near-by city. This clerk was quickly brought to Camden and identified Woodward as having purchased strychnin in amounts of from 3 grains to 5 grains on two separate occasions. Woodward then admitted the purchases of strychnin, stating that he had purchased it for the purpose of killing animals that were destroying his pigeons. The trial lasted until November 17, when the jury rendered a verdict of guilty of murder in the first degree. In due time Woodward paid the penalty of his crime.

THE ANTISEPTIC TREATMENT OF SMALLPOX.¹

BY

SAMUEL M. WILSON, M.D.,

of Philadelphia.

During the last few years an unusual interest in smallpox has been shown, particularly in regard to its diagnosis. Interest is always felt in the question of treatment. This has two objects: Assisting the patient to recover his health and, if possible, to protect him from disfiguring scars. Most clinicians treat the disease on general principles, light diet, and cold baths or sponging, during the primary fever; symptoms that assume prominence being met by any means that appear suitable.

When the suppurative stage is reached, we have to deal with a general septic condition, calling as usual for supporting treatment and the free use of stimulants, particularly alcohol. Internal antiseptics appear useless.

Various plans to avoid scars have been tried. Many still follow the old method of excluding light from the sickroom, and applying some emollient, such as vaselin or glycerin, incorporating usually an antiseptic, but mainly with the object of preventing early rupture of the pustule. Others prefer to puncture the vesicle and apply a wet dressing of an antiseptic solution or plain water. The use of red window glass or red curtains seems useful, but is said to prolong convalescence, and it is doubtful if the withdrawal of the ultraviolet rays of light is not injurious to the patient, as well as to the microorganisms at fault.

The frightful scarring shown by some of those who have recently recovered from the disease proves that the plans in common use frequently fail. I would like, therefore, to draw attention to a method that has been recommended by several writers: The daily use of scrub baths. Some of the more recent textbooks refer to it. Perhaps the main reason that it is not generally adopted, is that it is rather painful to the patient, after vesiculation has commenced. Used thoroughly before the primary papules develop, it appears to prevent vesiculation.

¹Read at a meeting of the Philadelphia County Medical Society, April 13, 1904.

Instituted too late for that, it does away, to a great extent, with the repulsive appearance and foul odor characteristic of patients treated without this means.

If the patient is not seen until vesiculation has begun, the summits of the vesicles must be punctured, compresses of full strength hydrogen dioxid solution applied, and these followed by a mask wet with some antiseptic. A solution of mercuric chlorid—1 to 1,500, gives good results. This need remain in place for a few minutes only. The hydrogen dioxid followed by the mask may be used several times daily if desired, and appears to add to the comfort of the patient, as well as to promote desquamation.

In two unvaccinated young girls in whom vesiculation was commencing when the patients were first seen, the scrubbing, combined with puncture of the vesicles, was very successful. Where the treatment was thoroughly applied, on the hands and face, the vesicles, although large and numerous, left only a few faint traces, almost imperceptible, except on close examination. The legs and feet received less care, and several wellmarked pits resulted. Neither patient was seriously sick after the seventh day of the disease.

If the characteristic umbilicated pustule fails to develop, it is practically impossible to declare a case, in which recovery occurs, to be one of smallpox. In several cases in which a probable diagnosis of beginning varioloid was made, the scrubbing treatment, with toilet sandsoap, was applied promptly. Four of these patients were in one family. In each a vesicular rash appeared, drying in a few days, but leaving a few perceptible scars. In two other cases, a daughter, and subsequently her mother, a macular rash developed, followed by desquamation, and the patients showed no further evidence of being ill, the disease lasting four days in the mother and five in the child.

The treatment was used in other cases also; but the six mentioned are reported because, in them, the severity of the primary symptoms left little doubt of the diagnosis.

STRANGULATED FEMORAL HERNIA CONTAINING THE VERMIFORM APPENDIX.

BY

EMERY MARVEL, M.D.,

of Atlantic City, N. J.

While the inguinal canal has been found the receptacle for nearly every organ contained in the lower abdomen, such as for instance, the intestines, omentum, vermiform appendix, appendices uteri—even the bladder and the uterus itself—it is rare that the content of a femoral hernia is other than small bowel or omentum. It is this rarity of occurrence that prompts my reporting the following case:

The patient was a Russian Hebrew, aged 68, married, and the mother of five healthy children. She has been forced to work hard all her life, but has had no severe illness. She first noticed a mass in her right groin about six years ago, which she says came on while she was lifting a filled wash-tub. Since then this mass has frequently come down, but it could always be easily replaced. She has suffered considerable abdominal pain, and has been obliged to go to bed with the distress and to remain there two or three days at a time on several occasions during the past three years. It was in a similar condition that she went to bed during the present attack, June 13, 1902. This last attack began with abdominal pains, most severe in the right inguinal region, followed by nausea and vomiting. A physician was summoned who told her she was suffering from appendicitis. He put her to bed, prescribed castor-oil and some other remedies. The pain and vomiting continued, and great prostration followed.

June 15, 1902, two days after the onset of the attack, I found her markedly prostrated, with sunken eyes, and severe cramp-like pains coming on at intervals of 15 to 20 minutes. Vomiting was persistent, and she showed an apprehensive expression. Upon examination a mass the size of a hen's egg was found in the right groin, just beneath Poupart's ligament. The right abdomen was rigid, and whenever she would have the cramp-like pains, a circumscribed mass the size of a double fist would form in

the abdomen. This would disappear with the cramp to form again with the next cramp in another part of the abdomen. This changing abdominal mass was most probably due to resisted peristaltic action, which also produced the colicky pain. A diagnosis of femoral hernia was made, and immediate operation performed two hours later at the Atlantic City Hospital.

Operation.—An incision was made directly over the mass down to the sac of the hernia, sac was opened, the incarcerated bowel recognized, the constricting ring was cut and the bowel freed and replaced in the abdomen. The finger was inserted in the abdomen through the femoral ring, when the vermiform appendix was recognized and brought out. It was folded upon the cecum and constricted at a level with the cecal constriction produced by the incarceration of the ring. The appendix was about seven inches long, enlarged at the tip, with a foreign substance in the lumen. The mesoappendix, as well as the mesocecum was very much elongated, and allowed of my bringing the appendix easily out through the femoral canal. The appendix was dissected out, amputated, stump invaginated, and cecum replaced again. The opening was treated to obliterate the canal, silver wire being used.

Union was gained by first intention, and the patient left the hospital on the thirteenth day.

The patient was seen February 7, 1904, 20 months later. She had been doing the same laborious work as before, and says she has no more pain, and is perfectly well. Inspection of the parts shows a firm closure of the canal.

This case seems worthy of consideration on account of the infrequency of the appendix being found in a femoral hernia; the predisposing factors in permitting the appendix to be removed without enlarging the femoral ring; and as showing the favorable reaction and repair in the aged.

It is not so uncommon to find the appendix in various diseased conditions in the inguinal canal, yet the infrequency of its being found in the femoral canal is proved when one looks up the literature of the subject. Two cases are reported by J. Henry Barbal;¹ another by A. E. Barker.²

The predisposing factors in this case were evidently those usual to hernia—weakened spot, intraabdominal pressure, etc.—with the addition that the mesocolon (cecum) and mesoappendix were greatly elongated and permitted of unusual excursion of the organs suspended by these ligaments. Reynolds³ reports an obstruction due to torsion of the colon, in which case the mesocolon was sufficiently long to permit the cecum to find its way to the left hypochondriac region. The elongated mesocolon I consider the special contributing cause.

The removal of the appendix through so small an aperture in so remote a position may be of interest, but with a long mesoappendix and one drawn out very thin it was most easily accomplished.

Much has been written to show the great danger in major operations upon the aged. Wyeth's recent series of papers has done much to remove this prevalent delusion. This case, it is true is but one, but it can well be added to the evidence to prove that the aged may, and most often do recover and repair with favorable comparison to the young.

Increase in Mortality of New York.—According to the Bulletin of the New York State Department of Health, 13,700 deaths occurred during the month of April. The bulletin states that this month has generally the uniform mortality of about 10,500, and is seldom subject to fluctuation. However, the number of deaths for this April is within 300 deaths of April, 1891, and within 600 of that of the month preceding, so that it stands the third highest on the record of monthly deathrates. It is further exceptional in that it is sequent to a series of months of excessive mortality. In the four months of this year there have been 53,000 deaths in this State, against 44,500 for the same months in 1903, and 43,300 in 1902. At this rate for the year there would be 160,000 deaths against 130,000, or against our average yearly mortality of recent past years of from 125,000 to 130,000. The chief increase in mortality is in diseases of the respiratory system, and especially from pneumonia, from which there were 2,500 more deaths than in the four months of the two preceding years. The increase has been general throughout the State.

SPECIAL ARTICLES

STATE REGISTRATION OF NURSES.¹

BY

MAUD BANFIELD,
of Philadelphia.

Superintendent of the Polyclinic Hospital, Philadelphia.

It has seemed to me that I should be shirking an obvious responsibility if I neglected this opportunity of putting before you the case for the State registration of nurses. Graduates very soon scatter, and are difficult to reach, and so are their friends, but private nurses and the general public are really much more concerned in the subject of registration than those who occupy well-defined positions in institutions. With comparatively few exceptions the need for registration is but little understood, and the evils consequent on the lack of it are put down to many other causes. And yet one can hardly pick up a nursing or hospital journal nowadays without seeing articles about it. It is, however, nothing new—nothing which has not already been tried. In New Zealand, registration has been in successful operation for more than two years. Australia has had a State registration law in satisfactory operation since 1899. England, always conservative, has now a bill before Parliament, and although one bill was blocked on the second reading, that is a mere preliminary.

In this country, registration has already been secured in five States—North Carolina, New York, New Jersey, Virginia and Maryland. A bill passed both Houses in Illinois, but did not succeed in becoming a law. Massachusetts hopes to pass its bill at the next legislative session. Iowa is making more or less tentative efforts, and Pennsylvania—well, Pennsylvania depends upon each one of its friends present tonight to assist it, and with their assistance and approval we hope that a bill will pass the next Legislature. It is a nonpolitical bill, and there is nothing to be gained by its promoters but hard work and the public good. With the example of the other States before us, we should be enabled to avoid many of their difficulties, and there is no reason why Pennsylvania should not distinguish itself by passing one of the best bills.

The objects of the State registration of nurses are: 1. The protection of the public. 2. The protection of the nurse. 3. Improvement in educational standards. If a doctor or a patient desires a nurse who will have sufficient knowledge to call the physician at the first sign of hemorrhage after a bad operation, or the first symptom of collapse in typhoid or pneumonia, he will not desire to pay \$20 to \$25 a week to a young woman from a correspondence school who may never have seen a sick person, but he will desire a woman of knowledge and sense who will do all that can be done to prevent a precious life ebbing away through lack of warning to the physician. Registration, however, will not prevent anyone from employing the young woman from the correspondence school if he prefers to do so. It will lay down no law as to the money her employers should pay her. They may, if they please, pay as much or more than they do to a nurse who is really a nurse. It will merely enable them to ascertain, in a manner which is at present impossible, whether they are getting what they pay for. It will enable them to ascertain at once that the woman whom they admit to their homes and families in a most intimate relation, is, for instance, not a Jane Toppen, who proved to be a dismissed pupil from a large New England hospital, and who was said to have poisoned five of her patients, apparently because it interested her to do so; but it will not prevent them employing a Jane Toppen if they prefer. It will not prevent any woman, who may choose to nurse the sick, continuing to do so; it will only prevent her claiming to be a trained or registered nurse, when she is not, and often thereby bringing shame and disgrace on a body of honorable, hard-working women.

Thus you will see that it does not go so far as the doctors' laws which prevent anyone practising medicine without a license. Women may still practise nursing without a license,

¹ An address delivered at the Commencement Exercises of the Polyclinic School for Nurses, April 29, 1904.

but it will not be impossible for the public to ascertain that they are employing such a person, as is frequently the case now. There is nothing to be alarmed at in the proposed legislative action, unless by those people who do not wish to be known for what they are. Legislation, as all are aware, is never retroactive, and it therefore will not affect, and has not affected, in any State where such a bill has been passed, those who are at present practising nursing.

Judge Harlan, of the Supreme Court of Maryland, said recently, while speaking of the legislation already in force in New York, New Jersey, Virginia, and North Carolina:

An examination of the legislation in these States will show that no new departure has been attempted; that only the same protection for the public and for the profession has been sought in the case of the trained nurse as that which has long been enjoyed by the professions of law and medicine and various other callings, whose following by unskilful or incompetent persons is supposed to touch the public health or public weal. With this exception, that, whereas no one is permitted to practise law or medicine, or some other callings, unless duly licensed thereto, the trained nurses with that modesty and fairness characteristic of their sex have not asked that all unregistered shall not be permitted to nurse, but only that they shall not be allowed to do so as registered nurses.

If the lawyer and the public receive protection against the knave and the shyster—if the doctor and the public receive protection against the charlatan and the quack—if even the sanitary plumber and the public receive protection against the bungling upstart, why are not the public and the trained nurse equally entitled to protection against ignorance and incompetence?

The legislation which you are about to seek is conservative, salutary, beneficial. I see no just reason why a wisely framed bill should not receive the approval of the Legislature, and I can only say, in conclusion, that if my poor aid can help you in any way in accomplishing your desire, I shall be glad to have you command my services.

Dr. William H. Welch, of the Johns Hopkins University, says in connection with the same matter: "I feel confident that it will succeed, because it is so manifestly right."

One of the most noteworthy benefits observed in those States which have already secured registration is the improvement in, and the attempt at uniformity of, training in the best hospitals of those States. Very many training school committees, and even training school superintendents, desire to do the very best thing which can be done with the resources at their command, but it is certain that they frequently do not quite know how or where to begin, and the task seems to them entirely beyond their strength. The first result of these bills, I might say the immediate result, is the establishment of central examining boards for nurses. In New York, the State Board of Regents has just issued an application form for registration or accrediting of training schools, in which are given the details of the graduation standard fixed by statute for New York State. It states clearly a certain standard of preliminary education, of professional education, and the subjects of State examination. It also gives a few simple and practical suggestions for lines of development.

It is noteworthy that the board of governors in each State but one is composed entirely of nurses appointed by the governors of the various States from nominations sent in by the State associations of nurses.

Dr. Welch, further on in the address from which I have quoted, says:

The great advantage of this legislation will be for you, as it has been for the medical profession, an elevation of the standards of education of the trained nurse.

He also says:

I noticed in several of the States the law was almost imperilled by efforts to secure the presence of physicians upon these examining boards. Now I am quite sure that it is not the function of the physician to examine nurses. They have something to say in the training of the nurses; the nurses should not go forth without having come under the guidance of the physician, but your profession is a skilled profession which requires special knowledge, and a special knowledge that is possessed by the trained nurse, and not by the physician. Akin as the professions of medicine and nursing are, they are still distinct professions, and there is no necessity, in my opinion, and there are certain disadvantages in the requirement that physicians should be members of the examining board. Most of these laws provide that the examining board shall consist of persons chosen, or at least nominated, by the State Association, and that seems to me probably the wisest method.

These two features then are the ones which insure that the registered nurse has the requisite training and has the requisite knowledge. They insure that she has been graduated from a recognized training school, one with the proper standards as regards the period of study and practical training. The law further provides that after the nurse has given evidence that she possesses the preliminary training she must pass an examination, not by her own training school, where conditions come in that do not absolutely insure the necessary qualifications, but before a separate and distinct examining board. Those are the essential features, as I understand it, of the law—the existence in the first place of a State Association of nurses, in the second place a provision in the law for a suitable preliminary training, and in the third place, the passing of the examination of a board of examiners who have not of necessity been the candidate's own teachers.

Now, what objection can possibly be raised against this desire on the part of the nursing profession? No real objection, but you are likely, I suppose, to encounter some opposition, and I suppose that opposition will be based upon the idea that such a law as this sets up an unjustifiable distinction; that it sets apart a certain class from others. But the distinction is one eminently desirable, namely, that the term "registered nurse" shall mean that here we have nurses who possess certain defined qualifications. At present a diploma does not mean that, of necessity, so that you require protection on account of the inflow into your profession of those who claim the same without having fulfilled the same qualifications. Therefore, this argument, which is the only one that occurs to me, is one that you will be able to meet when you go before the Legislature at Annapolis—that you are proposing a distinction, but one based upon right and justice, and one that it is certainly eminently desirable to make. The best argument, perhaps, is that of the benefit to the whole community, because the great majority of people have at present no way of determining who are the really qualified nurses, while the institution of the title of "registered nurse" would overcome this difficulty.

From every point of view that occurs to me, your movement is one that should have the support and sympathy, especially of the members of the legal profession, of the members of the medical profession, and of all women who are interested in improving the opportunities for women of higher professional and practical work, for skilled nursing is a great field for woman's activity. I wish you all success in your efforts, and shall be glad to be of any assistance to you in my power in securing the desired legislation.

In every State in which this matter has come up, the best element in the medical profession has been of the greatest help. You might well ask: If this is the case, if it is such a manifestly desirable thing from the point of view of the public, and of the nurses, what objection can there be to it, and why is it necessary to discuss it at all? In some States there was little or practically no opposition. Objection is sometimes made, however, by so-called schools which profess to turn out nurses competent to care for the sick, after a ten weeks' course of lectures in a commercial building, or by mail. During this time the students may or may not learn a certain number of details by rote, but the care of the sick, the symptoms and accidents of disease, it is indisputable, cannot be learned in ten weeks, even if more than an hour or two a day of lecturing is devoted to them. That is surely sufficiently obvious on the face of it. Opposition may also possibly come from special hospitals, which do their nursing cheaply by calling themselves "training schools." By arranging an interchange of work, however, these latter can probably be ultimately benefited by this educational movement.

It is, perhaps, worth while to devote a small amount of attention to the commercial schools before alluded to, inasmuch as in this city a claim has been put forth and widely advertised, that this is the only way of providing the people of moderate means with cheap nursing, or at least nursing within their means. This is a very specious plea, and, of course, receives immediate sympathy from all who do not know better. It has not been found necessary in other countries and in other cities to solve this problem in this way. It seems to me it can never be necessary or wise under any conditions to attempt to solve a difficulty by merely pretending to supply that which you do not and cannot and never will be able to supply. That might do for children or fools, but surely not for the wideawake American with his wits about him. For it can hardly be considered reasonable to suppose that well-educated and intelligent women would spend long days and longer nights for three years and more, studying disease, learning to observe symptoms and report them with absolute sureness and accuracy, acquiring a knowledge of how to meet emergencies, and, not least, that deftness of

touch which comes through practice alone—if all or any of this could be acquired in a few weeks in a few dilettante lectures! The workingman, too, or the clerk with a small income, what has he done that he should suffer thus? His life, his health, is of really more immediate value and importance to him than is that of the millionaire to him. For every week during which he is incapacitated means a serious strain on the family resources. It is undisputed that really good nursing care hastens recovery in the majority of instances. Hence our hospitals. *Charities* of last week said:

It is a well-established and conceded fact that there is a commercial value to human life; that it costs a certain amount of money to bring a child up to the earning point, and that once brought to the earning point that human life is worth to the State a certain sum of money. The sum varies in different States, and it cannot be estimated in America at less than \$1,000 per capita.¹

So it hardly seems sensible to allot to the care of a person who admittedly cannot know her business, the charge of anything which is of \$1,000 value to the State, and infinitely more to the family of the individual. No one advises cheap doctors for them, or even first year medical students. The best talent, surgical, medical, and nursing, is provided in hospitals. The President of the United States could secure no better. They "don't like hospitals." Well, that is rare now. And few of the working-class are sick because they like it, anyhow. The only sensible thing to like is to get well as quickly as possible. If, however, there are reasons which seem to the patients good and sufficient for remaining with their families, the difficulty of caring for them is not necessarily met by sending incompetent nurses. The district or visiting nursing system of England was well organized even before the Queen's Jubilee Fund was established. This, as perhaps you know, was an offering made by the women of England to the Queen on the occasion of her silver jubilee. It amounted to several hundred thousand pounds, and was devoted by the Queen to founding and endowing a very comprehensive and thorough system of nursing, by thoroughly trained nurses, under central authority, for the care of the sick poor in their own homes, and also for the care of those who were able to pay only a small fee. This system covers like a fine network the large cities of England and Scotland, and many of the country districts. It is also beginning in Ireland.

In Chicago, one of the wisest and most acceptable charities is the Crerar Fund, which sends a nurse to just such families as you have in mind on the payment of four, six or seven dollars per week, and makes up the nurses' pay to the regular living wage. In this city there is the Visiting Nurse Society, which will provide properly trained nurses free, or on payment of 50 cents per visit. If this society were properly supported by the charitable, and efficiently organized so as to cover the whole city of Philadelphia as required, you would find lecture and correspondence school nurses, as such, obviously no addition to the competence and wealth of the community. Surely, in this very generous country, Philadelphia will one day possess such an endowment as we have spoken of. Until then, let those of moderate means patronize the numerous hospitals, or the Visiting Nurse Society.

Now we have spoken of the advantages of a law recognizing and regulating our work as a profession. We have considered what we want and what we wish others to do to help us, but the most important matter of all is, what is the nurses' own responsibility in the matter and what they will themselves do to help it forward. A Chicago nurse who had done much for her profession said a year or two ago:

It is exasperating to the leaders in any line of work to see about them those who could be their helpers, but who will not exert themselves. These are they who sit back and criticise the often faulty work done by others. Perhaps the work is faulty through lack of help which they could have given. Perhaps they think that if their own personal work is well done they have fulfilled their duty. They fail to realize that those who are not helping are hindering, that affairs of moment which will affect them personally in time are hanging in the balance, and that the influence of each person counts in the turning of the scale.

Emerson says:

If you act, you show character; if you sit still, you show it. You think because you have spoken nothing when others spoke, and have given no opinion on the times, that your verdict is still expected with curiosity as a reserved wisdom. Far otherwise; your silence answers very loud. You have no oracle to utter, and your fellow-men have learned that you cannot help them.

It has been realized that the technical training of a nurse is of great help in many vocations beside that of actual nursing: In school inspection, in settlement work, in charity organization work, as sanitary inspectors, factory inspectors, sweatshop and bakery inspectors. In all these branches it is rapidly becoming recognized that the special training received is of the greatest utility to those whom she serves. It may well indeed make us feel very humble to think of the enormously wide and varied field there is open to us just as soon as we are able and willing to accept our opportunities. I say "accept" advisedly, for in this work it hardly seems as if we had to seek them. They seek us, and if happily we are able to do anything which is worth while to others it seems to me it meets with full appreciation. In claiming the right to registration and recognition by the State, it must be remembered that we add to our responsibilities. It seems to me that too often we claim responsibility without realizing that the first requisite is that we ourselves should be capable of worthily and adequately mastering the responsibility we claim. When we get our bill, if we do get it, we shall but be beginning work. It will not be the end but the beginning. You will not be able, it will not be possible for you, to stand aside and say: "O well, I don't care about it, I take no interest in it, it is nothing to me." Remember that indeed your silence speaks very loud. You are a hindrance and a stumbling-block. This I am sure none of you here present tonight would wish to be. I would therefore beg you to remember always the importance not only of invariably doing good work, but of living up to your obligations in every way. These are exacting, but since you have chosen to make yourself a member of the profession of nursing you must abide by your choice. You could not, in my estimation, have chosen better work, but you have not chosen a pathway strewn with roses, or if indeed there be roses, as who shall deny, there are likewise many thorns.

The privilege of service is, however, a very great one. You will remember that the motto of the King of England is "Ich dien"—I serve. The king is indeed the servant of his people. He frequently puts aside his own comfort, his own convenience, his own taste, in order the better to serve his people. His people expect it of him as their right, and so it is. You also serve. We expect it of you. It is our right that you think before all things of your responsibilities. See that having chosen this noble service you serve not only the individual but the State and your profession at large, and in every way "walk worthy of the calling wherewith you are called."

The Odor of Races.—According to an editorial in the *New York Times*, a Japanese doctor of medicine publishes a treatise concerning the odor of the occidental races, sustaining the proposition that at first the orientals do not like it. They grow used to it in time, however, and finally, with continued experience, do not notice it at all. It seems to be his opinion that each race has its peculiar fragrance, that it is partly radical but is in a measure influenced by dietary and other conditions. So far as his people are concerned they do not smell each other, but he does not think this is conclusive proof that they are odorless. They probably have their own perfume perceptible to aliens—the Russians can smell them a long way off—but among themselves it is not noticed. It is, however, nothing like the pungent and penetrating emanation proceeding from the western nations, in which traces of garlic and ancient cheese and the volatilization of a coarse and overabundant dietary are so sure to be found. The theory thus developed is a curious one, and it is more curious still that it was left to Japan to give it development and formulation. If it signifies a particularly refined sensibility to odors among that interesting people their possession of it may readily be admitted, as their old dower is refinement and not in any single manifestation, but covering every phase of perception. Perhaps in this they do not exceed their near neighbors the Chinese, who may equally find the smell of foreigners disagreeable, but who have hitherto been too proud and stoical and contemptuous of the pungent and effluvious barbarian to say so. That country has had unrivaled opportunities to study the odor of countless tribes of outlanders from the beginnings of its recorded history and before, but so far has not said a word about it.

5.—**Prophylaxis of Tetanus.**—S. C. Stanton gives the statistics showing the distribution of tetanus in the various States, and the death curve according to months, the upward start occurring in May, and reaching its maximum in July, and then declining to October. The greatest mortality is before the age of 19, and that below 14 is three times as great as that between 15 and 19. In 1903 the total of deaths from Fourth of July injuries was 465, of which 406 were due to tetanus. There is no convincing evidence that blank cartridges contain tetanus bacilli except as a rare contamination. They are present in street dust and on the persons and clothing of the injured, and are carried into the wound at the time of the accident. Prophylaxis requires the enforcement of existing laws regarding the sale of toy pistols and other dangerous toys; the enactment of laws by Congress, State legislatures, and municipalities prohibiting the manufacture and sale of toy pistols, blank cartridges, dynamite canes, and caps, cannon crackers, etc.; the open treatment of all wounds, swabbing them with 95% carbolic acid, followed by open dressing and drainage; the immediate use of tetanus antitoxin in all Fourth of July wounds, and those received in barnyards, gardens, or other probably infected places. Antitoxin should also be injected as soon as symptoms appear, though the percentage of recoveries is small when the treatment has been delayed so long. [H.M.]

1.—See *American Medicine*, Vol. VII, No. 24, p. 939.

2.—**Carcinoma Basocellular.**—S. C. Emley states that Krompecher has called attention to a peculiar superficial tumor of the skin, which he places in a class by itself, because it is neither typical carcinoma nor typical adenoma. Clinically, they appear as fungoid tumors or as ulcers, occurring most frequently in the skin of the face or of the female breast. They may occur on other parts of the body, but never at the junction of mucous and epidermal surfaces. Histologically, they originate from the malpighian basal layer or its embryologic equivalents. Emley has examined 37 of these tumors removed from 35 patients. Clinically, the glands were not found involved in any instance. The average age of the patients was 51; recurrence has been observed in 8 of the patients; the duration of the growths varied from 40 years to 2 months. The development of these tumors from the basal layer of the epithelium, from hair follicles, or from the necks of the sebaceous glands, is definitely established. The tumors showed a preponderance of flask-like masses of cells, and most of the 37 tumors studied Emley designates as "bulbous"; those which are not characterized by such formations correspond to the "cystic" or "styloid" varieties of Krompecher. These varieties are described in detail, rodent ulcer being classified as belonging to the last. [A.B.C.]

3.—**Relation of the Burn to the Bullet Hole as Evidence of Homicide vs. Suicide.**—In this paper Jay Perkins

recounts the circumstances, which in brief are as follows: A drunken Frenchman and his wife occupied a tenement basement. In the early morning a shot was heard by neighbors and presently the woman announced that her husband had committed suicide by shooting himself. The ball had entered 1½ in. above and a little anterior to the junction of the ear to the head, on the right side. The hole was surrounded by a burn, which, however, extended farthest from the hole, in the direction of the mouth. The wife was arrested and tried for murder. Perkins, who was called to testify for the State, had observed in experimental work that when a bullet hole is surrounded by a burn in clothing or hair, the burn always extends farthest from the hole on the "hammer" or "sight" aspect of the revolver. He contended that it was highly improbable that the dead man in this case would have held the pistol as indicated by this burn. In a review of literature, he found an article by Fish,¹ in which he took the same ground as Emley does. Reese and Draper hold to the same opinion. The defendant was acquitted, but Emley insists that all of his work makes him more firmly convinced than at first that in the relation of the burn to the bullet wound we have an accurate guide as to the position in which the revolver was held as regards the sight side of the revolver, this relation being more marked the farther the revolver is held from the object fired at until the point at which the burn fails to appear is reached. [A.B.C.]

3.—**Medical Aspects of Decapsulation of the Kidneys for the Cure of Chronic Bright's Disease.**—A. R. Elliott says the condition is produced by a chronic toxemia, either systemic or infective in origin, widespread arterial and cardiac degenerative changes which are permanent, and in their development constitute the threatening element of the disease. General edema or anasarca in chronic renal disease is in many instances largely cardiac dropsy, brought about by advancing myocardial degeneration. It is occasionally so in chronic parenchymatous nephritis, and almost invariably so in chronic interstitial nephritis. In like manner, developing anuria and uremia in chronic nephritis may be largely cardiac in production, the functional inadequacy of the kidneys having its inception in the fall of blood-pressure incident to circulatory failure. In the later stages of chronic nephritis, of whatever character, the case is apt to take on these cardiac aspects, which virtually convert the therapeutic problem into a question of sustaining a failing heart. Albuminuric retinitis must be looked upon as one of the terminal symptoms of chronic nephritis. The concordance of opinion places a limit of two years upon the prognosis after development of this complication. The statistics gathered by Suker of cases operated on, show that in place of prolonging this limit of expectancy, operation has a decidedly contrary effect. Elliott says the mere fact that the general condition of the patient improves somewhat after decapsulation does not establish the validity of the operation for hygiene and

¹ Boston Medical and Surgical Journal, October 2, 1894.

rest will do the same for the patient to a remarkable degree in many cases. As the factors of hygiene and rest are invariably associated with the surgical procedure, it is possible that the resulting benefit may, to some extent, accrue from those sources. The results of experimentation demonstrate that within a period of three and a half months after decapsulation, a new, and in most cases, a tougher fibrous envelope has taken the place of the original capsule. This fact may account for the many relapses and deaths after that period in cases operated on, and in chronic cases, at least, it narrows the prospect of improvement to a period of months. [C.A.O.]

4.—The Surgical Treatment of Chronic Bright's Disease from the Ophthalmic Standpoint.—G. F. Suker concludes as follows: (1) As at least 25% of all cases of chronic Bright's disease present evidences of retinal or other serious fundus complications; (2) as these various fundus complications are usually of the degenerative inflammatory type, attended by like changes in the kidneys; and (3) as the cardiovascular system is, or shortly will be, seriously involved; and (4) as such changes may develop without any subjective symptoms on the patient's part; and (5) as these retinal complications have been accepted as indicative proof of a general circulating systemic toxin, and designating the acme of the development of the Bright's disease; and (6) as the death-rate of this class of cases under the best medical treatment (both hospital and private practice) is about 75% for the first year, and at least 85% for the second, scarcely any subjects surviving three or four years, while, in cases operated on it is 100% for the first year; and (7) as these fundus findings are of paramount prognostic import in an inverse proportion to the age of the patient; and (8) as the medical aspect of this question, as presented by Dr. Elliott, offers as good, if not far better results than the decapsulation in like cases—therefore must this climactic array of positive clinical data not be disregarded on the part of the surgeon in endeavoring to establish the validity of this operation under discussion. This is at least true for the complicated cases; especially so, when it can be said that the patients in some cases verily died because of the operation and others in spite of it, while all complicated ones operated on fell within the two year limit. Finally, the writer says that he has ample reasons to believe conservatively, from facts above detailed, that he has conclusively proved decapsulation of the kidney for chronic Bright's disease to be absolutely contraindicated in such cases as present a retinitis or a neuroretinitis, with or without hemorrhages. [C.A.O.]

5.—Puerperal Sepsis.—Swithin Chandler describes an operation which he believes to be the advisable procedure in severe cases. He makes an incision posteriorly to the cervix in the posterior vaginal wall; then passes a pair of long blunt-pointed forceps, slightly curved, in the cervical canal, up into the cavity of the uterus; then punctures the posterior wall of the uterus in the center, near the top of the uterus. He then introduces with two fingers a piece or strip of iodoform gauze through the posterior vaginal opening previously made, clasps the gauze with the forceps, and drags the same through the uterine wall and out through the vagina. He repeats this by puncturing the uterus on each side, but posteriorly and just about the middle of the body of the same, drawing the gauze through the same as in the first attempt. Chandler reports four cases. He considers the operation conservative, easily performed by the experienced and logical, because it treats the organ as an infected part, and gives drainage to the uterus and those tissues and vessels shown by postmortem examinations to be affected. The mortality is greatly lowered and the operation gives superior results. [C.A.O.]

6.—Early Atheroma and Aneurysm.—The case reported by C. R. Andrews is that of a man of 21. Prior to his death a marked initial regurgitant murmur was recognizable, and at the postmortem his heart was found somewhat hypertrophied; on the upper surface of the mitral valve was discovered a large warty growth capped with calcareous deposits. The aortic valves were also sclerotic and thickened. The arch of the aorta was atheromatous and studded with several ulcers, which had extended through the intima. The arteries of the extremities were atheromatous, though not so markedly so as the arch of the aorta. Just about the location of the celiac axis was a

sacculated aneurysm 4.5 cm. in diameter. The thrombus within the aneurysmal sac was rather firm and laminated, the blood having coagulated in concentric layers at different periods of time. The patient complained of no pain, and gave no symptoms which would have led one to suspect the condition. [C.A.O.]

4.—See *American Medicine*, Vol. VII, No. 24, p. 946.

5.—Pathology and Treatment of Simple Fractures of the Patella.

—The conclusions of Ellsworth Eliot, Jr., are: 1. Owing to the not infrequent uncontrollable rotation of the lower fragment, through an arc of 90 degrees on its horizontal axis, accurate apposition of the fractured surfaces cannot always be secured and under these circumstances the ultimate result of conservative treatment could scarcely prove satisfactory. 2. Suitable apposition may also be prevented by the interposition of torn shreds of capsule, by extravasated blood clot and possibly also by the interposition of untorn periosteum, conditions which can be recognized and remedied only by exploration. 3. Suture of the fragments permits of simultaneous suture of the torn capsule, a procedure of the greatest importance for restoration of joint security. 4. The results of suture are almost invariably excellent, and the risk of operation is comparatively slight. 5. In no way does the writer desire to belittle the risk of operation. On the contrary, the exercise of the most rigid aseptic precautions both in the preparations for and in the carrying out of the operation itself cannot be too greatly emphasized. Far better, in any instance, where for any reason, the highest degree of surgical asepsis cannot be practised, to advise some non-operative procedure than to subject the patient to the possibility of a septic arthritis with all its direful consequences. A. O. J. KELLY

REVIEW OF LITERATURE

Typhoid and Malarial Fevers.—Major Edward Carter¹ gives a review of the morbidity and mortality in Chickamauga while the troops were stationed there in 1898. He deals at length with the condition with reference to typhoid and malarial fevers, and mentions an improvised method of reducing temperature in the fever cases when a cold plunge or cold sponge could not be had. A rectangle of bolsters, muslin, etc., was made about the patient, and these were covered with a rubber blanket, which was pressed down between the patient and the long side bolsters to make a waterproof trough on each side of the patient; cracked ice was laid on the rubber blanket over the legs, thighs, abdomen, and thorax of the patient, and a thermometer placed in his mouth and an ice-cap to the head. His conclusions are: (1) The waters of Crawfish Springs and the Chickamauga river were contaminated; (2) the contamination was greatest probably in June and in the early part of July, 1898, due to storm water; (3) flies contaminated the food; (4) while typhoid fever generally exists near Chickamauga Park, it hardly arises to the dignity of an epidemic; (5) many cases, diagnosed malarial fever at Camp Thomas and among the rural population near Chickamauga, were cases of typhoid fever with no malarial complication; (6) malarial fever did exist to some extent at and near the general hospital at Crawfish Springs; (7) malarial and typhoid fevers may coexist in the same patient, but this rarely occurs. [A.B.C.]

Simulation of Urethritis and Cystitis among Soldiers.

¹ Journal of the Association of Military Surgeons, February, 1904.

—Artificial stimulus is sought by soldiers to produce the effects of bladder disease and gonorrhea, in the desire to avoid service. Gallenkowski¹ has found epithelium of ciliated type, and evidently of nasal origin, in the urine of soldiers at the military hospital. Urethral injections of lemon juice and quinin have been employed to cause an appearance of cystitis. It will be necessary to secure the diagnosis through microscopic and chemic tests, for the ingenuity of these malingerers is limited only by their opportunities. [T.H.E.]

Early Recognition of Tubercle in the Lungs.—Isambard Owen² states that the means of making an early diagnosis in pulmonary tuberculosis still rests chiefly upon physical examination; bacteriology has supplemented, but can not replace it. We must not only detect the presence of tuberculous lesions when they exist, but must make sure of their absence when they do not exist. Training not only in physical diagnosis, but in the postmortem room is of the highest importance. In necropsy of bodies which present no evidence of tubercle, the proportion in which the occurrence of healed tuberculous ulcers is found is placed by some authors as high as 30%, by others considerably lower. It is one of the earliest experimental observations on tuberculosis that caseous material remains permanently infectious, that the tubercle bacillus can rarely be detected in it, yet it can be readily cultivated from it in the body of susceptible animals, hence the importance then of recognizing the disease before caseation is apparent. Except in cases where early hemoptysis draws attention to the lungs, it is doubtful if we often see the patient in the initial attack. A slight attack of tuberculosis may cause either no symptoms or none [that will lead the patient to seek medical advice. Intermission and remission in the symptoms of pulmonary tuberculosis are to be remembered, and the intermission which is normal in the disease is often attributed to some drug used in the course of treatment. Chronic consolidation of the apical portions of the lungs is seldom anything but tuberculous, and the preliminary search for signs of trouble is, to a large extent, a search for the consolidation, the direct signs of which are tubular, or harsh breathing, bronchophony, dullness on percussinn, etc. [A.B.C.]

Yellow Atrophy of the Liver.—Edwards and Smith³ report the case, calling attention to the rarity of the disease. In Guy's Hospital during the 27 years from 1864 to 1890 only 11 cases were met with; Osler mentions in 1898 that it had never happened to him to see a case. The disease is more common in women than men; the various causes assigned are mental emotion, syphilis and alcoholism. None of these were in evidence in the reported cases. The whole duration of illness in the present case was but 11 days. Not only did the patient make no complaint previous to the date assigned, but there was no jaundice nor any other sign pointing to illness. The patient was a man of 47, who had previously been in good health; he suddenly complained of feeling ill and was found to be jaundiced. The jaundice increased in spite of purgation and on the eighth day the patient became delirious, the icterus was more intense, the liver dullness was markedly diminished; on the ninth day the condition was unchanged, except that liver dullness was still further diminished and there was obstinate constipation. On the tenth day delirium had passed into coma, there was stertorous breathing, inability to swallow, contracted pupils and on the following day the patient died; the temperature never rose above 99°. Necropsy showed a flabby liver which weighed 32 ounces; the remaining viscera were apparently normal. Microscopic examination of the liver showed it to be a case of acute yellow atrophy. [A.B.C.]

The Early Diagnosis of Tuberculosis of the Lungs.—C. G. H. Baumler² states that in the majority of cases a somewhat persistent cough is the only symptom which induces a patient to seek medical advice; commonly, however, other symptoms subjective or objective, are always present, which, in connection with cough or without it, may raise a suspicion that tubercles have formed in the lungs. Foremost among these are febrile symptoms, lassitude, pallor, shivering, night sweats, loss of appetite and weight. In these suspicious cases

it is of importance to take the temperature several times daily continued over a considerable period. A continuous slight elevation of temperature or loss of appetite, if not explained by other discoverable disease, is extremely suspicious of pulmonary tuberculosis, which sooner or later will become apparent by distinctly local signs. These latter vary according to the kind of change which the disease induces; alveolar, lobular infiltration, and bronchial breathing being the gross anatomic evidences of the disease, together with diminished or altered resonance on percussion and altered breathing, especially over the apices of the lungs, which in the overwhelming majority of cases are the first parts to be affected. A careful comparison of the two sides and of corresponding points will lead to the discovery of very slight changes, though it is to be remembered that slight differences in the two sides exist normally. The microscope is, of course, of importance, but after all, the principal reliance, especially after failure to find tubercle cells, rests on physical examination. [A.B.C.]

GENERAL SURGERY

MARTIN B. TINKER

A. B. CRAIG

C. A. ORR

REVIEW OF LITERATURE

The Anatomic State in Appendicitis and Indications for Appendectomy.—Karewski¹ believes that appendicitis granulosa is the beginning of various forms of the disease that may either recover quickly or may terminate rapidly in death. The condition may become chronic and extend throughout a period of years without producing any appreciable change in the organ. The symptom-complex is varied and in many instances it is difficult to come to a definite diagnosis. Karewski believes that with the first symptoms pointing to the appendix the organ should be removed. [J.F.]

Tropical Liver Abscess.—J. A. Koch² says in all probability the ameba giving rise to liver abscess is identical with the ameba of dysentery. Since the parasite is found in all the layers of the intestinal wall it is reasonable to suppose the ameba coli reaches the liver by the portal system. There seems to be some doubt in Koch's mind whether the ameba is alone responsible for the production of the abscess, or whether there is associated with it other pyogenic organisms. He does not agree with other authorities that alcoholism accounts for the frequency of liver abscess in the male, since in many of his patients alcohol was rarely taken. If the pain is constantly referred to the same place in the region of the liver, the abscess in all probability is then superficial; in deep-seated abscesses the pain is usually diffuse, or referred to different places. He recommends aspiration as a means of localization, but says the puncture should never be made below the margins of the ribs, nor does he advise multiple punctures. After finding the abscess, Koch says that at least 15 gm. or 20 gm. of pus should be withdrawn to relieve the tension and to prevent the possible escape of the abscess contents into the peritoneal cavity after withdrawing the needle. He says it is much better to let the needle remain in the abscess and operate at once. [J.F.]

The Treatment of Ozena with Paraffin Injections.—Fliess¹ maintains that ozena is due to widened nostrils; he meets this alteration in the nasal passages by injecting paraffin into the tissues bordering the widened or atrophied parts. This method does not cure a well-established ozena, but it ameliorates the condition greatly. In all the patients he treated by this method there was a marked improvement. [J.F.]

Postoperative Engrafting of Echinococcus Cysts.—Madelung² in a man from whom he removed a hydatid cyst of the liver two years later found two cysts in the scar of the original wound. The patient told him these nodules appeared three weeks after leaving the clinic. Madelung at a second operation ascertained that these nodules were true hydatids and were in the wall of the abdomen only. He believes the small cysts lodged in the abdominal wall at the time of the operation and found a suitable soil there for their growth. [J.F.]

Free Public Baths.—With the advent of warm weather comes the necessity of providing free public bathing opportunities for all who may wish them. It is a public health question, one of money saving and good policy, not one of benevolence or pleasure giving. That veteran general in this cause in New York City, Dr. Baruch, may feel that few have accomplished more actual good for the community than he. After years of tireless advocacy the New York Academy of Medicine finally gave formal approval of his method, while two or three charitable societies took it up and constructed public baths in accordance with his ideas. In 1895 a mandatory public bath bill was passed by the Legislature. The mayor gave his permission, and steps were taken toward the building of the bath in Rivington street. Last year 700,000 working people made use of this bath, and in the public schools 30,000 children used the rain baths which have recently been established in the school-houses through Dr. Baruch's efforts. In opening the Millbank bath, Dr. Baruch said: "Naturally enough, it is a matter of considerable satisfaction to me to be able to tell you that outside of New York there is no city in the world where anybody may go into a public bath, as he goes into a public park, and enjoy its privileges without cost. I think the realization of that fact alone is ample compensation for all the years of hard work it has cost, to say nothing of what has been achieved in other communities all over the world." There should be a Dr. Baruch in every city and town of the country, and the profession will second his efforts whenever he appears.

The noisy, sickness-creating, wound-making, and death-bringing Fourth of July will soon be here and the medical profession will be called upon to meet the unwelcome burden of caring for the injured. The Women's Christian Temperance Union has started a crusade against the noise of explosions in the vicinity of hospitals, and thus again shows its recognition of great social evils and of right methods of overcoming them. Chicago, where the toy pistol has been barred for some time, is, if possible, to allow no giant crackers, no revolvers, nor any explosive that has dynamite in its composition. To make amends to the small boys, however, the city authorities contracted with an amusement company to set off fireworks in designated parts of the public parks, and furnish to all the youngsters who

apply, free crackers of the small and traditionally harmless Chinese type. They will be shown how to explode them, and, presumably, warned against holding them between the teeth as they go off. A policeman, a fireman, a doctor, a teacher, and a member of the Illinois Naval Reserve will be stationed at each celebration center. Cleveland has passed a municipal ordinance against the sale of toy pistols and blank cartridges. St. Paul has provided against the sale of fireworks in that city during the thirty days preceding the Fourth. Discussion of the oratorical substitute for the real fireworks and the reading of patriotic essays have all but ceased; and the general opinion seems to be that Chicago has hit upon the right solution. Cannot the rulers of other American cities be moved to check the mimic wars which kill and maim more victims than many deplored battles of great armies? If the united local professions would bring their influence to bear upon mayors and police departments, the evils might be largely prevented.

Fourth of July Tetanus.—The annual "patriotic" sacrifice to Moloch is close at hand, and, unless the people have become wiser within the last twelve months, we shall have a repetition of the fatalities from lockjaw that startled the country a year ago, when 413 cases of the disease occurred, with only seven recoveries. According to the investigations of the *Journal of the American Medical Association*, 363 of these accidents were the result of the use of blank cartridges. Injuries with shooting crackers, Roman candles, and other kinds of fireworks seem far less prone to lead to tetanus. The tetanus bacillus is widely disseminated in street dust, garden earth, stable manure, etc. It is doubtful whether it is contained in the blank cartridge itself; it is more probable that the wads carry the bacillus from the dirt on the children's hands into the wound. The bacillus is anaerobic; therefore, it thrives best in small wounds that are more or less occluded. When, as is usually the case, there is mixed infection, the other organisms, by using up the oxygen, render the soil more suitable for the development of the tetanus bacillus. The bacillus is not found in the blood, but only at the site of the wound. Its toxin is extremely virulent, and seems to reach the central nervous system principally by traveling up along the nerve sheaths and axis cylinders. For this reason there is a period of incubation of considerable

length, during which preventive measures, such as antitoxin injections, are of unquestionable value. When the symptoms have once developed, however, the power of the antitoxin to cure the disease is greatly reduced; and if the symptoms appear the first week antitoxin is almost powerless to prevent a fatal termination. It is probable that the antitoxin, when subcutaneously injected, reaches the nerve cells concerned in the same manner as does the toxin, through diffusion along the nerve fibers; but by injecting it into the spinal canal it is brought into more immediate contact with the ganglion cells. During the last epidemic, notwithstanding the extensive use of antitoxin, the mortality was over 95%. This goes to show that to prevent the disastrous results of our barbarous methods of celebrating the Fourth, we cannot depend on antitoxin, but must have recourse to anticipatory injections in every case in which a child receives even the slightest wound through playing with fireworks. The tetanus bacillus is very resistant to antiseptic agents and to heat, and its spores can stand boiling and strong solutions of carbolic acid. Hence mere cleansing of wounds, and even cauterization, are entirely inadequate measures. Caustics, moreover, have a tendency to seal the wound, and thus to give the anaerobic tetanus bacillus a better opportunity to develop. The only rational treatment is to lay the wound freely open and remove all foreign particles. It must be remembered that the explosive force of the toy pistol is so great that wads and dirt particles are often driven deep into the tissues, and sometimes several inches along the tendon sheaths. After the wound has been laid open and thoroughly cleansed—and, of course, this is possible only under an anesthetic—it must be lightly packed with iodoform gauze. It will probably be difficult to persuade parents to allow their children to be anesthetized when they have sustained only trifling wounds on the hands or the face; nevertheless, as this is the proper treatment, we must make every effort to obtain their consent for carrying it out. We fear physicians have been somewhat derelict in teaching the importance of radical methods in treating Fourth of July injuries.

Responsibility of the Authorities.—In order to bring the matter before the public in as impressive a manner as possible, circulars should be printed and distributed to all the houses of the city, through the police force, or in other ways, just as is done in the poorer districts each summer, in order to instruct mothers in the proper care of infants during the hot weather. The circular might be worded somewhat as follows:

"Over 400 fatal cases of tetanus, or lockjaw, followed last year's Fourth of July celebration. The majority of these were in children, and were sustained through the use of the toy pistol. You are therefore warned not to allow your children to use this dangerous toy. If, however, they should receive a wound in this way, or from using any of the customary fireworks, they should, no matter how small the wound is, be at once taken to the family physician or to a hospital. The wound should be thoroughly cleansed; and, if necessary, permission for the use of an anesthetic should be given. Washing the wound with antiseptic solutions, or even cauterizing it, is insufficient and will not prevent lockjaw. This disease can be

averted only by the treatment suggested, and by injecting a proper amount of antitoxin.

BY ORDER OF THE BOARD OF HEALTH."

Hospitals should be prepared to give injections of antitoxin, the prophylactic dose of which is 10 cc., or, for a small child, 5 cc. The expense of prophylactic injections should, it seems to us, be borne by the city, inasmuch as, by permitting the use of dangerous toys, the municipality is indirectly responsible for the development of many of the cases of tetanus. In addition to supplying the antitoxin for this purpose to hospitals, Boards of Health should furnish it on demand to physicians for use among the poor. A careful record of all cases of lockjaw following the celebration of Independence Day should be kept in hospitals and by physicians in private practice. These records should be sent to the Bureaus of Health. *American Medicine*, also, would appreciate the receiving of such reports from physicians.

Metaphysic methods in therapeutics are advised by the superintendent of an asylum in a recent annual report, which, if accepted by the profession, must add a multitude of new agents to the already terrifying lists of the books on materia medica. For an attack of melancholia a sudden change of native to a foreign tongue is commended. But would not the patient have first to learn the foreign language? For patients frenzied by excitement the repressing quality of the color blue is advised. This suggests a number of questions as to the colors of wall papers and decorations in the various rooms and wards of hospitals and asylums, and their effects upon the different diseases of the mind. Doubtless, all office seekers should be received in the blue room of the White House. In the words of the report: "It is probable that a field, as yet unexplored, lies beyond the ken of this age, in the mental sway of vibratory light and sound on the brain through the eye and ear systematically applied in the treatment of mental and nervous diseases." Still more decided grows the doubting smile of the quizzical reader, as he reflects upon the frank acceptance of the *Hold-in-Thought* methods of the faith-curists. "One is happy because he laughs and sad because he cries."

Lately in the case of a young woman depressed in spirits the experiment of verbal substitution—suiting the action to the word—was made with considerable evidence of encouragement. In lieu of the reiterated voicing of her grief, "if sister Sallie had not died, I would not be here," she was induced to repeat after the nurse in drill form, for several short periods daily, the reassuring sentiment, "I will be brave, I will be brave," with appropriate intonation and gesture.

One of the odd reversals of logic, as regards this therapeutic method, is that "it shows the marvelous influence of the body over the mind and what may sometimes follow its application." Possibly that is added to avoid claims of conversion by the faith-curists, but it will scarcely prevent them.

The Keeping Quality of Butter.—Recent studies upon the keeping quality of canned butter by Lore A. Rogers, Government Expert in Dairy Bacteriology, have led to certain very important conclusions. Abnormal

changes in butter may be brought about by decomposition of one or all of three groups of chemic compounds, sugar, nitrogenous constituents, and fat. Jensen has shown that the action of air upon butter does not directly increase its acidity but supplies oxygen to certain organisms that are active in acid production. This, however, cannot explain the changes in canned butter which, though it is hermetically sealed, becomes after a time acid and assumes a disagreeable, biting flavor that is described as "fishy" or even becomes rancid. The studies in question were made upon samples of butter of this description, most of it having been kept for at least a year. In addition, two lots of fresh butter were examined from time to time until the "fishy" flavor developed. Briefly, the results show that these changes in butter are most probably due to the action of fat-splitting enzymes instead of nonspore-forming organisms, the only other alternative. The practical deduction from the studies is that in preparing butter that is to be held for any extended period of time hermetically sealing is not sufficient, as this does not exclude certain anaerobic yeasts nor prohibit the action of the fat-splitting enzyme carried into the butter from the milk. To remove these two factors, the milk or cream should be pasteurized at a temperature high enough to destroy the enzyme and the starter prepared in such a way as to minimize the danger of contamination by yeasts. The life of unpasteurized butter will be prolonged by holding it at a low temperature.

The Specialist and the General Physician.—New light is thrown on the old question of the relative provinces and abilities of the general physician and the specialist by a learned writer in that learned periodical, *The Medical Brief*. The learned writer is evidently scornful of specialists, and by implication advises his fellow general practitioners not to refer their cases of diseases of special organs to the specialist, but to treat such diseases themselves. He illustrates by "a case of iritis conjunctivitis." The poor parents sacrifice everything in order to consult the specialist, according to the foolish advice of the incapable general physician. "The specialist, after making considerable to do about the matter, prescribes a 2% solution of cocain, charges a good round fee, and sends the parents home rejoicing." Now the way the learned writer would advise is shown in a case thus reported:

The child was suffering with a small ulcer on the outer border of the iris; this had caused considerable inflammation of the cornea and conjunctiva, from which the child was unable to bear light or see. I prescribed a 2% solution of cocain, to be used until the inflammation had subsided.

There are a number of queries and conclusions concerning the report and advice, as, for instance:

1. What is "iritis conjunctivitis"?
2. What sort of anatomy and diagnosis is shown in the statement "an ulcer on the outer border of the iris?"
3. Is the treatment of these two diseases with cocain alone common among the general physicians and the specialists who write for or subscribe to *The Medical Brief*?
4. How often is cocain used in ocular diseases to cover

up the ignorance of the disease present and give the patient temporary relief of pain?

5. How frequently are conjunctivitis, iritis and keratitis confounded in diagnosis, with consequent failure to prescribe the appropriate remedies necessary to save the eye in each type of disease?
6. What is the use of medical journalism of a certain kind?

Logomachy in medicine has in some departments reached such a degree of absurdity as to defeat its own object and become a suicidal *reductio ad absurdum*. To name a pathologic condition properly is always wise and desirable, but as each individual case of disease differs in some one or in many respects from that of every other, it manifestly becomes impossible to devise any nomenclature which shall apply to and adequately express the single clinical and pathologic fact before one. The multiplication of terms delighted in by the logomachy scientists may serve no other purpose than that which Goldsmith hinted in his description of the village schoolmaster:

For e'en though vanquished he could argue still;
While words of learned length and thundering sound
Amaz'd the gazing rustics rang'd around;
And still they gaz'd, and still the wonder grew
That one small head could carry all he knew.

Such an effect upon a few innocent practitioners some medical journal articles may have, with confessed pleasure, also, and increased consultation practice upon the part of the writers. But do they help toward an understanding of the case? Do they unravel any mysteries? Do they aid in curing the patient? It would sometimes seem that the design is to mystify, rather than clarify, and as for therapeutics, that is not considered at all, and is wholly "another matter."

Cures for Migraine.—The extent to which clumsiness and unscience can go in ignoring the etiology of a disease, and in attempting to cure the effects without the least search for the persisting cause, is well illustrated in the history of the mysterious affection called migraine. The profession has seemingly settled down to a condition of utter apathy as regards this mysterious and protean disease, out of which a few physicians arouse themselves occasionally to jeer at any one who suggests a cause and cure on rational grounds. The street car signs are sure of an infallible cure-all. A few of the proprietary preparations that have been dignified with names are "migrol," "migrosine," "migranine," etc., for putting into the stomach. The most amusing of the articles of the materia medica, however, designed against the disease are those for external application. One of these was called the "migrainator," from which one would naturally and philologically suppose it was designed to cause and not cure the disease. It is described as an apparatus for the relief of migraine, consisting of two plates held by a spring, in order to produce compression of the temporal arteries, and the regulation of blood to the head. Why not put a constricting band about the neck, the tension to be varied *pro re nata*?

AMERICAN NEWS AND NOTES

GENERAL.

American Dermatological Association.—At the twenty-eighth annual meeting, held at Niagara Falls, on June 2 and 3, 1904, the following officers were elected for the ensuing year: President, Dr. William T. Corlett, of Cleveland, Ohio; vice-president, Dr. Frank H. Montgomery, of Chicago; secretary and treasurer, Dr. Charles J. White, of Boston; member of council, Dr. John A. Fordyce, of New York. It was decided to hold the next meeting of the Association in New York City, on December 28, 29 and 30, 1905.

Public Health Conference.—At the second annual conference of State and Territorial Health Officers with the United States Public Health and Marine-Hospital Service, held in Washington, June 3, Surgeon-General Wyman announced two new divisions of the service—zoology and pharmacology. Committees were appointed to consider the questions of prevention and spread of epidemic diseases, morbidity and mortality statistics, State legislation, and education. Committees also were named for the special investigation of cholera, yellow fever, plague, smallpox, tuberculosis, leprosy, and typhoid fever.

Pan-American Congress.—The next meeting will be held in Panama, the latter part of December. The Pan-American Congress meets every three years. It was started by Dr. William Pepper, of Philadelphia; Dr. C. A. L. Reed, of Cincinnati; Dr. Albert VanderVeer, of Albany; and Dr. H. L. E. Johnson, of Washington. The first meeting was held in Washington, in September, 1893, the second in Mexico, in 1896. The third was to have been held in Venezuela, in 1899, but was given up on account of the war in that country. The place of meeting was changed to Cuba, but had to be postponed until 1901, on account of the fever there. These meetings have always been well attended, and it is thought that Panama will be an interesting place for the convention. Further particulars will be sent out from time to time to the journals, together with notifications of the different officers appointed to represent this and other countries.

Dairy Inspection and Pasteurized Milk.—A New York exchange, commenting editorially on the impure milk-supply of New York City, says: This is a matter to which the public does not give sufficient attention. Pasteurized milk is free from impurity, and its use should be encouraged in every way possible. There should be a guarantee as to the purity of milk served in every city, but no such guarantee exists, except as to a comparatively small quantity, such as the pasteurized milk. About 1% of the milk sold in New York is called "certified milk," because the owners of the cows have voluntarily submitted to an inspection of their animals, and have received certificates that their cows are free from disease. But the purity of the remainder of the milk sold is uncertain. Tuberculous cows are frequently discovered, and the milk from such is sold in various cities. Dr. Koch, of Berlin, expressed the opinion that the germ of bovine tuberculosis is not transmissible to human beings. There has been good authority to the contrary, and an English commission which has been investigating the question has recently published a report to disprove the Koch theory. There should be an inspection of the cows that furnish milk for sale in any city. It is a necessary safeguard. But until such a system is provided and carefully enforced, the only safeguard is to use pasteurized milk, or that which is known to have undergone proper inspection.

Miscellaneous.—**California:** Dr. Walter Lindley, the editor of the *Southern California Practitioner*, has recently been elected Dean of the Medical College of the University of Southern California. This Los Angeles school is now entering its twentieth session. Dr. Lindley was one of the organizers of the school, and is professor of gynecology in that institution.—**Boston:** The number of deaths reported to the Board of Health for the week ended June 11, was 164, as compared with 189 the corresponding week last year. This makes a mortality for the recent date of 14.17 per 1,000. A number of important changes and additions will be made in the faculty of the Boston University School of Medicine at the beginning of the next school year. The curriculum will also be changed to meet the needs of the modern practitioner. Charles H. Thomas has been elected associate professor of clinical medicine, J. E. Briggs associate professor of surgery, and Edward E. Allen associate professor of anatomy. All three have been connected with the faculty as instructors and lecturers. Those newly elected are: Walter T. Adams, M.D., of Waltham; Edwin W. Smith, M.D., of East Boston; Albert S. Briggs, M.D., of Newton; and Frederick W. Colburn, M.D., of Boston. The other appointments are: Chas. T. Howard, lecturer on minor surgery; William H. Waters, lecturer on pathology and curator of the museum; and Orville R. Chadwell, instructor in microscopy and assistant in pathology.—**Philadelphia:** Sir Frederick Treves, the noted English surgeon, has recently been the guest of Dr. J. William White, and he had conferred upon him the honorary degree of LL.D. by the University of Pennsylvania at the recent commencement exercises.—Dr. W. C. Holloper has resigned from the visiting staff of the Methodist Episcopal Hospital, Philadelphia.

Patent Medicines and the Postal Department.—On June 1 Postmaster-General Payne made a declaration defining the attitude of the United States Postal Department to patent medicine advertisements. It is as follows: A large number of complaints having been received by the first assistant postmaster-general protesting vigorously against the United States mails being used for the purpose of circulating newspapers and other literature containing advertisements of alleged cures; the acting postmaster-general transmitted a number of these advertisements to the assistant attorney-general for the postoffice department, with the request for an opinion as to whether or not their transmittal through the mails constituted a violation of law. Mr. Robb, the then assistant attorney-general for the postoffice department, rendered an opinion, holding such advertisements a violation of law. The only intention which has ever been entertained by the administrative officers has been to suppress the advertisements, which the law officer of the department has held to be improper. Of course, the postoffice department has never had any intention of starting a crusade upon patent medicines, or of establishing a censorship upon advertisements printed in newspapers. There has been no change in the policy or practice of the department; the facts simply are, that certain abuses having been called to its attention, it has acted thereon as required by law. In the regular course of business in the office of the assistant attorney-general a number of cases were presented, in which so-called cures were complained of as being worthless, as well as the literature of the company selling the article of being improper. Analyses of these so-called remedies developed the fact, that in most instances the ingredients were simply starch and sugar. In a number of instances the pills and drugs contained ingredients injurious to the system and forbidden by law to be sold. It having thus appeared that these companies were defrauding the public by means of false and fraudulent representations made through the mails, the issuance of fraud orders was recommended to the postmaster-general, and accordingly issued by him. No action has been contemplated by the department save in these cases of impropriety and fraud.

EASTERN STATES.

Got \$18,500 for an Injured Eye.—A verdict of \$18,500 against the New York, New Haven & Hartford Railroad Company was given for personal injuries to Bessie M. Dresser. She lost an eye by being struck by a piece of casting from the tender of a passing train while she was a passenger on another train between Myrick and New Bedford on March 22, 1902. She sued for \$50,000 damages, and the company denied its liability. The piece of iron broke through the window glass opposite her seat and lodged in her eye.

Free Dispensary Work in Boston.—Commenting on the work accomplished at the Boston Dispensary, an exchange states that 20 years ago it had a staff of 39 physicians and its callers who sought aid numbered 31,725, or an average of 103 a day; last year the visits numbered 89,207, or 295 a day on the average, and it had the services of 77 physicians and surgeons, given without compensation. Besides this "office practice," as it might be called, the dispensary's 13 district doctors made 20,501 visits to patients' houses, and altogether 92,162 prescriptions were put up by its apothecaries. In spite of the fact that the Boston Dispensary is dependent on charitable generosity, it has kept out of debt and has so managed its affairs as to have an income to meet current expenses.

NEW YORK.

Bequests to Charity.—Miss Emily A. Watson has given \$25,000 to the Home for Incurables, for the purpose of adding a story to the south pavilion.

Money for Public Baths.—More than a million dollars has been appropriated by the Board of Aldermen for free public baths, \$345,000 being allowed for Brooklyn, \$633,000 for Manhattan, and \$75,000 for the Bronx.

Adulterants in Sweets.—Adulterants highly injurious to the health have been found in innocent looking cakes, cheap caramels and other sweet stuffs sold freely to children in New York City, and a report has been made to the Attorney-General of the State by chemists working under direction of the State Department of Agriculture. In one instance 11 grains of paraffin were found in four small chocolate covered cakes. The chemists declare that paraffin resists the action of strong acids, and is highly injurious to the digestive organs. Evidently it had been used by the bakers and candy manufacturers to keep their products from becoming stale. Other samples of candies disclosed anilin dyes and lead poisons. Injurious coloring matter was not confined to cheap candies, but was found in some of the most expensive varieties that are made.

Pulmonary Tuberculosis in Street Cleaners.—Dr. Woodbury, Street Cleaning Commissioner of New York City, has begun a personal investigation of the physical condition of the 6,000 street cleaners employed by the department. With the assistance of six physicians assigned to him by the Health Department, he will continue the examinations daily until all the men have been examined. This investigation has been

undertaken because of numerous printed reports which claim that many of the street cleaning force have become tuberculous from inhaling the dust of the streets. Already many cases of tuberculosis have been found but as a result of the examinations made thus far Dr. Woodbury states that the number of men suffering from pulmonary troubles would not be anywhere near a third of the total sweepers, and that he believes the number would be even less than a third of the men who are on the sick list. Out of 910 drivers in Manhattan, between January 1 and May 1, 144 reported ill from pulmonary diseases, of these cases 112 were bronchial and only three tuberculous. Of 430 drivers in Brooklyn 61 had pulmonary troubles, 43 being bronchial and 10 tuberculous.

SOUTHERN STATES.

To Vaccinate Policemen.—Orders have been issued by the Police Board of Baltimore, Md., that the entire Police Department must be vaccinated. The work is the result of a request made by the Health Department to the Police Board that members of the department, who frequently come in contact with persons suffering from smallpox, should, as a precaution, be vaccinated. The work is to be done by the health wardens, and the matrons, stablemen, and scrubwomen are all included in the order.

Doctors' Decision Final.—News from Washington states, that at the Cabinet meeting held recently it was decided that hereafter neither the President nor the Navy Department would entertain appeals from applicants for admission to the Naval Academy at Annapolis from the decision of the medical examining board. This decision is probably due to the fact that with the system of stricter examination of candidates much confusion has arisen from the appeals and protests which have been made to the authorities at Washington.

WESTERN STATES.

The Lowest Maximum Temperature.—Maximum temperatures at western cities Sunday, June 12, from the Weather Bureau reports: San Luis Obispo, 80°; Los Angeles, 80°; Portland, 80°; Carson City, 84°; San Francisco, 90°; Red Bluff, 100°; Fresno, 104°; Yuma, 104°; Phoenix, 110°; San Diego, 66°.

Fresh Milk on the Latin Plan.—A Chicago exchange states that St. Louis capitalists are reported to be interested in a plan to relieve Chicago's scarcity of milk and improve the quality of food given to infants. They propose to establish a number of distributing stations in Chicago from which goats will be sent out whenever an order for fresh milk is received. And, since there are dangers for the babies in the nursing bottles as well as in the ordinary milk of commerce, it is planned to have the infants take their nourishment entirely from the goats, a method which is said to be in vogue among the Latin races.

Mortality of Michigan during May, 1904.—The total number of deaths registered in Michigan for the month of May was 2,937, corresponding to a deathrate of 13.9% per 1,000 population. There were 275 fewer deaths than for the preceding month, and the rate was nearly 2% per 1,000 lower. Important causes of death were as follows: Pulmonary tuberculosis, 208; other forms of tuberculosis, 30; typhoid fever, 60; diphtheria and croup, 42; scarlet fever, 20; measles, 46; whoopingcough, 10; pneumonia, 271; cancer, 114; accidents and violence, 186. Typhoid fever diminished in prevalence, while considerable increase may be noted in deaths from measles. By ages there were 521 deaths of infants under 1 year; 195 deaths of children aged 1 to 4 years, and 935 deaths of elderly persons over 65 years of age. There were 3 deaths from smallpox during the month, 1 in Beaver township, Bay county; 1 in the city of Three Rivers, St. Joseph county, and 1 in the city of Saginaw.

FOREIGN NEWS AND NOTES

GENERAL.

Chinese Medical School.—News from Peking, under date of June 15, states that Si Liang, viceroy of the province of Sze Chuen, is arranging to open a medical school with French instructors. Thirty students from the Chinese troops have been designated to receive medical instruction, returning eventually to their respective regiments.

Mosquito War in Samoa.—It is reported that the United States naval authorities in Tutuila, Samoa, have begun a general crusade against the mosquito. The effort is being made not solely nor even principally because of the annoyance of the mosquito, but as a means of saving the Samoan people of Tutuila from the scourge of elephantiasis. It is believed that this disease, which claims nearly half the people of Samoa as victims, is due to a parasite which lives in the mosquito. The mosquitos dying and falling into the stagnant pools of the islands liberate the parasites, scattering them broadcast in the water which the natives drink. The naval commandant believes that by warning the natives of the danger, and by

draining and filling up the worst pools and eventually all of them, the spread of the disease may be checked.

Bubonic Plague in Peru.—News from Guayaquil, under date of June 11, states that news has reached there of an outbreak of bubonic plague at Paita, Peru (on the border of Ecuador and Peru), and is causing a great panic. The Board of Health is acting energetically to prevent the introduction of the plague there. The port has been closed to arrivals from infected ports, and a sanitary cordon has been established at the frontier to prevent the introduction of the plague by land.

The Sixth International Congress of Physiology will be held at Brussels, in the Institut Solvay, from August 30 to September 3, 1904, with Professor Heger as president. One session will be devoted to the report of the International Commission appointed at Cambridge in 1898 for the unification of standards in physiology, and to the nomination of a committee of arrangements for the following congress. If the number of communications warrants, special sections in physiologic chemistry or in experimental psychology will be organized.

Decrease in London's Deathrate.—According to statistics recently issued the deathrate for London for the year 1903 is the lowest hitherto recorded and was below that of 1902 by 2.00 per 1,000. The estimated population of Greater London was 6,806,296 and the mortality rate was 14.5 per 1,000 as compared with 18.5, 17.7, 16.3 severally in the four preceding years. Of this number 4,613,812 were estimated to be living in Inner or Registration London, the deaths numbered 72,109, births 130,906, showing an excess of 58,797 births over deaths. Smallpox was returned as the certified cause of only 13 deaths during the year 1903, as compared with 229 and 1,314 in the years 1901 and 1902 respectively. Pulmonary tuberculosis accounted for 7,347 deaths, which compares with an average of 8,176 in the 10 years since 1893. The birthrate for the whole United Kingdom for the three months ended March 31, 1904, was 28.1 per 1,000 and the deathrate 18.7 per 1,000.

Surgical Treatment of a Wound of the Heart.—A correspondent writes from Paris to the London *Lancet* that at the meeting of the Society of Surgery which was held on April 27, M. Richet read an account of an operation performed for wound of the heart. The left ventricle had been perforated by a revolver bullet 8 mm. in diameter, which had also grazed the greater curvature of the stomach, the upper border of the spleen, and the lower border of the left lung. The patient, a man, aged 34 years was taken into hospital 15 minutes after the accident. He was at once given injections of caffeine and of artificial serum and the operation was begun in 1½ hours after the accident. The wound of entrance was in the fifth interspace and there was pneumothorax. A large flap was made from the whole thickness of the thoracic wall and the two wounds in the heart and those in the pericardium had been sutured with catgut, when the heart ceased to beat despite direct massage of the organ being employed. M. Richet reminded the meeting that his first similar case had been successful, and that he had shown the patient before the society in perfect health.

OBITUARIES.

Nathan Smith Davis, the eminent Chicago physician and author, June 16, aged 87. He was a native of New York City, having been educated at Cazenovia and was graduated from the College of Physicians and Surgeons, at Fairfield, N. Y., in 1837. He practised in Binghamton, N. Y., from 1847 to 1849, during which time he was lecturer at the College of Physicians; in 1849 he was called to Chicago to occupy the chair of physiology and pathology in Rush Medical College; later he was called to the chair of practice of medicine in the same institution. He became editor of the *Chicago Medical Examiner* in 1860, and conducted the *Northwestern Journal* for more than twenty years. He was one of the founders of the Northwestern University, of the Chicago Academy of Science, and of the Washington Home for Reformation of Inebriates. In 1883 he was called to the editorship of the *Journal of the American Medical Association*, which position he held for six years. He was president of the International Medical Congress in 1887, and was for many years Dean of the Northwestern University, which position he resigned in 1898. He was a member of the staff of the Mercy Hospital for forty years; was a voluminous writer and a highly esteemed and public-spirited citizen.

Charles Mann, at his home in Nicholasville, Ky., June 1, from paralysis, aged 67. A graduate of the Medical College of Ohio, Cincinnati, in 1861, and for forty years a member of the American Medical Association; member of the Kentucky State Medical Society and of the Jessamine County Medical Society. He was an army surgeon in the Confederate service during the Civil war. He was well known and esteemed in the vicinity of his home.

James Simpson, of Philadelphia, at the German Hospital, June 20, aged 65. He graduated from Jefferson Medical College, and during the Civil war had charge of the Government Hospital, in Alexandria, Va., for several years. He was chief of the staff of physicians to St. Mary's Hospital. He was well known in Philadelphia, where he had an extensive practice in the southwestern section of the city.

Joshua C. Noyes, of Oshkosh, Wis., in St. Mary's Hospital in that city, June 7, after an operation for amputation of the leg for osteosarcoma, aged 64. A graduate of Rush Medical College, in 1863; member of the American Medical Association and army surgeon in the Confederate service during the Civil war.

Pohattan A. Jordan, of Beaumont, Texas, at the Sister's Hospital, in that city, May 31, aged 67. A graduate of the University of Pennsylvania, and formerly preceptor in anatomy in the University of Georgetown, Medical Department. He was an army surgeon in the Confederate service during the Civil war.

Lawrence G. Andrews, formerly of Youngstown, Ohio, at the Western Pennsylvania Hospital for the Insane, Dixmont, where he had been a patient for 20 years, June 1, aged 75. A graduate of the Cleveland Medical College, in 1854. An army surgeon in the Federal service during the Civil war.

John M. Jackson, at his home in Columbus, Ky., May 31, from Bright's disease, aged 76; a graduate of the University of Louisville, medical department, in 1859, and an army surgeon in the Confederate service during the Civil war.

Myron H. Andrews, at his home in Detroit, June 3, from pneumonia, aged 87. A graduate of the University of Buffalo, (N. Y.), in 1847. City physician in Detroit from 1888 to 1891.

Emanuel L. Howerter, of pneumonia, at Kempton, Pa., March 25, aged 41. A graduate of the University of Pennsylvania, in 1889.

Elmer A. Johnson, of Danville, Ill., in Champaign, Ill., June 3, aged 36. A graduate of Rush Medical College, Chicago, in 1897.

Edgar R. Rust, formerly of Westmoreland County, Va., recently in Southern California, where he had gone for his health, aged 44.

Fred. L. Henkel, of Staunton, Va., near New Market, Va., May 21, aged 50; a graduate of the University of Pennsylvania in 1879.

James M. Clement, in Philadelphia, Pa., June 12, aged 67. A graduate of the University of Pennsylvania, in 1862.

THE PUBLIC SERVICE

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended June 17, 1904:

SMALLPOX—UNITED STATES.		Cases	Deaths

Changes in the Medical Corps of the U. S. Army for the week ended June 18, 1904:

RAND, Captain **IRVING W.**, assistant surgeon, is granted leave for twenty days, to take effect June 14.

HAVARD, Colonel **VALERY**, assistant surgeon-general, is relieved from duty at the U. S. Military Academy, West Point, N. Y., and will proceed about September 1 to Governor's Island, N. Y., and report to the commanding general, department of the East, for duty as chief surgeon of that department.

GILCHRIST, First Lieutenant **HARRY L.**, assistant surgeon, is granted leave for ten days, to take effect June 20.

BARRY, **EDMUND**, contract surgeon, is relieved from duty at Fort Dade, to take effect at such time as another medical officer shall be assigned to duty at that post, and will then repair to Washington, D. C., for annulment of contract.

WHITE, **FOREST E.**, sergeant first class, will be sent to Columbus Barracks for temporary duty as soon as his services can be spared at Columbia Arsenal, Tenn.

KIERSTED, First Lieutenant **HENRY S.**, assistant surgeon, now on duty at Camp U. S. Troops, Mount Gretna, Pa., will return to Fort Myer upon the arrival of First Lieutenant **Percy L. Jones**, assistant surgeon.

ADAIR, **GEORGE F.**, contract surgeon, now on temporary duty at Fort Hamilton, will return to his proper station—Fort Wadsworth.

MINOR, **J. C.**, contract surgeon, is granted leave for fifteen days, from about June 25.

PORTER, **LEWIS B.**, contract surgeon, will, upon the expiration of his present leave, proceed to his home for annulment of contract.

EISENMAN, **FRANCIS J.**, sergeant first class, now at Brooklyn, N. Y., upon expiration of furlough granted him from the Philippines Division, will report at Fort Leavenworth to relieve Sergeant First Class **Brown F. Atkin**. Sergeant First Class **Atkin** will be sent to Columbus Barracks for duty.

HARTUNG, **HENRY**, sergeant first class, Fort Myer, will be sent to Columbus Barracks, reporting to the commanding officer, third infantry, for duty with that regiment en route to Alaska. Upon arrival in Alaska he will be sent with Company D, Third Infantry, to Fort Davis to relieve Sergeant First Class **Thomas Person**. Sergeant First Class **Person** will be sent to Seattle, Wash., reporting by telegraph on arrival, to the military secretary, War Department, for further orders.

HARSON, **HARRY**, sergeant first class, is relieved from further duty in the Philippines Division, and will be sent to San Francisco, Cal., reporting for further orders.

KEENEY, **JOHN M.**, contract surgeon, leave granted January 2 is extended one month.

PHILLIPS, **Major J. L.**, surgeon, temporarily in charge of the office of chief surgeon of the department of the East, is relieved temporarily from his present duties as post surgeon, Fort Jay, and attending surgeon at headquarters, and will report direct to division headquarters for duty in connection with the field exercises at Manassas.

STILES, Captain **HENRY R.**, assistant surgeon, leave on surgeon's certificate granted May 21 is extended three months on account of sickness.

Vose, First Lieutenant **WILLIAM E.**, assistant surgeon, is granted leave for two months, to take effect upon the arrival at Fort Logan H. Roots of a medical officer to be ordered there to relieve him.

FISHER, **WILLIAM C.**, contract dental surgeon, is relieved from duty at Columbus Barracks, and will proceed to Fort Sheridan for duty.

STONEY, **RANDELL C.**, contract surgeon, is granted leave from June 18 to July 3.

GIDDINGS, First Lieutenant **EDWARD F.**, leave granted May 5 is extended one month.

ALLEN, **IRA A.**, contract surgeon, is relieved from duty in the Philippines Division, and, upon expiration of leave, will proceed from New York City to Fort Dade for duty.

Changes in the Medical Corps of the U. S. Navy for the week ended June 18, 1904:

HART, **G. G.**, acting assistant surgeon, ordered to the Alliance for temporary duty, and on arrival of that vessel at Culebra, W. I., detached and ordered home to wait orders.—June 10, 1904.

MINK, **O. J.**, and **PORTER**, **F. E.**, assistant surgeons, appointed assistant surgeons, with rank of lieutenant, junior grade, from June 7, 1904—June 13, 1904.

CHAPMAN, **R. B.**, assistant surgeon, detached from the Naval Hospital, Mare Island, Cal., and ordered to the Navy Yard, Washington, D. C.—June 15, 1904.

SOCIETY REPORTS

AMERICAN MEDICAL ASSOCIATION.

Fifty-fifth Annual Meeting, Held at Atlantic City, N. J.,
June 7 to 10, 1904.

[Specially reported for *American Medicine*.]

(Continued from p. 977.)

House of Delegates.

Committee on Hygiene.—J. N. HURTY (Indiana) read the report, recommending the adoption of the report referred to it relative to vital statistics, and the report was adopted.

Delegates to International Congresses.—President MUSSER was empowered to appoint any members as delegates who desired to attend the following meetings and whom he might designate: (1) International Otological Congress, which meets in August this year at Bordeaux; (2) the Röntgen Ray Congress, which meets in Berlin, 1905; and (3) the International Congress of Medicine, to appoint an organizing committee of 12 or 15 to take up the organization in this country.

Proposed Committee on Cancer Investigation.—J. C. HEMMETER (Baltimore) offered a communication with reference to the organization and the appointment of a Committee on Collective Cancer Investigation; referred to the Reference Committee on Hygiene and Public Health. This was later recommended favorably and the report adopted.

Committee on Legislation: Purification of the Mails.—The National Auxiliary Congressional and Legislative Committee, to whom was referred the resolution indorsing "the action of the postmaster-general, in enforcing the statute which prohibits the use of the United States mails for the distribution of obscene advertisements and fraudulent compounds and appliances," reported that they recommend the adoption of the resolution. The committee also advised the adoption of the resolution urging the proper federal and State authorities to take the necessary steps to protect life and eyesight from the pernicious influences of wood spirit or methyl alcohol and its various preparations. The committee then recommended the adoption of the report of the Committee on National Bureau of Medicines and Foods and the accompanying resolutions. E. ELIOT HARRIS (New York) moved the adoption of the report and its consideration in the committee of the whole of the House of Delegates immediately. The House then went into the committee of the whole with Harris as chairman. After considerable discussion, the committee arose, and the House of Delegates was called to order by President Musser. Harris reported to the House that the committee had instructed him to report unfavorably on the report of the special Committee on Medicines and Foods. He also reported instructions that the report on the communication from the Michigan State Medical Society was laid on the table. The report of the committee of the whole was adopted, and the original Committee on Medicines and Foods discharged.

Committee on Reapportionment of Delegates for the respective States and Territories for 1905, 1906 and 1907, reported as follows, the report being adopted:

State.	Members.	Delegates.	State.	Members.	Delegates.
Alabama.....	1,295	3	Missouri.....	1,400	3
Arizona.....	95	1	Montana.....	60	1
Arkansas.....	711	2	Nebraska.....	658	2
California.....	1,505	4	New Hampshire.....	350	1
Colorado.....	518	2	New Jersey.....	1,122	3
Connecticut.....	605	2	New Mexico.....	63	1
Delaware.....	154	1	New York.....	1,704	4
Dist. of Columbia.....	447	1	North Carolina.....	800	2
Florida.....	236	1	North Dakota.....	115	1
Georgia.....	650	2	Ohio.....	2,451	5
Hawaii.....	1	Oklahoma.....	163	1
Idaho.....	75	1	Oregon.....	222	1
Illinois.....	3,981	8	Pennsylvania.....	3,799	8
Indian Territory.....	168	1	Rhode Island.....	274	1
Indiana.....	1,947	4	South Carolina.....	207	1
Iowa.....	1,511	4	South Dakota.....	160	1
Kansas.....	562	2	Tennessee.....	1,004	3
Kentucky.....	1,361	3	Texas.....	2,321	5
Louisiana.....	819	2	Utah.....	89	1
Maine.....	461	1	Vermont.....	403	1
Maryland.....	715	2	Virginia.....	1,096	3
Massachusetts.....	2,681	6	Washington.....	420	1
Michigan.....	1,672	4	West Virginia.....	600	2
Minnesota.....	863	2	Wisconsin.....	1,185	3
Mississippi.....	606	2			

An additional report was adopted later, apportioning to New York a delegate for each 500 of its actual members and minor fraction, this for the years 1905, 1906, 1907.

Permanent Committee on Sections.—The Reference Committee on Constitution and By-Laws reported that in the opinion of this committee a permanent committee on sections and section work "to direct and advise in matters of section work," "to effect and maintain needed reforms," and "to devise ways and means of preparing the programs," would interfere with the prerogatives and autonomy of the chairmen and secretaries of the various sections, and therefore they do not recommend the appointment of such a committee.

Orations.—*Medicine*, CHARLES G. STOCKTON, Buffalo, N. Y.; *Surgery*, JOHN COLLINS WARREN, Boston, Mass.; *State Medicine*, GEORGE BLUMER, San Francisco, Cal.

The time for the next annual meeting was, on motion, left to the President, Secretary, and the Chairman of the Committee of Arrangements.

Scientific Exhibit.—A. P. OHLMACHER (Ohio) on behalf of the Reference Committee on Sections and Section Work, reported that the committee recommended to the Board of Trustees of this Association that an annual honorarium of \$500 be granted to the director of the Scientific Exhibit, and that F. B. Wynn be continued in the capacity of director of the Scientific Exhibit. The report of the committee was adopted, and the recommendation was reported favorably and referred to the Board of Trustees.

Committee on Hygiene.—J. N. HURTY (Indiana), chairman, said that the second annual report of the Committee on Prophylaxis of Venereal Diseases is an able and full report, treating of the moral and economic necessity of the prevention of venereal diseases, and that the Reference Committee recommends the acceptance of the report in general, but does not indorse the suggestion that "the time has arrived for the organization of a national society for the study and prevention of venereal diseases," but believes that for the present the Section on Hygiene and Sanitary Science will be equal to the task of doing the work necessary for the opening of this important matter. Adopted as read. Hurty also presented the endorsement of the Reference Committee on Hygiene and Public Health upon the following resolutions:

WHEREAS, The acquisition by the United States of insular possessions, in which a considerable amount of leprosy exists, particularly in Hawaii, has increased the responsibility of the government in the case of these unfortunate beings; therefore, be it

Resolved, That the American Medical Association urges on the Federal authorities the establishment of an experimental station, including hospital and laboratories, at the leper settlement in the Island of Molokai, Hawaii, for the investigation and study of leprosy, looking especially toward the cure of the disease. Adopted.

Amendments to Constitution.—S. L. JEPSON offered the following amendments to the Constitution:

Amendment to Chapter 7, Section 1 (page 7 as revised): Nominations for office, except that of the Treasurer, shall be made orally, but no nominating speech shall exceed two minutes in length. Any nominee receiving a majority of the votes cast shall be declared elected.

The Treasurer shall be nominated by the Board of Trustees.

J. N. McCORMACK offered the following amendments:

To amend Section 1, Chapter 4, of the By-Laws by striking out Section 1 and inserting in lieu thereof the following: "Time of Elections.—The election of officers shall be the first order of business of the House of Delegates after the reading of the minutes on the morning of the last day of the session."

And to amend Section 3 of the same chapter by striking out said section and inserting in lieu thereof the following: "Nominations for President shall be by ballot. All other officers shall be nominated by a committee of seven, representing the various geographic divisions of the country as nearly as may be."

These will lie over until next year.

Materia Medica Section.—The Section having received the report of the change of the present name of the section to that of "Pharmacology," by unanimous vote, requested that the title of the section be "Pharmacology and Therapeutics." G. ELIOT (Connecticut) offered the following amendment:

Proposed amendment to the By-Laws: Chapter 3, Section 1: That the name of the Section of Pharmacology be changed to the Section of Pharmacology and Therapeutics.

This will lie over until next year.

Section on Practice of Medicine.

SECOND SESSION (CONTINUED).

Treatment of Arteriosclerosis.—J. M. ANDERS (Philadelphia) divides cases of arteriosclerosis into these etiologic categories: 1. Those due to toxic agents in the blood, as in chronic alcoholism, syphilis, gout. 2. Those caused by constant ingestion of an excess of hydrocarbons or nitrogenous foods. 3. Cases dependent on constant hypertension due to muscular overexercise. 4. Cases of aortic regurgitation. 5. Cases due to senile degeneration. Prophylaxis should begin in early life. Regulation of the occupations of childhood is important; special attention should be given to the selection of foodstuffs in regard to the processes of katabolism that are engendered in their disposal. Athletic sport may cripple the arteries. Patients who are the subjects of arteriosclerosis are to be thoroughly investigated to determine their powers of assimilation, etc. Though many can resist the action of alcohol and gormandizing, diet in the great majority is of prime importance. When gormandizing or even overeating shows injurious effects the strictest living must be enjoined. Animal foods, if in moderation, may be beneficial rather than harmful. Water is to be freely ingested. Gouty individuals should live an outdoor life. In the early stages muscular exercise, well regulated, is of value in pumping from the system waste products. Massage is also to be employed. The quantitative estimation of the chlorids, urea, etc., while efforts are made to increase elimination must be constantly made. Without

proper attention the urea is usually 25% to 35% below normal. Warm baths materially lower blood-pressure and also assist in elimination. The expedients named are of major importance as compared with drugs in the management of cases of arteriosclerosis. Anders specially emphasized the importance of competitive athletics as a cause of the disease. The medical profession should urge moderation in games, particularly the more active ones. Warnings should be given those instructors in charge of universities and schools where athletics enter so largely into the life of the students. Here is where prophylaxis is of the utmost value. There is serious doubt if arteriosclerosis is ever arrested by the use of drugs, but they may retard its progress. The iodids do not lower blood-pressure in the early stages, but may do so later in the course; they are specially valuable in luetic cases. The results with nitrites and nitroglycerin were illustrated by charts showing sphygmographic tracings before and after their administration. Both dilate the arterioles and lower blood-pressure; the best results were obtained from the nitrites. Their effects are however evanescent.

Discussion.—ALFRED STENGEL (Philadelphia) said that arteriosclerosis from the aspect of the clinician differed from that of the pathologist. From the standpoint of treatment there is but little use to recognize the disease when nephritis or angina pectoris has supervened. It must be taken at an earlier period. Stengel still believes that alcohol is an etiologic factor, though of more importance is the relation of athletics, infectious diseases, etc. The latter are, to some extent, under the control of the physician, while alcohol and syphilis are but slightly manageable. An individual may apparently recover from an infectious disease, but later on arteriosclerosis comes to the front and steadily progresses. This means that physicians are to conduct convalescence with greater care, especially in typhoid fever. Some say that a year or more should be taken to recover from this disease, and this time is not excessive. It does not mean that the physician should actually visit the patient during this time, but his advice is needed regarding work, diet, and other points in the daily life of the individual. Cardiovascular diseases do occur in athletes at varying periods after their active exertions. The important point in arteriosclerosis is the early recognition; this is possible only by careful observations of blood-pressure, both at systole and diastole and by observance of the heart sounds. F. C. SHATTUCK (Boston) said that the papers on arteriosclerosis emphasized the fact that causes in medicine are rarely seen by the physician; he sees the results. The statistics of CABOT are possibly somewhat misleading, because they deal entirely with the poorer classes; it is in men who carry the burdens of business life, the captains of industry, who are under great strain, and who often carry strain badly, that alcohol is not well borne. From these men, statistics were not obtained. Such men may be apparently well, but add alcohol, and disease results. The alcohol drinkers who escape arteriosclerosis are not the weight carriers in the strenuous life. W. KRAUSS (Memphis) spoke of the parenchymatous changes in organs due to toxins in the blood, and the difficulty of eliminating other factors as causes of the condition. Patients who have had an infectious disease are much more liable to be affected by alcohol. He prefers to study syphilitic disease of arteries by itself, instead of under the head of arteriosclerosis. C. G. STOCKTON (Buffalo) reiterated the importance of abdominal pain as possibly depending upon arteriosclerosis; when this occurs the disease is usually far advanced. Treatment to be effective must be begun early, but it is not absolutely hopeless even in advanced cases. He cited several personal observations where individuals with arteriosclerosis and renal lesions are still alive and if anything, in better health at the expiration of five to seven years. Treatment has been simple and consists of restricted diet, exercise, taking of fluids, shunning of alcohol, and the systematic use of baths, that dilate the capillaries without markedly affecting the circulation in general. For this purpose, short hot air vapor baths, frequently given, produce the best results. If nitroglycerin is employed, it should be given hourly in small doses instead of at longer intervals. Stockton speaks a good word for the iodids; these, with vapor baths and nitroglycerin when necessary, form the principal active treatment. S. J. MELTZER (New York) spoke of the effect of local causes in producing arteriosclerosis as trauma, activity of organs, etc. If these findings of certain observers be true, then the deductions of Thayer may need revision if they are based on radial artery conditions alone; the latter may be local arteriosclerosis. Neither has Cabot the right to say that the etiologic power of alcohol is a myth unless he has studied the arteries of the splanchnic area. Meltzer closed by saying that alcohol in disease is often a blessing, in health often a curse. R. H. BABCOCK (Chicago) agreed with the remarks of Shattuck. At the present time one is not safe in attributing etiologic influence to any one factor. In all studies of the question the manner of taking alcohol should be considered. If large quantities of beer are consumed, the amount of fluid must be taken into account; in addition to this is the nutritive material in the beer. Babcock emphasizes the importance of strain as well as of alcohol in the production of the lesion. The types accompanied by hypertrophy of the heart are the ones that soon terminate fatally. F. R. WEBER (Milwaukee) believes that the explanation of the lesion must be sought in the poisoning of cell protoplasm. Osmosis is also of importance. Experiment with barium chlorid resulted in the pro-

duction of endarteritis in five months. BOARDMAN REED (Philadelphia) called attention to one point that was apparently overlooked by the previous speakers; that is the dose of alcohol. When this is considered, Cabot's view that alcohol does not cause arteriosclerosis may not appear inconsistent. Alcohol, in small or moderate doses, may produce arteriosclerosis indirectly by its action upon the gastrointestinal tract. The habitual whisky "soak" largely lives upon the alcohol that he takes in enormous quantities, and it may not result in arteriosclerosis. A. MCPHEDRAN (Toronto) in replying to remarks of a previous speaker said that the consumption of stronger alcohols in Canada is not excessive, and neither is arteriosclerosis. In connection with the epidemic of arsenical neuritis from English beer some few years since, he stated that probably some accessory condition was necessary before alcohol could cause arteriosclerosis. The variability of vitality of tissue in different persons must always be remembered. He thought that in decrying excessive muscular exercise some of the speakers had not said enough regarding the good effect of judicious athletics. It is constant instead of intermittent tension that causes arterial disease. A. JACOBI (New York) said that we employ mercury and the iodids for syphilitic arteritis, and yet we are told that the drugs themselves may cause the condition we are treating. The two do not agree. WELCH spoke of obstruction as a cause of hypertrophy of the heart; this brought to mind certain cases of congenital smallness of the arteries, in which a large heart would naturally be expected. On the contrary, the heart in such cases is normal in size or smaller than normal. Hence, obstruction itself does not appear to be the cause of hypertrophy. THAYER, in closing, said that in his investigations he had taken the condition of the radial only as an index of changes elsewhere. All evidence points to the fact, that continued or intermittent strain is the main great cause of arteriosclerosis. DRENNEN replied that we must use iodids and mercury in the treatment of syphilis; he does not object to their use, but he is opposed to the methods by which they are commonly employed. They should be used for a limited length of time only. Cabot said that in regard to competitive athletics as a cause of arterial disease, rowing is immoderate if any of them are, yet the published results of an examination of the Harvard men failed to show arterial changes. In the autopsy cases of his series the splanchnic area was not involved.

[To be continued.]

Section on Surgery and Anatomy.

FOURTH SESSION.

A Large Retroperitoneal Tumor Successfully Removed by Operation.—GEORGE BEN JOHNSON (Richmond, Va.) The tumor described was a retroperitoneal lipoma, a rare form of tumor of which 42 cases have been collected by Adami. The patient, a woman of 35, suffered from indefinite pains in the abdomen and was very much run down in health. At the time of operation a tumor was found which extended from the diaphragm to the pelvis. As the kidney was involved, it was necessary to remove it with the tumor. One of the great difficulties of the operation was in freeing the vena cava. The patient made an uninterrupted recovery. At the time it was removed it was thought to be a tumor of the pancreas, and it was sent to Opie, of Baltimore, for examination. The pathologic diagnosis given in detail showed it to be a fatty tumor. Tumors of this kind give very indefinite symptoms, which are usually caused by pressure, in this way interfering with circulation, the flow of intestinal contents, or of the bile, or they give trouble in breathing through pressure on the diaphragm, or pain from pressure on the nerves of the lumbar plexus. The difficulties in operation are caused by involvement of important organs.

Drainage of the Biliary Passages the Most Important Feature in the Surgery of the Gallbladder and the Bile Ducts.—MAURICE H. RICHARDSON (Boston) has come to take the position that gallstones should be removed whenever their presence is known, whether they offend or not, provided the condition of the patient permits. A few years ago he presented a paper advocating the removal of gallstones in case they caused trouble, but since that time he has become more radical in his views. The gallbladder should be drained in every case, he believes, until bile has entirely ceased to flow. If a biliary fistula persists, it is evidence either that the common duct is obstructed or that a stone has been left. A muscle-splitting incision should be used, which greatly lessens the danger of postoperative hernia, and also avoids injury to nerves. Gastric or hepatic symptoms, even if slight, are often of great significance, and failure of patients to make a complete recovery after abdominal operations, is often explained by the presence of gallstones. Gallstones never do any good, and they frequently do great harm. No other means of removal exists, except operation. In his experience Richardson has had better results from simply draining the gallbladder than from removing it entirely. When excision is done, symptoms frequently appear some time after the operation. In all operations on the biliary passages he advises drainage.

Gallstones in the Common Duct.—ARCHIBALD MACLAREN (St. Paul, Minn.) believes that it is doubtful if gall-

stones very often pass through the common duct leaving the gallbladder entirely free, and as long as they exist in the gallbladder the patient is usually subject to recurring attacks of cholecystitis. In passing through the common duct, stones are very likely to lodge, producing cholangitis, pancreatitis, or giving rise to the formation of a larger crop of gallstones back of the obstructing stone in the gallbladder or in the duct. Robson estimates that there is one case of stone in the common duct for every five cases of gallstone. Mayo places the frequency at one to seven. The inflammatory changes often produce contracture of the gallbladder and give rise to chronic obliterative inflammation. Operation was advised before stones had an opportunity to reach the common duct or give rise to other symptoms. Beside the diseased conditions mentioned, cancer is a common late result of stone in the duct. In order not to overlook stones, MacLaren advises using a long incision, giving free opportunity to examine the duct, using a sand bag to arch the spine forward toward the incision, and great care in thoroughly exploring the duct. In his own experience he has seen 47 cases of gallstone with 12 common duct stones.

Discussion.—JOSEPH D. BRYANT (New York City) agrees with Richardson as to the necessity of using drainage in all cases, and in operating in all cases as soon as a diagnosis is made. THIENHAUS (Milwaukee) called attention to the three distinct sections of the common duct which we have to deal with in operations of this kind. In the case of stone in the papillary portion of the duct he believes that the stone can best be removed by opening the duodenum as was first suggested by McBurney. MOORE (Minneapolis) regards the gallbladder as a safety valve which should not be removed in these cases if it is avoidable. He reported the case of a girl of 13, who had been jaundiced for several years, upon whom he operated, removing a stone from the common duct. On the third day after operation the patient showed symptoms of cholemia and had a convulsion. He made an incision into the loin, and through this drainage opening removed over a quart of bile. The patient recovered. This case emphasizes the necessity for draining not only the biliary passages, but the surrounding space, for slight leakage is inevitable. LAPLACE (Philadelphia) approves of long incisions, believes in the necessity for drainage, not only of the duct but the surrounding space, and believes that the irritation of the stone frequently tends to produce cancer. MAYO (Rochester, Minn.) believes that early operation for gallstones is as necessary as early operation for appendicitis. He does not agree that cholecystectomy is an obsolete operation. When the gallbladder is thrown out of use by stone, and contracture follows, it is safer to remove it. It is perfectly safe to leave the cystic duct open and drain with gauze and tube. BLOODGOOD (Baltimore). The results of operations at the Johns Hopkins Hospital would uphold the position taken by Richardson and MacLaren. Cholecystectomy has been employed in a large number of cases with very satisfactory results, Finney having been a strong advocate of this operation when it was not in general use. While the results of this operation have been satisfactory, splendid results have also followed cholecystostomy in suitable cases. Unfavorable results have occurred only from the presence of stones left in some of the ducts, or in cases where there has been prolonged inflammation. RICHARDSON, in closing, agreed that the gallbladder should be removed in certain cases, or it would prove a source of trouble later. MacLaren said that he had also had Moore's experience as regards leakage, but not in cases in which a drainage-tube had been properly sutured in place with catgut and surrounded by a pursestring suture.

Appendicitis in Children.—A. J. MCCOSH (New York City.) No surgical disease offers more surprises than appendicitis, and the diagnosis is frequently difficult. The best results both as regards saving life and the strength of the abdominal wall follow early operation, but in children, particularly, the symptoms are often masked and the diagnosis is somewhat more difficult than in adults. It is hard to definitely locate pain with children, they are often restless, they generally dread palpation, and complain that the pain is as great in one place as another. The abdominal walls are usually everywhere rigid. Vomiting is the most persistent symptom. The diagnosis has to be made between gastroenteritis, diaphragmatic pleurisy, and a low pneumonia. The blood count is of value, the differential count of more value than a simple white cell count. The iodine test he has also found of some value. The progress of the disease is often insidious, and in doubtful cases it is wise to operate at once. Of late, however, McCosh has been inclined more than formerly to delay operation in certain cases. In over 1,100 cases the patients were between 20 and 35 years in over 50%. Under 15 years in only 15% of the cases; his youngest patients were 12 months, 12½ months, and 16 months of age. Because of the difficulties in diagnosis, early operation is of more importance than in adults. The onset of general peritonitis is more insidious.

Should the Appendix be Removed When the Abdomen is Opened for Other Causes?—FLOYD W. McRAE (Atlanta) has performed 272 appendectomies, and in 40 cases he has removed the appendix at the time of other operation. In one case he did dilation and curetment, removed a cyst of the cervix, anchored a floating kidney, and removed the appendix at one operation without unusual shock or without unduly prolonging the operation. Nonremoval of the appendix, he believes, is the most frequent cause of incomplete cure following

abdominal and pelvic operations, for the inflammation frequently coexists with floating kidney, gallbladder, and rectal troubles, as well as with inflammatory conditions within the pelvis. In this, as with other operations, the golden rule should be observed when we decide whether the appendix should be removed or not.

[To be continued.]

Section on Obstetrics and Diseases of Women.

THIRD SESSION.

Surgical Treatment of Bilocular Uterus and Bifid Vagina.—H. W. LONGYEAR (Detroit) called attention to the scarcity of the literature on this subject, explained his method of treating such malformations, and reported two cases. A biseptate vagina is nearly always accompanied by a bilocular uterus. Longyear's method consists in grasping the vaginal septum for its full length with forceps, both posterior and anterior. He then cuts with scissors as near to each forceps as is convenient, and then sears the cut surface with the cautery. He now introduces the cervical dilator, one jaw into each os of the double cervix, cuts between them with the cautery, now with blunt-pointed scissors he cuts the septum well within the uterus, swabbing and packing with iodoform gauze. In both of the two instances reported the patients suffered much from dysmenorrhea. One patient showed the whole left side of the body better developed than the right, even to the uterus itself. In this instance the patient was extremely neurotic, a badly diseased ovary was removed, but the dysmenorrhea continued so severe that the patient became a drug fiend, and finally as a last resort the other ovary was removed.

Discussion.—BACON (Chicago) could see no reason why a double vagina and a bilocular uterus should produce dysmenorrhea. DUNNING (Indianapolis) has had two such cases. In neither instance was the deformity discovered until the woman came into labor. In both cases the septum between the ovaries and in the vagina was torn through, and in one instance in which the septum was thick and tough, a bad laceration resulted. He doubts the wisdom of ever cutting the septum within the uterus. JOHNSTONE reports a case in which a woman had a miscarriage, and he later curetted her uterus thoroughly. Somewhat later it was noticed that the abdomen was enlarging, she had fainting spells and other disorders attributed to the uterus, her life was threatened; abortion was induced, and she was delivered of a five months' fetus. This could not have been in the uterus, normally, at the time of the curetment, and investigation showed a bilocular uterus. Thus two impregnated ovaries were in the uterus at the same time, and in each locale. CARSTENS (Detroit) reports that a woman in the third miscarriage had a retained placenta. In removing it a septum was found in the uterus. This was removed and several successful pregnancies resulted. DORSETT (St. Louis) reported an instance in which he divided the vaginal septum and also for a short distance that in the uterus. He feared to go too high in the uterus least he open into the peritoneal cavity. Operation should depend on the nature of the condition.

A Plea for More Thorough Examination of Doubtful Specimens of Ectopic Pregnancy.—J. WESLEY BOVÉE (Washington, D. C.) held that many cases of so-called tubal pregnancies, when thoroughly and systematically examined by the microscope are found in reality not to have been pregnancies, but tubal hemorrhages, or some condition other than pregnancy. The tacit conception that all such are pregnancies does great wrong to virgins and widows who may happen to suffer from this condition. Among the cases he has operated on since he began a systematic microscopic examination of these removed masses there have been 10 which proved other than pregnancies. Of these a hematosalpinx existed in six. He urges microscopic examination in all doubtful cases. The symptomatology is the same in all these cases.

Ectopic Gestation with Atypical Symptoms: Report of Cases.—WALTER B. DORSETT (St. Louis) said our knowledge of the symptomatology of ectopic pregnancy is far from complete. Bland Sutton has said that a healthy tube is more apt to contain an impregnated ovum than is a diseased one. Right-sided tubal pregnancy may be mistaken for appendicular abscess. He had operated on 41 cases of extrauterine pregnancy with six deaths. In some the diagnosis of the true condition was not made prior to the operation, but the patients' symptoms demanded surgical interference regardless of the exact condition. A ruptured pregnant tube may reveal no direct evidence of the pregnancy at the time of operation because the peritoneal fluid may have digested the small fetus and the chorionic villi. Several specimens were exhibited, and cases were reported in detail. Extrauterine pregnancy is more frequent than is commonly supposed, and its symptoms are often atypical.

Discussion.—F. F. LAWRENCE (Columbus, O.) reported an instance in which two tubal pregnancies occurred in the same patient within 14 months. There is no dependence to be placed in the pulse and temperature in these cases. Every doubtful specimen should be examined microscopically. MASSEY (Philadelphia) believed too many of these patients are operated upon. Watch the patient and be guided by her condition. HUMMISTON insisted that the uterus and adnexa may be normal

and yet there occur a tubal pregnancy. Early operation in rupture gives the only hope. He would operate even in shock, giving hypodermoclysis at the same time. STONE held that the microscope may not reveal positive evidence of a pregnancy, even when the mass is such, because the fetus and chorionic villi have been digested. DUDLEY (New York City) insisted on early diagnosis and early operation. In a nonseptic condition he would not remove the tube and ovary of the affected side. This is the practice of Ohlshausen, and is correct. In conclusion, BOVÉE held that the microscope should show positive evidence of pregnancy two or three months after rupture, should such a time elapse before operation became imperative or death occur. He would never leave the tube and ovary of affected side.

[To be continued.]

Section on Diseases of Children.

FOURTH SESSION.

Hematuria as the Earliest or only Symptom of Infantile Scurvy.—JOHN L. MORSE (Boston) stated that hematuria, though generally considered to be an unusual and unimportant symptom of infantile scurvy, was in many cases the earliest and only manifestation of the disease. He cited several cases showing how the hematuria had led to a diagnosis of scurvy, the bloody urine being present days or even weeks before any other symptom appeared. The speaker said the most common cause of uncomplicated hematuria in infants was scurvy.

Discussion.—AGER (Brooklyn) spoke of the difficulty of collecting urine in young children asking that the speaker explain his methods. STOWELL (New York) employed a small rubber catheter in securing urine for examination. He emphasized the importance of a more careful and systematic examination of the urine in children. He discussed the etiology of hematuria, citing the rarity of calculus as a causative factor in children as compared to its frequency in adults. He thought hematuria might be due to some specific germ. He said adrenalin at present gave the best curative results. McCLANAHAN (Omaha, Neb.) believed scorbutus was easily cured if recognized early, but too frequently it had progressed too far when diagnosed.

Intestinal Obstruction in Children.—JOHN F. ERDMAN (New York City) spoke first of intussusception. He said the diagnosis of this condition was made more often by the presence of mucus, bloody mucus or bloody stool than by the sausage-shaped tumor in the right iliac region. He thought the tumor was more likely to be round, or nodulated and movable than sausage-shaped and that the condition must exist some time before the tumor could be palpated. Sudden and violent pain is the first symptom, later becoming recurrent and colicky. There is a rise of temperature of 1° to 2° F. He discussed the difficulty of making a differential diagnosis from appendicular masses and other conditions simulating intussusception. He doesn't advise the use of enemas for reduction after the condition has existed six hours but advocates the use of enemas just prior to operation. He described in detail his method of operating and advised against the employment of traction in reduction. The appendix is usually removed. He usually makes his incision through the right rectus muscle as the ileocecal variety is the commonest and it lessens the liability to hernia. Examine carefully the abdominal contents for other causes of intussusception which not infrequently exist. The child usually has an enteritis following correction of the condition, passing greenish, foul-smelling stools. He spoke of cases of spontaneous reduction but thought they were rare and not usually complete. He spoke of the diagnosis and methods of treating strangulated hernia saying that 8.8% of all cases occur in children.

Discussion.—ABT (Chicago) thought cases of intestinal obstruction were not all mechanical, but often paralytic. He cited several cases he had seen that simulated obstruction, but thought they might be instances of ptomain poisoning. FISHER (New York) stated that children did not bear laparotomies well, the question of shock being the greatest factor. KELLY (Cleveland) advocated the use of opium early in the attack to produce spontaneous reduction as it quiets peristalsis. He thought manipulation if correctly employed was beneficial. In the use of injections of air and water to reduce an intussusception he thought air would be better if it could be measured. He often employed air first and followed it by water. A pressure of four or five pounds kept up for fifteen minutes he considered better than a higher pressure for a shorter time. HAMILL (Philadelphia) discussed the methods used in experimenting upon animals for the reduction of intussusception. MORSE (Boston) stated that children bear operation well if kept warm. In summing up, ERDMAN said that pressure of even six pounds could not be kept up. He said shock was primarily the cause of death in operating upon these cases. Hemorrhage from bowels nearly always follows reduction by manipulation. He stated that his operations were done in from 11 to 20 minutes, including the excision of the appendix. Intussusception will completely occlude the caliber of the gut.

Perinephritis in Children.—W. R. TOWNSEND (New York City) defined the condition as an inflammation of the tissues around the kidney, and said it was frequently dis-

cussed under the terms paranephritis, epinephritis, and perinephritic abscess. The disease is comparatively infrequent in children, but an erroneous diagnosis is made in 50% of cases. A correct diagnosis of the condition is rarely made before the appearance of the abscess, though it is possible in most cases if proper examination is made. The disease is described as primary or secondary, acute or chronic. In discussing the etiology he said it usually followed exposure, injury, excessive exercise, infection of perinephritic tissue, perforation of intestinal tract, extension from surrounding tissues, etc. It may follow typhoid, gallstones, pleurisy, pneumonia, etc. Eighty percent of primary cases, and all secondary cases end in abscess. It may be mistaken for neuralgia or lumbago. Frequently it is diagnosed as Pott's disease, as the spine is held rigid to lessen the pain. If psoas contraction occurs there will be flexion of the thigh and lameness with inclination of the body toward the affected side. Constipation is the rule, probably due to the great pain caused by defecation, though diarrhea has been noted. The disease is probably most often mistaken for Pott's disease, hip-joint disease, or infectious osteomyelitis of the spine. The speaker brought out the principal points of differential diagnosis between these conditions. If abscess exists, prompt surgical interference is necessary. He reported a number of cases in which an erroneous diagnosis had been made, all of these recovering promptly after operation.

Discussion.—JACOBI (New York) said the condition may be caused by a distended colon or by infection from the colon and suggested constipation as a cause as well as an accompaniment of the disease.

Diagnosis of Enlarged Bronchial Lymph-nodes in Children.—ALFRED FRIEDLANDER (Cincinnati) described these various glands and their anatomic relations. He discussed the frequent occurrence of these enlarged lymph-nodes saying they were but the precursor of tuberculosis, in fact, the autopsies in the majority of cases proved them to be tuberculous. He spoke of the liability of measles, whoopingcough and allied conditions to lay the foundation for tuberculosis. Tuberculosis in childhood is almost always a lymphatic involvement. It is very important that at least a presumptive diagnosis be made early, because of the amenability of the condition to treatment at that time. One of the first symptoms of enlarged bronchial glands is a paroxysmal cough. The appetite is capricious and anemia is often present which should always be looked upon with suspicion. The bronchial glands lie under an unyielding portion of the chest and when enlarged give many varieties of pressure phenomena. A sign of value in diagnosing this condition is a greater degree of enlargement in the subclavicular glands than those of the cervical region. A sign of some diagnostic value is a venous hum heard over the manubrium sternal when the child holds its head back and eyes looking toward the ceiling. An examination of the blood revealed a lymphocytosis in all cases studied.

Discussion.—GILBERT (Louisville, Ky.) spoke of the diagnosis of enlargement of the bronchial lymph glands, saying he usually recognized the condition by the appearance of a paroxysmal cough not relieved by the ordinary cough remedies. In such instances he employs iodid of potassium, which usually clears up the condition. JACK (Buffalo) believes the spasmodic cough of asthma and allied conditions was due to enlarged glands rather than to muscular spasm of the bronchial tubes. He believed the enlargement was due to material carried there by the circulation, these glands being the dumping ground for the blood. The question of adenoids and their harmful results was dwelt upon at length by the various members of the section. FRIEDLANDER thought that adenoids had received their full quota of consideration, and that other conditions might occasionally be present, demanding attention.

The Importance of an Early Aural Examination in Acute Inflammatory Diseases in Children.—JAMES F. MCKERNON (New York City) emphasized the necessity for frequent aural examinations during the course of acute inflammatory diseases. He said thorough and systematic examinations of the ear should be made regularly in children suffering from the exanthematous diseases. He described the methods of manipulating the parts so as to give space for viewing the deeper structures. The failure of the temperature to subside after an acute infection is not infrequently due to middle-ear disease. In an acute coryza, where the nose is blown often, mucus may be forced into the eustachian tube and an otitis media set up. Disease of the labyrinth often occurs in the course of enteric fever. In an acute middle-ear suppuration, with some temperature and a discharging ear, the danger of intracranial involvement is great. The writer had seen at least seven cases of involvement of the jugular bulb without the mastoid structures being affected. If acute cases were early recognized and treated, there would be no chronic cases.

Discussion.—JARECKY (New York) also recommended routine examinations of the ear in acute infections. He discussed the methods of examining ears of children as compared with those used in the adult. If any bulging occurs promptly incise the drum and wash out with an antiseptic solution. WALKER (Chicago) said otitis media could simulate almost any disease and cited a case diagnosed as pneumonia and typhoid which later proved to be middle-ear suppuration. HAMILL (Philadelphia) stated it was almost impossible for a man other than a specialist to diagnosticate otitis media before rupture of

the drum occurs. FISCHER (New York) discussed the temperature of otitis and its fluctuating character. He had seen cases in which the temperature was apparently normal and thought too much stress should not be laid on this symptom as a factor in diagnosis. Too strenuous cleansing of the nose may result in otitic disease. NYACK (New York) cited a case in which he had made careful observations and strongly endorsed routine, aural examinations. Chairman KERLEY said in 51 cases he had examined, the temperature was about his only guide. He emphasized the importance of otoscopic examination. He had three cases in which there was involvement of the jugular bulb and streptococci were found in the blood. McKERNON advised against the use of peroxid of hydrogen in irrigation as it may displace infectious matter and induce mastoid disease. He would incise immediately in all cases of bulging of the membrane and sometimes when no bulging occurs. He thought that in every case there had been temperature even though it were not present at the time of the examination. Never use a douche or spray in the nose of a child but wipe out the nasal chambers with a cotton drip probe.

Section on Ophthalmology.

SECOND SESSION.

Is Bilateral Operation for Cataract ever Justifiable, and if not, How Soon after the Operation on the First Eye is it Safe to Extract the Second Cataract?—A. W. CALHOUN (Atlanta, Ga.) read a paper with this title and referred to a circular letter he had sent to 57 American ophthalmologists to determine this question. He briefly stated the replies, which were equally divided on both sides of the question. He quoted cases in which anomalous healing, infection, and other complications affecting the first eye would have been more serious in prognosis had both eyes been operated upon at the same sitting. He also cited cases in which unfavorable results followed the bilateral operation and cases in which the eyes were operated upon separately, with a bad result in the first eye and a good result in the second at a much later period. He thought the dangers from temporary mental perturbation, sneezing, coughing, etc., were of more serious import following the bilateral operation. Personally, he would not submit to bilateral operation and said he believed it to be unjustifiable for the following reasons: The danger and numerous sources of infection; the menace to the eye through the occasional anomalous healing process of the corneal wound; the peculiar helpless condition of the patient with double extraction, and the depression of spirits in the event of serious inflammation retarding recovery; the great advantage and value of the experience gained by the single operation; the various accidents followed by a possible sympathetic inflammation which necessitate enucleation of the eye upon which the operation is performed; and the disturbed mental condition, such as hallucinations, acute mania, etc., that may arise and retard the healing process. He also gave a number of sound reasons why the second cataract should not be extracted at all if the first operation was successful. He never urges the second operation when the first is successful unless the patient especially desires it, then if at the end of six or eight weeks there is an entire subsidence of inflammatory symptoms the second operation is performed.

Discussion was opened by J. M. RAY (Louisville, Ky.), who agreed with the essayist as to the unjustifiability of the operation, and stated that it was seldom necessary to consider the procedure, as few cataracts mature at the same time. Usually one is mature before the other. He had never performed the bilateral operation, but saw no reason why the second eye should not be operated upon eight days after the first if the patient so desired it, and there were no inflammatory symptoms. He objected to the bilateral condition in patients over 70 years of age. J. L. THOMPSON (Indianapolis) related his early experiences with the bilateral operation and the good results he obtained, but stated that now he prefers not to consider the operation except under certain circumstances. He urged the necessity of iridectomy and especially a preliminary iridectomy in all cases. H. A. HANSELL (Philadelphia) said he had operated upon 12 cases bilaterally with encouraging results, and that he could see no greater danger in the double than the single operation with the usual precautions. He always consulted the desires of the patient in the matter, allowing him to share the responsibility. S. B. MUNCASTER (Washington) also discussed the paper, giving his opinion and results in the operation. P. A. CALLAN (New York City) believed Calhoun to be too radical in condemning the operation, and stated that he had frequently performed the operation without bad results. He always operates thus if the patient desires it and the cases are uncomplicated. He thinks the patient should be given all the vision possible. CLARK (Columbus, Ohio), did not think the patient's desires should influence the question of operation, and believed that the surgeon should decide the matter on his own judgment, as the responsibility rested entirely with him. THORPE took part in the general discussion, and asked the essayist if he had ever performed the bilateral operation on a patient 40 years of age for congenital cataract. Calhoun, in closing the discussion, remarked on the unanimity of opinion concerning this operation. He stated that at one time he operated

bilaterally, with success, but seeing a case of failure in the hands of a colleague, has since deterred him from employing this procedure. He thought the period of eight days suggested by Ray was too short, and believed a period of six to eight weeks was none too long. He recalled no case of bilateral extraction for congenital cataract in a patient of 40 years. He then related the histories of several cases of traumatic cataract and showed their relation to the bilateral operation.

Reclination of the Lens, under Certain Conditions a Justifiable Operation.—E. T. ROGERS read this paper which consisted of a definition of the operation and the various forms of couching together with a brief history of the procedure and the various methods employed by regular and irregular surgeons. He quoted statistics from various sources and reported several cases with favorable results. He also made a comparison of the results following traumatic dislocation of the lens. The essayist made reference to a circular letter he sent to 73 leading ophthalmologists concerning the operation of reclination and tabulated their opinions with a view of determining whether or not the operation was justifiable and the conditions in which it may be of value. The reader then recited the history of a case in which one eye alone was present and was cataractous and other operative measures were impracticable on account of an intractable conjunctivitis and dacryocystitis. Six months after the operation of reclination vision was fairly good but the result at the end of a year was not so good. Neuralgia was present as a complication. He concluded from his observations that in cases in which opening of the eyeball for the extraction of the lens was contraindicated for any reason that this operation should be at least considered.

Discussion was opened by L. W. FOX (Philadelphia) who stated that he rejected the operation on account of the great liability to be followed by glaucoma and iridocyclitis which complications more than overbalance its good results. He urged treatment of the conjunctival and lacrimal conditions over a much longer period and the employment of less strong solutions. He advised in intractable cases with cataract, ligation or extirpation of the sac and then removal of the lens by extraction. He briefly referred to his antiseptic technic in the preparation of the patient for operation stating that it was especially applicable to these cases. He applies gauze pads saturated with a 1 to 5000 bichlorid of mercury solution to the eyelids continuously for several hours before the operation and immediately before the operation thoroughly flushes the cul-de-sac with sterile boric acid solution by means of a pipet connected to an irrigating bottle by means of rubber tubing. He also made mention of Manthner's method of reclination and stated that he spoke of it only to condemn it. He said he was opposed to the routine practicing of the procedure and to teaching of it as such but would be slow to criticize it in individual cases taking into consideration the personal equation of the operator. H. V. WÜRDEMANN (Milwaukee) said he was convinced that it should be rejected and did not think that conjunctival and lacrimal disease to be sufficient indications for its performance as he feared puncture of the eye in these cases more than corneal section. He had only seen one case in which reclination was indicated. In this instance nature had performed a partial reclination in one eye and he then performed a complete reclination in the other eye, holding the lens down for five minutes, and obtained good results. J. R. THOMPSON (Indianapolis) stated that in fluid vitreous in which nothing else was practicable he had performed it with gratifying results, but preceded it and other cataract operations with a preliminary iridectomy. PARK (Harrisburg) mentioned a case in which reclination was accidentally performed during an attempt to perform the extraction operation. The results were good and had remained so for 8 years and the patient was thinking of having a similar operation on the other eye. S. D. RISLEY (Philadelphia) related the history of a colored man on whom a surgeon reclined the lens on the roadway with an ordinary needle; 12 years later he consulted Risley and then had fluid vitreous, floating lens, atrophic choroiditis, and extremely poor vision almost to the degree of blindness. He believed that atrophic choroiditis was a common sequel in all these cases. In closing the discussion, Rogers stated that he thought the cases in which it was indicated were very rare, but they did exist. He accepted the dangers and complications mentioned as possible, but he thinks the individual features of each case should be considered. In response to Risley, he doubted whether the choroidal condition had not previously existed.

[To be continued.]

Section on Pathology and Physiology.

THIRD SESSION.

Physiology of the Middle-ear.—J. HOLINGER (Chicago). The middle-ear consists of the eustachian tube, the mastoid cells, and the drum cavity which contains the membrane and the ossicles. The first two are accessories of the third. The middle-ear apparatus consists of the membrane plus the chain of ossicles. The paper further discusses the physiologic action of this apparatus according to Helmholtz's analysis of the work of Zimmermann, and of Bezold's contradictions of the same and the theories which the latter has elaborated. The function of the mastoid cells and of the eustachian tube is, according to

Holinger, simply that of an air reservoir. One of the main points brought out by the paper is the value of the careful observation of pathologic conditions in the analysis of old theories and in the formation of new.

The Anatomy of Bartholin's Glands; Cysts of Bartholin's Glands.—THOMAS S. CULLEN (Baltimore). These glands, first described by Duvernoy (1631) and first carefully studied by Bartholin (1676), are situated in the lateroposterior wall of the vagina, about 1 cm. from the posterior margin and are about the size of an elongated pea. The glands consist of a collecting duct with many secondary ducts running from them into definite lobules of irregular form. In the early embryo the glands appear as solid cords passing from the urogenital sinus. The main duct near the vagina is lined by squamous epithelium, nearer the gland by transitional epithelium, the superficial layer of which is cylindric; the secondary ducts are lined by transitional epithelium or one layer of cuboidal; the gland proper is lined by one layer of cylindric epithelium which closely resembles that of the glands of the cervix uteri. As a result of inflammatory processes the duct may become occluded and retention cysts result. The form of the cyst will naturally vary according to the point where the occlusion occurs.

The next paper, **Further Studies on Bacterial Intracellular Toxins**, VICTOR C. VAUGHAN (Ann Arbor), excited the greatest interest of any of the papers presented to the session. The toxins are obtained by chemie extraction of masses of bacteria grown in tanks containing 22 square feet. The studies have been followed for the past six years, and show that many bacterial cells are more or less poisonous. The work has been done mainly with colon, typhoid and anthrax. From these pathogenic organisms toxic substances have been split off by the use of dilute acids. It seems to matter little whether this acid be a weak or a strong dilution, which goes to prove the chemie nature of the process. These toxins are called basic toxins and are not protamins. With aqueous alkalin solutions the extracts are mucilaginous, almost impossible to filter. But if the cells be treated with 2% solution of caustic soda in alcohol the extract is perfectly clear and filters readily. The substance purified by repeated washing and redissolving is soluble in water. This is powerfully toxic, killing guinea pigs of 400 gm. weight in a few minutes. Experiments are now in progress to determine if the injection of these extracts will confer an immunity to subsequent inoculation with the living germ. The work has progressed sufficiently to show that immunity can thus be induced. On the basis of these results Vaughan has elaborated a slightly new idea of immunity, though it is really nothing more than the reduction of Ehrlich's theory to more definite chemie terms. The paper is of the greatest value and interest, since it is the first step, and a long step, toward placing the theory of immunity upon a definite, chemie basis.

The discussion by TERRELL (Galveston), CLEMENS (Rutledge), SEWALL (Denver), MELTZER (New York), and VAUGHAN dealt with several minor points which were not quite clear in the paper. HALL (Chicago) moved a vote of appreciation of the excellence of Vaughan's paper, which vote was unanimously passed.

The Pelvic Ureteral Sheath and its Relation to the Extension of Carcinoma Cervicis Uteri.—JOHN A. SAMPSON (Baltimore). The pelvic portion of the ureter is surrounded by a sheath which is apparently derived from the tissues which surround the ureter. This sheath is of a definite anatomic structure, and is of great importance to the ureter, since it forms a channel in which the ureter may slide as it contracts, and protects the ureter, together with its bloodvessels, from the invasion of newgrowths or of inflammatory processes. On the other hand, the involvement of the sheath by a neoplasm or an inflammatory process compresses the ureter, causing hydronephrosis, and predisposing the kidney to infection.

The next in order was the business meeting of the session. Upon motion of Rosenau, Washington, the secretary was instructed to cast a unanimous ballot for the names presented by the nominating committee, for president, Winfield S. Hall, Chicago; for secretary, Henry A. Christian, Boston; for delegate, Joseph MacFarland, Philadelphia.

The Passage of Different Foodstuffs from the Stomach.—W. B. CANNON (Boston). Different foodstuffs mixed with bismuth subnitrate can be studied in passage from the stomach by the röntgen ray. Aggregate length of shadows cast by food in the small intestine indicates the relative amount passed from the stomach at different observations. The three kinds of foodstuffs, similar in amount and consistency, were fed separately. Carbohydrates and fats begin leaving the stomach soon after ingestion; carbohydrates leave rapidly, fats slowly. Proteids begin passing out much later than the others, and go slowly. The remarkable difference between proteids and carbohydrates can be explained by assuming that free acid opens the pylorus. Proteids delay the appearance of free acid and therefore do not pass out immediately. Acid proteids leave the stomach as quickly as carbohydrates; and carbohydrates made alkaline leave slowly, like proteids. Proteids fed first delay the passage of carbohydrates fed later. As is known, acid in the duodenum prevents food leaving the stomach. This effect is exerted on the pylorus. Free acid, therefore, opens the pylorus from the stomach and closes it from the duodenum. In the duodenum the acid is soon neutralized, whereon acid in the stomach opens the pylorus and more food passes.

Discussion by HALL (Chicago), HARRINGTON (Boston), BERGEY (Philadelphia), TURCK (Chicago), SMITH (Atlanta), and CANNON, turned upon minor details of the subject.

Extensive Thrombosis of the Sinuses of the Cerebral Dura, with a Report of Two Cases.—WILLIAM G. SPILLER and C. D. CAMP (Philadelphia). The first case was in a feeble-minded child. Many of the sinuses of the dura were occluded, and some of the cerebral veins were greatly distended with coagulated blood. Inflammation of the pia was found. The specimen in the second case showed old occlusion of the superior longitudinal sinus, and the formation of new blood passages within the dura. The difficulties of clinical diagnosis and the theories of the causation of this form of thrombosis were discussed; the writers inclined to the idea that the process could be explained by some of the newer ideas concerning the coagulation of the blood. In the discussion, WELCH (Baltimore) pointed out the mechanical conditions which must be considered in every case where a small vessel empties into the side, or at an angle in a large vessel, causing a vortex in the blood current, and favoring the formation of agglutinated masses of blood-platelets or of Arnold's bodies, which is more probably the cause of the thrombosis than the coagulation of blood.

A Case of Diffuse Encephalitis Showing the Pneumococcus.—W. N. BULLARD and F. R. SIMS (Boston). **A Case of Cortical Hemorrhage following Scarlet Fever.**—E. E. SOUTHARD and F. R. SIMS (Boston). These two papers were read by E. E. SOUTHARD (Boston). The two cases were very briefly presented. Southard calls especial attention to the faults of the technic which is usually followed in the study of the pathology of the brain, namely, that of throwing the brain into a 10% solution of formalin, and then expecting the neuropathologist to obtain a clear idea of bacterial invasion or of the encephalitic process.

Borated Food as a Cause of Kidney Lesions.—CHARLES HARRINGTON (Boston). Adverse opinions concerning the advisability of permitting the use of boron compounds as food preservatives are based chiefly on untoward results of boron medication, not infrequently observed, and on acute symptoms occurring soon after experimental ingestion of borax and boric acid or of foods containing them. Favorable opinions are based mainly on the absence of subjective symptoms in experimental feeding, and also on the fact that certain individuals have taken borax daily for long periods with no apparent injury. The object of most of the scientific work done with reference to the borax question has been the determination of the effect of the drug on digestion and metabolism. Research to determine what lesions may be caused by long-continued ingestion of borated food. Of 12 cats kept under precisely similar conditions and fed on the same food, 1 received no added chemical, 6 received a daily dose of borax, and 5 received a daily dose of another food preservative. After 16 weeks they were killed and their organs examined microscopically. Extensive lesions of the kidneys, and practically nothing else, were found in 5 of the 6 borax-fed cats and in none of the others. Conclusion drawn that borax is a dangerous food preservative.

At the close of the session, MYASHIMA, who is representing the Imperial Japanese Institute for Infectious Diseases, of Tokio, at St. Louis, presented, upon invitation, some very remarkable drawings and specimens, and read an important contribution to our knowledge of malaria. The only type of malaria encountered in Japan is the tertian form; there is also but one species of Anopheles to be found there. But in Formosa several of the types of malaria are seen, among them the estivoautumnal form, and cases of this disease are constantly being imported into Japan from Formosa, yet no cases are seen except in patients who have contracted the disease in Formosa. The conclusion is drawn that the species of anopheles which occurs in Japan is able to transmit the parasite of tertian fever, but not the form which causes the malignant type; in other words, a given species of mosquito may be able to harbor the plasmodium of only one form of malaria, and be immune to the other forms of plasmodiums. In the discussion, WELCH (Baltimore) pointed out the great importance of this observation, and expressed the pleasure of the section in greeting the representative of Japanese research.

[To be continued.]

Section on Laryngology and Otology.

THIRD SESSION.

Hemorrhage of the Larynx.—JOHN EDWIN RHODES (Chicago) classifies hemorrhage of the larynx as (1) cases in which loss of blood through the mucous membrane of the larynx manifests itself mainly by hemoptysis; (2) in which there is no spitting of blood, but in which evidences of hemorrhage are found on careful laryngoscopic examination of the larynx in an extravasation of blood in the tissues beneath the mucous membrane; in these cases precision in diagnosis is desirable. The etiology is dependent upon injuries, inflammation, local diseases, bloody dyscrasia and unknown causes. Particular stress was laid upon the fact that the exciting cause is often from unusual vocal effort, though it may be from coughing, vomiting, etc. The condition is rare and the pathology little understood. All forms of ulceration may lead to hemorrhage. The paper embodies a very careful and thorough review

of the literature on the subject with a report of cases of his own, as well as those which came under the observation of other authors. Under treatment the most important factor is always rest of voice, upon which too much stress cannot be laid.

Discussion.—DONNELLAN (Philadelphia) mentioned a case observed in association with the gouty diathesis, which was at first supposed to be of tuberculous origin. He referred to the importance of laryngeal hemorrhage in reference to insurance. He also mentioned a case in which the stopping of bleeding hemorrhoids was followed by laryngeal hemorrhage. CASSELL-BERRY (Chicago) mentioned two cases resulting from violent use of the voice, one in the case of a "rooster" at a football game, and the other a speculator at the Board of Trade. Another case referred to was a hemangioma of the vocal cord caused by cauterization.

A Review of 100 Operations for the Correction of Deviation of the Nasal Septum: Remarks on Septal Operations.—JOSEPH S. GIBB (Philadelphia). This was a report of cases in which several methods for the correction of septal deviation were employed. The following is a summary of the conclusions: (1) No single operation suitable for all cases of nasal septal deflection is known; (2) each case should be a study in itself, and the judgment of the surgeon must determine the operative measure best suited for that particular case; (3) the Asch operation is eminently satisfactory in the large number of cases in which the cartilaginous septum alone is deflected; (4) deviation of both cartilaginous and osseous septums offers the most difficult problem to solve, and no one operation meets every indication, but in many the Watson-Gleason offers a good chance for success; (5) there are some cases in which the removal of spurs, either cartilaginous or bony, will accomplish the best results without the formidable division of the septum; (6) there is a certain number of cases which must be classed as inoperable; (7) perforations occur in about the same number of cases in all operations in which an entire division of tissues of the septum is effected.

Discussion.—MYLES (New York) reported in his experience success and failure in all methods and stated that in some cases he has found it better to take off a part of the deflected projection of the septum and a part of the outer wall. WHITE (Boston) and FREER (Chicago) spoke in favor of the resection method as being the most satisfactory yet devised for every class of cases. This is the operation devised by Freer and reported for the first time two years ago.

Throat Complications of Typhoid Fever.—FRANCIS J. QUINLAN (New York) brought out in a very clear and forcible manner the importance of symptoms on the part of the larynx and trachea in typhoid fever which are frequently considered as of little consequence, yet may result in sudden and unexpected death. Pharyngitis: May be slight catarrhal: membranous, serious and fatal; diphtheric, not very uncommon. Tonsillitis: Special of typhoid—tonsillotyphoid or pharyngotyphoid. Laryngitis: Under this class he makes two divisions: (1) Laryngotyphoid, respiratory disturbances sometimes initial stage of typhoid; (2) late manifestation of typhoid apparently less frequent in America than on the Continent. Varieties: Mucous, edematous, diphtheric, perichondritic. Following this he treated of symptoms, physical signs, history of cases, treatment and termination.

Spontaneous Tonsillar Hemorrhage.—LEWIS S. SOMERS (Philadelphia). This paper consisted in the report of a case, a woman, aged 71, with left peritonsillar abscess, which was followed by spontaneous rupture, profuse hemorrhage, two days later, controlled by pressure. There was destruction of tonsil by abscess, and erosion of the artery of anterior pillar of the fauces. Following this was a brief report of similar cases from literature, from which he brought out the point that early evacuation is necessary to prevent erosion of arteries, especially the internal carotid, which was involved in most cases. Severe or fatal hemorrhage usually occurs late in second week and may or may not be preceded by several moderate bleedings. The relation of hemorrhage to time of rupture of abscess shows that any serious loss of blood does not usually occur for several hours or even a day after the pus has spontaneously evacuated. Usually two or more severe hemorrhages occur before the patient succumbs, and the outcome of every case is very grave. In all cases the gravity requires energetic treatment, even to the ligation of the carotid artery.

Tuberculous Laryngitis: Prognosis and Treatment.—THOMAS J. GALLAHER (Denver, Colo.). The reparative process in the larynx is influenced by the amount of pulmonary involvement. Nil if extensive and rapidly breaking-down pulmonary areas; more favorable if slight pulmonary changes and good general condition. Unless the pulmonary and general conditions improve there will be no local reparation. If the entire larynx is involved including the perichondrium and cartilages the case is hopeless. Ulcerations in the commissure and on the epiglottis are most intractable; those on the cords less so, while superficial ulcerations are more amenable to treatment than deep ones following marked infiltration. Lesions in the larynx he classified as follows: Infiltration, superficial and deep; ulceration, superficial and deep; both associated with more or less edema. Treatment: Palliative; cleansing larynx and soothing applications. Radical: Curetment, followed by strongly germicidal remedies; insufflations. Where there are ulcerations with vegetations, remove adventitious tis-

sue so that the remedies may reach the parts. After such process the author finds best results from formaldehyd solution, 3% to 5%, followed by insufflation of aristol and orthoform. Lastly, intratracheal and laryngeal injections of oil containing menthol and oil of cinnamon.

A Report of Some Unusual Intubation Cases.—BURT RUSSEL SHURLY (Detroit). The paper included a consideration of intubation in private practice, giving technic with complications, with report of cases. Summary of conclusions: 1. The O'Dwyer tubes and instruments are generally satisfactory; no cheap modifications or substitutes are desirable. 2. Digital exploration of structure about the entrance of the larynx important in diagnosis. 3. Failure to intubate due to operator more often than condition of larynx. 4. Obstruction of tube more frequent after large doses of antitoxin. 5. Early intubation advocated in private practice and removal of tube on fourth day. 6. Antitoxin shortens the time of wearing tube from two to three days. 7. In dangerously obstructive papillomatous cases in children, intubation is indicated as the primary operation, as it is also in acute laryngeal stenosis of adults.

The Radical Operation for Chronic Suppurative Frontal Sinusitis.—W. FREUDENTHAL (New York) stated that in order not to be misunderstood in his conclusions he believed that the great majority of cases improve under intranasal treatment. In others the symptoms may be more pronounced, but the patients would rather endure them than undergo a serious operation, hence by all means first try intranasal procedures. Conclusions: 1. He commends the conservative treatment suggested by Kuttner of Berlin. 2. In those cases in which operation is necessary, Killian's method seems at present to give the best results. 3. The first opening in the frontal sinus must always be made below the outlined bridge, and only after exploring the sinus should another above it be made. 4. In the latter case we may leave a bony bridge, which helps toward improving the cosmetic effect. 5. Closing of the external wound immediately after operation is by far preferable for such cosmetic effect.

Following this the section adjourned for a demonstration by A. LOGAN TURNER (Edinburgh) who by special invitation presented a paper on **The Operative Treatment of Chronic Suppuration of the Frontal Sinus, with Special Reference to the Method of Killian**. Owing to the universal reputation of Turner attained by his extensive and thorough research of sinus disease, this paper had been looked forward to as one of the most important events of the meeting. Beside the members of the Laryngological Section many from the other sections of the Association were present. His paper was greatly elucidated by lantern demonstration of specimens of cadaveric dissections and actual operations. From several points of view the subject is one of deep interest and along with the surgery of the other nasal sinuses the history of its gradual development is a very engrossing one. In connection with the advances in this department, Americans have taken a prominent place, in proof of which need only be mentioned the names of Holmes, Lothrop, Douglass, Mosher, Howard, Ingersoll, Pearce and Bryan, among others.

Indications for opening the sinus: The somewhat numerous fatalities which have occurred after operation, the fact that relapses are not infrequently met with, and the possibility of considerable disfigurement attending a radical procedure are factors which must naturally cause the surgeon to weigh carefully the circumstances connected with each case before he urges operation upon his patient. Till more extended experience and improvements in our operative technic make it possible to recommend operation in every case with almost certain knowledge of obtaining permanent cure, with smallest amount of disfigurement, we must recognize certain symptoms and local conditions which make surgical interference imperative, namely: (1) symptoms suggesting cerebral complications; (2) pain, usually of the nature of headache, which may be of a very severe and persistent type; (3) distention of one of the bony walls of the cavity, or the presence of a fistula discharging externally. If the general health of the patient is evidently affected by the continued suppuration, or if he should suffer from great mental depression and anxiety regarding his condition, a state of affairs which sometimes exists in these cases, we should not refrain from urging the operation. So far as we are able to ascertain, we cannot draw definite conclusions as to the percentage of cases of frontal sinus suppuration in which intracranial complications arise. That they do occur, there is ample evidence to show, and there is the possibility that they may even occur more frequently than statistics would indicate, the more aggravated symptoms in some cases relieved by treating the intranasal condition. If nasal polypi are thoroughly removed, along with anterior end of middle turbinated bone, and the anterior ethmoidal cells opened into, better drainage may be established and the outflow of secretion rendered more easy.

Operative procedure: Notwithstanding numerous operations and their various modifications, many of which are associated with names of different surgeons, there are only two main principles involved. (1) The sinus is opened and drained into the nose, but its cavity is preserved; or, (2) the sinus is obliterated by the removal of one or more of its bony walls so that there is no longer a cavity to deal with. The Ogston-Luc operation consists in opening the frontal sinus through its

anterior wall, size of opening being relative to the dimensions of the cavity in careful curetting of its interior, and in establishing a large communication between the sinus and the nose at the same time destroying the anterior ethmoidal cells in the region of the nasofrontal duct. Drainage into the nose is insured by the introduction of a strip of gauze through the nasofrontal aperture and the operation is completed by immediate suture of the skin incision. Probably used more widely than any other, yet results show that the class of cases suitable for it is small, due to anatomic causes. Illustrated with figures; considered in all its aspects. The frequency of ethmoidal suppuration associated with frontal, noted, as observed by different authors, the total figures showing that in 172 cases in which chronic suppuration of frontal sinus existed the ethmoidal cells were implicated in 102, or in 60%. In operation for obliteration of sinus, the method of Kuhnt is described, in which the whole of the anterior wall and also to greater or lesser extent the floor is removed. Postoperative mortality considered. Disfigurement. Osteoplastic operation used by some by raising a bone flap from anterior wall of sinus. Killian operation, for which the author claims the best radical treatment of the disease with a minimum disfigurement. Killian advises it in all cases even when there is no discomfort beyond slight nasal discharge. Should a more general and extended experience prove equally satisfactory, it is possible that in the Killian operation we have at least obtained a method of dealing with chronic frontal sinus, suppuration in large and complicated cavities, which may be regarded as the method *par excellence*. The whole sinus with its recesses and partitions is thoroughly inspected and the cavity is almost completely obliterated by the resection of its anterior and inferior bony walls. Further by the removal of the ascending or frontal process of the superior maxilla, excellent access is obtained to the ethmoidal cells and a large opening of communication is thus made between the frontal sinus and the nasal cavity, establishing good drainage. To reduce to a minimum the deformity, which may follow so extensive a dissection, the supraorbital bony margin is preserved as a bridge between the gap formed by removal of the anterior sinus wall and the floor.

Conclusions: No single method of procedure applicable in all cases of chronic suppuration in frontal sinus. When sinus is small and can be thoroughly inspected through aperture made in anterior wall, and when no ethmoidal disease coexists, simple opening by Ogston-Luc method may prove satisfactory. In every other class of cases he would recommend and practise obliteration of sinus by removal of its anterior and inferior walls. Whatever be the exact radical procedure adopted, there is no doubt of the value of removing the ascending process of the superior maxilla in order to gain better access to the ethmoid labyrinth and nasal cavity. The section extended a unanimous vote of thanks to Turner.

Section on Materia Medica.

THIRD SESSION.

Drugs Irritant to the Kidneys, and Hence to be Avoided in the Impaired Kidney Function.—TORALD SOLLMANN (Cleveland, O.). Read by Hatcher. If all irritants to the kidneys are to be avoided, stimulants cannot be given nor can diuretics or the potassium salts be employed. He emphasizes the fact, that the experiments made upon animals are not always applicable to man. He believes the urine should be examined before and after the experiment. Sollmann lays stress upon the importance of the percentage of proteids in the urine of nephritis. This percentage is not increased by either water or diuretics, but the reduction of the water increases the albumin content. Irritants absorbed injure the kidneys in small doses, and some irritants attack certain structures of the kidney more severely than others, as for instance, cantharides, which affects the glomeruli primarily, and secondarily the tubules.

Some Aspects of the Newer Physiology of the Gastro-intestinal Canal.—LAFAYETTE B. MENDEL (New Haven, Conn.) announced that, according to some of the later investigations, it is found that there is very little peristalsis in the cardia of the stomach; here salivary digestion continues for some time. The motility of this organ is principally confined to the pyloric end. Free hydrochloric acid, he says, in the stomach stimulates the pylorus to relax and allows the food to pass out, while acid in the duodenum stimulates the same structure to contract and causes the flow of bile. He attributes the flow and production of secretion as being due, to a certain extent, to chemic and psychic influences. In speaking of the functional adaptability, he calls attention to the fact, that the quality of the diet influences the amount and character of the elements in a secretion; for instance, a large meat diet gives rise to an abundance of trypsin, and a large vegetable diet calls for an abundance of amylase. Errors in diet produce alterations in the quality of the secretions. The acid chyme seems to be influential in the stimulation of the intestinal juices, for when this chyme is no longer acid the intestinal juices are no longer secreted. To the mucous membrane must still be ascribed the

power of changing the peptones before entering the blood. The absence of autodigestion in the pancreas is due to the lack of trypsin in this organ. The autodigestion of the stomach and intestines is prevented by antipepsins and antitrypsins. The intestines, he believes, are greater excretory organs than is generally held, for he said the strontium salts, no matter how administered, are largely excreted by the intestines. The feces, he says, are not merely residue of foodstuffs, but are composed, to a large extent, of metabolic products.

Etiology and Pathology of Gout.—THOMAS B. FUTCHER (Baltimore), in discussing the etiology of this affection, thinks heredity is a very important predisposing factor. The disease is more frequent in the white male; he has seen it in two negroes; the initial attack usually occurs between the thirtieth and fortieth years. Alcohol stands next to heredity as a predisposing cause, but is usually seen after the use of fermented alcohols; not very frequently after the use of distilled alcohols. Food is an etiologic element if taken in unnecessary quantities with insufficient exercise; if the amount of exercise is sufficient to utilize all the food ingested it is not a causative factor. Lead, Futcher says, is a frequent cause of gout. He maintains that the uric acid theory can not be ignored as yet. In gout, he asserts there is an increase in the amount of uric acid in the blood owing to the deficient excretion by the kidneys. In discussing the pathology of gout Futcher says the biurate of sodium is deposited in the superficial portion of the articular cartilages farthest from the circulation. He says the alkalinity of the blood is not diminished. The lesions associated with gout are chronic interstitial nephritis, arteriosclerosis, myocarditis, endocarditis, terminal pericarditis, and emphysema.

Section on Cutaneous Medicine and Surgery.

THIRD SESSION.

Dermatitis Herpetiformis.—WM. T. CORLETT (Cleveland, O.) reported a case treated with röntgen ray. Adult male, with a questionable family history; personally has had all diseases of childhood. Dermatitis began two years ago with progressive emaciation and glandular enlargement. General physical appearance of skin yellowish, with excoriations on back and extremities; epidermis quite thickened. Temperature, pulse and respiration normal. Externally treated by röntgen ray, the patient standing about six inches from tubes; internally, tonics. Three months later patient was found to be cured. CURRIER has seen a similar case that was sent to arsenic springs. Result, cure.

A Comparison of Radiotherapy, High-frequency Therapy and Phototherapy in Skin Diseases.—C. W. ALLEN (New York City) presented the paper. Each has its own therapeutics. In the actinic rays nearly every case receives burns of more or less degree. Mycosis fungoides, in Allen's experience, has been cured by röntgen ray. Arc-light therapy is limited to a few skin diseases. The ray influences mucous membrane infinitely better than actinic light. The greatest results of the treatment of lupus vulgaris have been obtained by Röntgen, of Copenhagen. Radiotherapy is advantageous in that it is less painful than röntgen ray. In epithelioma curettage should be practised in conjunction with röntgen ray. Phototherapy should be continued until a cicatrix is formed. The field of usefulness of röntgen ray is by far broader than that of the Finzen treatment. With high-frequency spark it is possible to remove lesions of lichen planus erythematosis. He cites a case which high-frequency current cured in one sitting. Röntgen ray is better in every respect than phototherapy or radiotherapy. Allen gave the technic in using high-frequency current.

Iodin, its Absorption and Elimination.—BAUM (Chicago) spoke of the therapeutic value of the inorganic salts of iodine, the channels through which it is eliminated and conditions under which vicarious elimination takes place. Metallic iodine is very difficult of absorption if applied locally. He gave examples of untoward effects of the drug on skin, mucous membranes, blood, and the blood-pressure, and reported a case in which potassium iodid had been administered in lethal dose and found 13 minutes later in the urine. He believes that iodine salts gives better results than iodine *per se*.

Röntgen Ray in Skin Diseases.—PFAHLER (Philadelphia) reported two cases of nevi, both of which were benefited by the application of röntgen ray, also a case of lupus vulgaris in a physician treated by röntgen ray, 13 applications given in six weeks with good results. There appeared a spicule of bone at the external canthus of right eye, which disappeared under treatment. Pfahler treated a case of epithelioma of the lip, using surgery as an adjunct to röntgen ray. In this patient he believes neither procedure alone would have produced a cure. Röntgen ray, in Pfahler's opinion, is the best treatment for acne, especially when carried to the extent of an erythema.

The Consideration of Late Hereditary Syphilis.—CAMPBELL (Chicago) read a paper describing the means of diagnosis. Long periods of latency occur in acquired syphilis. He mentions the diagnostic value of Hutchinson's teeth in

the condition; these are present in the minority of cases. Interstitial keratitis is also a valuable symptom in diagnosis. Deafness and acute ulcerative destruction of hard palate are good points to note. Late hereditary syphilis may affect the skin as gummas; these may ulcerate. Cases of late hereditary syphilis are not very frequent in literature. He reported a case of effusion in both knees, due undoubtedly to syphilis, as family history proved.

Discussion.—BRINKMAN has never seen locomotor ataxia in which a history of syphilis could not be elicited. BULKLEY has seen a case of hereditary syphilis in a man aged 30.

The Treatment of Lupus Erythematosus by Repeated Applications of Ethyl Chlorid.—HARTZEL (Philadelphia.)

A Case of Continuous Acrodermatitis Controlled by Röntgen Ray.—MONTGOMERY thinks that this disease should not be classed with dermatitis repens which it resembles closely. In acrodermatitis no cutaneous atrophy occurs. It has little or no tendency to invade parts other than the digits and extremities and is very difficult to cure as a rule. The condition manifests itself by vesicles which may become pustular. The disease is of long duration. The patient was a healthy male adult, in whom the affection was confined to the fingers entirely. He had been treated without benefit for a long period of time by others. Montgomery tried Lassar's paste with slight amelioration of the burning sensation of which the man complained. Finally röntgen ray treatment was instituted. Nine exposures were given an erythema developing therewith. The lesions disappeared entirely. Subsequently the patient returned with a few new vesicles, but these yielded quite promptly to the röntgen ray.

[To be continued.]

Section on Hygiene and Sanitary Science.

THIRD SESSION.

Purulent Conjunctivitis and Blindness.—EDWARD JACKSON (Denver, Colo.). Not all purulent conjunctivitis of the newborn is due to the gonococcus, but the gonococcus is the agent of that sort of purulent ophthalmia which terminates in life-long blindness, causing in Europe 30% and in this country 15% to 18% of this terrible disability. The true significance of these figures becomes apparent when one realizes that this blindness is almost entirely preventable. Clean midwifery will greatly diminish the number of cases of ophthalmia neonatorum, but will not wholly prevent it. Special local prophylactic measures are required whenever there is reason to suspect that the vagina may harbor the gonococcus. No better procedure has been suggested than the Crêde method of dropping a single drop of 1% or 2% solution of nitrate of silver from a glass rod upon the cornea and allowing the solution to flow to all parts of the conjunctival sac without any other manipulation than holding the lids apart. Nitrate of silver still remains the best agent for this purpose, though there is a hope that some of the less irritant salts of silver may be found as effective. When purulent ophthalmia occurs, treatment, in order to save the sight, must begin before the cornea is visibly involved. Frequent cleansing with bland fluids, avoiding mechanical disturbance of the inflamed area, and paying especial attention to the overhanging corneal margin, will give the best chance of avoiding corneal injury. The chances of acquiring gonorrheal conjunctivitis in adult life should be fairly impressed upon the public mind. Gonorrhea is a malignant contagious disease, and should be publicly recognized and dealt with as such.

HENRY D. HOLTON (Brattleboro, Vt.) reported the consideration of the subject by the Conference of State and Provincial Boards of Health, and the tentative recommendation of a circular letter to physicians asking for information concerning the prevalence of venereal diseases, and requesting the distribution to venereal patients of a circular of advice in the following form:

This is handed you by reason of the exceedingly disastrous results that follow these diseases, so destructive to the health of our population that sanitarians in all parts of countries have become seriously alarmed. A large percentage of the cases of blindness, as well as inability to perform any of the duties of life, and death at an early date, are results of these diseases. Syphilis (or pox) is especially a disease from which innocent persons may suffer, as it usually produces sores in the mouth or on the lips, hence may be conveyed by kissing, drinking from the same cup, or using anything that has been put to the lips or into the mouth of one affected by the disease. These diseases are often communicated when the patient thinks he has recovered. Hence marriages contracted at this time of the disease result in much unhappiness, and often in the death of the wife. To protect yourself and others, we earnestly advise the following:

IN THE INTEREST OF PREVENTION OF YOUR DISEASE.

What to do, and what not to do, to get well and to prevent giving your disease to any other person. Follow strictly the advice of your doctor, use no other treatment. Remember that it takes a long time to entirely recover. Wash your hands with soap and hot water whenever you have had occasion to in any way handle the private parts. Do not have intercourse, and avoid all sexual excitement until your physician says you are completely cured. Do not allow any person to use any cup, glass, spoon, fork, or anything that you have put in your mouth. Do not kiss any one, or wipe the face of a child with the handkerchief you have used. Always use a separate towel.

[To be continued.]

AMERICAN ACADEMY OF MEDICINE.

Twenty-ninth Annual Session, Atlantic City, N. J., June 4 and 6, 1904.

[Specially reported for *American Medicine*.]

[Continued from page 980.]

Ethical Pharmacy.—A. L. BENEDICT (Buffalo, N. Y.) stated that the one department in the modern drug store which receives the least attention is the prescription counter and if the prescription calls for drugs a little out of the ordinary, the purchaser may be told that it will require several days to fill it. This state of affairs is brought about by competition; in some localities there is one drug store to every five physicians and each store employs one or more assistants. These individuals, who are nearly all graduates in pharmacy, must derive their support from the profits of the store and it is difficult to see how this can be done on prescription work alone. Consequently the druggist must find some other source of profit and adds one department to another, and failing to do this his store would soon decline in popularity. The druggist cannot help himself out of the present predicament without the assistance of the medical man. The solution of the problem is simple in theory and in occasional instances is carried into successful practice: Find a pharmacist who is capable and willing to conduct a legitimate pharmacy and to dispense with all other departments, eliminate the middle store and the show window, and find 20 or more physicians to guarantee to him their active support. Other druggists may not like this, but they have the privilege of competing for the same class of trade. Such course may lead to a suspicion of interested motives, but this arises under existing circumstances.

A Protest against Proprietary Products.—A. MANSFIELD HOLMES (Denver) said it is startling at this date with our broad, high standards of civilization that there is such a prevalent mysticism in our therapeutics. With each year the number of "pathies" and "isms" increases, and with each advancing step of science and research the general public becomes more easily misled by sophistry. The proprietary trust and its parasitic allies are well organized, while the unsuspecting public is without organization. The harm from these proprietary preparations comes from employing harmless ingredients in secret concoctions made to rob the public. Other preparations may contain valuable ingredients in a secret formula, and on the mystery pertaining thereto, large profit is charged. The third kind, which should receive the most condemnation, is that class which contains not only the secret factor, but also dangerous poisonous ingredients, powerful therapeutic agencies to be placed before the public and used without restrictions. This induces the practice of self-treatment and over-treatment, the formation of the drug habit, injuring health and lowering the public standard. In dealing justly with the subject the other side should be considered. There should be some law of compensation for new discoveries in medicine. Steps should be taken to encourage original research with more than transient honor as a reward for brilliant discoveries. The discoverer of an alkaloid, such as cocaine, of organic or bacteriologic extracts or antitoxins, which confers worldwide blessings on humanity, should not be permitted to serve the remainder of his life with nothing more than an empty honor. The men who discovered the possibility of controlling and preventing the spread of malarial and yellow fevers deserve more than the honor of having their names placed on the pages of medical literature for a few days. The greatest benefactors have received the least honor. If this idea were carried into execution legitimate therapeutics would mount to a higher standard and the commercialism of the trust would find less field for conquest.

Synonyms in the New United States Pharmacopœia.—JOSEPH P. REMINGTON (Philadelphia) said a comparison of the nomenclature used in the first edition of the United States Pharmacopœia of 1820 with the present of 1890, would show that much progress has been made through the adoption of certain principles which are well recognized and have at last become thoroughly established among English speaking nations. There are radical differences in the views held by those in authority in the various countries. Synonyms which have come into common use are most bewildering to the scholar, but exceedingly interesting when traced to their original sources. The object of the paper is to draw attention to the nomenclature in the forthcoming pharmacopœia. The present edition recognizes several names for the same substance, that of commercial arsenic has five different names. The largest consumption of arsenic in all countries is not in medicine but in the arts. Difficulties have arisen in using terminology in the new edition. One of the principal objects of the pharmacopœia is to establish standards of official substances. Arsenic which comes from abroad need not be separated from its most natural impurities; the manufacturer merely needs to know the percentage of arsenic trioxid in a certain substance, but the pharmacologist must know to a fraction of a percent the impurities of the product and the physical and medical properties of the contamination. Within the last few years, by the passage of what are termed pure food laws, the United States Pharmacopœia has come into prominence on account of being taken as a standard

for these products. Some of the decisions have caused much embarrassment, even among honest druggists, some of whom have been penalized for substances not up to the standard and not intended for use in medicine. Such, for example, is HCl, used for renovating brick fronts. In the forthcoming pharmacopeia this will be removed by a clause that these substances apply only to those used in medicine and if the druggist dispenses cheap, impure substances for internal use the fault can be easily detected. In the use of synonyms great harm also has resulted. Laudanum, for instance, is sold in different strengths and the dosage varies accordingly; the best class of druggists will not dispense two preparations of different strength. Cold cream as made for a number of years has come to mean an oleaginous soft ointment containing rose water, frequently made by a process entirely different from the official formula. If the synonym cold cream is abandoned in the pharmacopeia no excuse can be offered in dispensing anything but the ointment of cold cream. The liability of prosecution will compel greater care on the part of druggists. Physicians sometimes do not exercise sufficient care in employing official names. It is not wise to abandon all control of synonyms by eliminating them from the book entirely, but they will be employed only in the index.

[To be continued.]

AMERICAN GYNECOLOGICAL SOCIETY.

Twenty-ninth Annual Meeting, Held in Boston, Mass.,
May 24, 25, and 26, 1904.

[Specially reported for *American Medicine*.]

[Concluded from page 978.]

Bathing During the Menstrual Period.—J. CLIFTON EDGAR (New York) presented the following conclusions on this subject: 1. All forms of bathing during the menstrual period are largely a matter of habit, and usually can be acquired by cautious and gentle progression; but not for every woman does this hold good, and surf bathing, where the body surface remains chilled for some time, should always be excepted. 2. A daily tepid sponge bath (85° to 92° F.) during the menstrual period is not only a harmless proceeding, but is demanded by the rules of hygiene. 3. In the majority of, if not all, women, tepid (85° to 92° F.) sponge bathing after the establishment of the menstrual flow, namely, second or third day, is a perfectly safe practice. 4. Furthermore, in most women the habit of using the tepid shower or tub bath after the first day or two of the flow can with safety be acquired.

The Streptococcus in Gynecologic Surgery.—HUNTER ROBB (Cleveland, Ohio) stated that in order to arrive at some definite conclusions with reference to *Streptococcus pyogenes* as a cause of death in his work, he had made an analysis of all his cases in which this organism had been found during the past 6 years. In the past 6 years he had had 137 cases of abortion, including a few cases of labor, in which it was necessary to carry out some form of treatment. Of this number, 104, or 75.9%, recovered; 17, or 12.4%, were improved; 1, or .8%, was unimproved; and 15, or 10.9%, died. In 16 of the 137 cases the streptococcus was found. The total number of all his cases in which the streptococcus was found was 40, consequently those in which this organism was found following an abortion or labor constituted 40% of the total number of streptococcus cases from every source. Of these 16 patients (streptococcus cases) following abortion or labor, 4, or 25%, recovered; 3, or 18.75%, were improved; 9, or 56.25, died. In the whole 48 cases from every source, in which the streptococcus was found, the results were as follows: Recovered, 20, or 50%; improved, 6, or 15%; deaths, 14, or 35%. The streptococcus was found in the following combinations given in order of frequency: (1) Streptococcus alone; (2) streptococcus and *Staphylococcus pyogenes aureus*; (3) streptococcus, *Staphylococcus aureus*, and *Bacillus coli communis*. In all these cases, except three in which they were obtained from the vagina, the organisms were obtained from the uterus, the adnexa, the culdesac, or from several of these situations. In other words, they were found to be present in places which were admittedly not their normal habitat. In the past 5 years he had had 724 abdominal sections, with a total number of 32 deaths, or 4.43%. In 7, or 21.9%, of them, the *Streptococcus pyogenes* was demonstrated. In all, there were 19 cases of abdominal operations in which the streptococcus was found. Of this number, 12 recovered, or 63.2%; and 7 died, a mortality of 36.8%.

The Nature of the Indications for Operation for Fibroid Tumors of the Uterus.—CHARLES P. NOBLE (Philadelphia) presented a table of the degenerations and complications in a series of 1,188 cases of fibroid tumors operated upon by Martin, Noble, Cullingworth, Frederick, Scharlieb, and in a series reported by Hunner and MacDonald. Especial attention was called to the relative frequency of adenocarcinoma of the uterus as compared with epithelioma of the cervix. The deduction drawn from this fact was that fibroid tumors were a direct predisposing cause of cancer of the cervix. A careful consideration of the facts presented, said the author, should convince anyone with an open mind that the classic teachings

concerning fibroid tumors were erroneous. This teaching was that fibroid tumors of the uterus were benign growths, which usually produced but few symptoms, and which after the menopause underwent retrogressive changes, becoming smaller or disappearing; that the chief danger of fibroid tumors consisted in the fact that at times they caused hemorrhages from the uterus, and that rarely they cause trouble because of their size or on account of pressure on adjacent viscera. An analysis of the 1,188 cases showed that because of the degenerations in the tumors about 16% of the women would have died without operation; about 18% would have died from the complications present. In addition, it was well known that a certain percentage would have died from intercurrent diseases brought about by the chronic anemia present in many of these cases, and by injurious pressure from the tumors upon the alimentary canal and urinary organs. In short, at least a third of the women having fibroid tumors, as shown by the author's table, would have died had they not been submitted to operation.

Treatment of Gonorrhea.—HENRY T. BYFORD (Chicago) advocated prolonged irrigations with hot water as a basis, and spoke of frequent injections of hot water as a substitute for prolonged irrigations. He detailed his experience with urethritis in the male, and referred to hydrogen dioxide and unirritating germicidal solutions as substitutes for plain water injections, and gave their application to gonorrhea in the female. He pointed out the advantages of this treatment.

PHILANDER A. HARRIS (Paterson, N. J.) exhibited and described a new uterine obstetric dilator.

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY.

Tenth Annual Meeting, Held in Chicago, Ill., May 30, 31,
and June 1, 1904.

[Specially reported for *American Medicine*.]

[Continued from page 978.]

What the Laryngologist may do for the Correction of Some of the More Common Forms of Defects of Speech.

—G. HUDSON MAKUEN (Philadelphia), after dwelling upon the growth and expansion of the work of the laryngologist, rhinologist, and otologist, continued by saying that they had neglected a field which seemed to him to be of great importance. He referred to that of defects of speech, the treatment of which had either been entirely neglected or relegated to quacks. The medical man should do all in his power to suppress quackery, both in the interest of suffering humanity, as well as in his own interest. It had been estimated that there were over 300,000 stammerers in the United States alone, and this was only a small portion of those having some form of defective speech. Every one of these cases, in Makuen's opinion, was a proper subject for medical supervision, and he thought that these disorders of speech should come within the domain of the laryngologist, rhinologist, and otologist, and that defects of vision were scarcely of more importance than defects of speech. He estimated that the exciting cause in 95% of all cases of stammering might be looked for in a morbid condition of some portion of the respiratory tract. Adenoids, enlarged turbinates and chronic rhinitis were causes of stammering. The laity and some physicians thought children would "grow out of" speech defects, and, therefore, they became nerve habits before any treatment was given. Makuen explained why children stammer, and he also explained his treatment, which consisted in the removal of all physical obstructions to normal respiration, and in the teaching of physiologic breathing and the elementary sounds used in language. Digestive disturbances should be corrected, tobacco and stimulants of all kinds interdicted and the nervous system supported by nourishing food and plenty of sleep. A little mental science must be judiciously mixed in with the treatment, and suggestion always plays an important part. Makuen had found the use of hypnotism of immense value, as an adjuvant in certain selected cases, and he emphasized the importance of syllabic speech. There were 44 elementary sounds used in language, represented by the letters of the alphabet. The articulation of a word was a combination of two or more elementary sounds arranged in their proper sequence, and a syllable was a combination of elementary sounds which might be given with a single respiratory impulse. Words of two or more syllables should have as many impulses as there were syllables. Stammerers should be taught to speak, and as far as possible even to think, in syllables.

Multiple Chronic Sinusitis Operated upon by the Maxillary Route.—T. PASSMORE BERENS (New York City) reported a series of 14 operations through the maxillary route, with empyema of the maxillary antrum, ethmoid cells, and sphenoid sinus. The operation which he described in detail was performed as he saw it carried out by Jansen of Berlin. Following the description of the 14 cases, Berens concluded with these remarks: "To summarize, all of the patients but one had disease of the sphenoid sinus; in 12 of these, occipital and vertical pains were present; in 8—all with sphenoid disease—the pains extended also into the face, and were neuralgic in character, while in 4 cases the pains closely simulated

tic douloureux. These cases were all cured except two, viz., Case 12, which was malignant, and Case 9, in which suppuration returned several times in the sphenoid, each return being marked by an attack of "tic." It seems to the writer that the presence of pain in the vertex and occiput or in trigeminal neuralgia when accompanied by pus in the posterior nares is symptomatic, almost diagnostic of sphenoid disease. In 12 of the patients there was pain in the region of the eye, especially in the region of the inner canthus. This pain was explained at the time of operation by the finding of disease in the most anterior ethmoid cells. In all of the cases excepting Case 5, there was a total absence of frontal sinus disease; and since they all were chronic cases, most of them of many years' duration, it is interesting to ask: What factor was present to preserve the frontal sinus from the primary infection, to cure it if was infected, or to protect it from subsequent invasion by the disease already established in the ethmoid region? Were the teeth the prime factors of the infection of the antrum, with a subsequent extension of the suppurative process upward and backward into the ethmoid cells and sphenoid sinus; and, if so, why, again, did the frontal sinus escape? In eight of these cases the teeth were found diseased at the time of operation, or there was a clear history of diseased teeth, at least of dentalgia. That diseased teeth cause many cases of antrum disease is not questioned, but, on the other hand, the writer believes that many a tooth has been sacrificed when proper treatment of the antrum would have saved it. A tooth having roots protruding into a suppurating cavity—the roots protected by only a thin mucous membrane periosteal covering—could readily become diseased by contiguity of tissue; and the writer believes that in at least some of his cases this actually has taken place, at least to the extent of producing dentalgia. In all of the cases excepting Case 12 and Case 9, there was a complete and permanent relief from pain following the operation. Of the nine cases operated upon more than a year ago, four have had a return of pus. Two of these cases were in the ethmoid region, and were cured by subsequent curetment; one was malignant, and one was in the sphenoid. The continued suppuration in the latter case was probably due to a prolongation of the sinus into the wing of the sphenoid bone, or some other similar condition. The return of pus in the ethmoid region was the result of fear born of inexperience of perforating through the internal plate of the ethmoids. Experience having given a better technic, the cases operated upon later had practically a complete exenteration of the ethmoid cells, and have not since suppurated. There has been a troublesome crust formation in four cases; but there was an atrophic process present throughout the whole of the nasal cavities before operation in these patients. The tear duct was cut off in at least half the cases, but this has caused no symptoms, the duct simply emptying higher up. Arterial hemorrhage deep in the wound was easily controlled by artery forceps in three cases. The possibility of hemorrhage in this locality certainly demands the most open kind of a wound that it is possible to secure in any operative procedure that may have to be undertaken. In any of these three cases the hemorrhage would have been practically beyond control had the operation been performed by the intranasal route." In conclusion, the operation as described was advised only after a careful study of each case, and where the hope of a cure by milder measures could not be held out to the patient.

LEWIS A. COFFIN (New York City) reported four operative cases of **sinusitis in children**, and presented specimens illustrating the development of sinuses.

H. HOLBROOK CURTIS (New York City) read a paper on **chronic empyema of the sphenoidal sinus**, with indications for treatment.

Treatment of Tuberculous Laryngitis.—S. E. SOLLY (Colorado Springs, Col.) read a paper on this subject. In his opinion, most physicians were too timid in handling the tuberculous larynx, resorting in their blindness to superficial treatment, and to sedatives in their mistaken kindness, when in most cases they had far better use radical measures.

JOSEPH A. WHITE (Richmond, Va.) reported a case of **mastoiditis**, which was complicated by nephritis and erysipelas.

Tinnitus Aurium, and its Treatment.—W. S. BRYANT (New York City) read a paper on this subject, in which local treatment only was considered. This was found to be the same as the treatment for deafness with few exceptions. Many of these arose because the disturbance was of more delicate nature than that causing a loss of hearing alone. It therefore required still greater care in manipulation. Too energetic treatment might tend to increase rather than decrease the symptom. In a large proportion of cases the sound-conducting mechanism was at fault, and required treatment more than any other defect in the complicated condition which gave rise to the tinnitus. Neurectomy had been tried in cases of grave tinnitus with unsatisfactory results, owing to the poor technic employed, and the selection of improper cases. Further attempts would undoubtedly develop a comparatively safe and sure method. Treatment in objective tinnitus was chiefly directed to lessening the sounds, and later to dulling the patient's perception of them. In subjective tinnitus the local treatment was chiefly directed to lessening the perception of the tinnitus by the ear, and the improvement of sound conduction; secondarily, to lessening the sounds themselves. Most of the tinnitus under this head was dependent on pathologic conditions of the mucous

membrane of the Eustachian tube and tympanum, which were themselves dependent on like conditions in the nasopharynx. The treatment was worked out on the lines required by a classification of the varieties of tinnitus, which the author submitted.

AMERICAN GASTROENTEROLOGICAL ASSOCIATION.

Seventh Annual Meeting, Atlantic City, New Jersey, June 6 and 7, 1904.

[Specially reported for *American Medicine*.]

The President's Address.—S. J. MELTZER (New York) gave a history of the Association since its organization in Philadelphia in 1897. He stated that the Association was not essentially an organization of stomach specialists, but that the aim of the society was to bring together all the workers in the United States, who contribute to the knowledge of the stomach and intestinal canal. He remarked the fact that the general practitioner's work necessarily led him into this field, which he stated was too large to be worked with profit by a single set of men, although it is essential that every student have a knowledge of the working part of the intestines. He recommended that the anatomists, the pathologists and clinicians all meet together and exchange their views.

Symposium on Gastric Ulcer: Clinical Recognition.—J. C. HEMMETER (Baltimore, Md.) gave a review of the history of the clinical recognition of gastric ulcer. He stated that there was no reference made to such a condition in the writings of Hippocrates, the first instance being recorded in the sixteenth century when in the report of a postmortem examination, there when noticed unmistakable ulcers and cicatrices. The next case is that reported by Bowie in 1679, in which a young woman 18 years of age was seized with a condition showing signs of perforating ulcer of the stomach, dying three days later, and post-mortem showed that such a condition existed. He stated that to Joshua Bailey belonged the credit of having first accurately described the anatomic properties of gastric ulcer, in 1793, which was followed by a full account of the symptoms by John Abercrombie in the *Edinburgh Medical and Surgical Journal* in 1824, including the latent cases, great diversity of symptoms and modes of death, he speaking of it as gastritis with infiltration. He stated that Craveley published in 1829 to 1845 the most classical picture of the disease ever given, the next to it being that of Rokitsky, which appeared 1836, and was based on an analysis of 39 cases. Since that time the literature furnished 304 articles, only a few of which would stand the test of modern criticism. He also referred to the works of von Jaksch, Brinton, Hauser, and Fittler.

The Bibliography of Gastric Ulcer.—CHARLES D. AARON (Detroit, Michigan) covered in his remarks a period from 1894 to 1904, and embraced 841 papers on gastric ulcer, dealing with the etiology, pathology, symptomatology, diagnosis and treatment, and the relationship between gastric and other diseases, considering the etiologic significance of syphilis, arteriosclerosis, tuberculous gastric ulcer, and gastric ulcer in pregnancy. There were 437 papers on the surgery of gastric ulcer during the past 10 years, including the reported cases of perforating gastric ulcer successfully treated by surgery, and outlining the means of diagnosis and symptoms of this condition. Almost every country in the world was represented in the contributions to this literature. He remarked upon the advances made during that period, which he believed could be mainly attributed to the increased skill in diagnosis.

The Pathologic Anatomy of Gastric Ulcer.—HARLOW BROOKS (New York) based his paper upon statistics from the Bellevue Hospital. In 1,000 consecutive autopsies the condition was present eight times, and spontaneous healing had taken place but two times. The lesions had been found to be present in every case in which it had been diagnosed as such. The records of the entire Bellevue Hospital from January 1, 1904, to May 1, 1904, show over 2,000 autopsies with gastric ulcer in but three instances. The condition is most frequently found in the young, and is generally single, although it may be multiple, and when of the latter type the age of the different lesions varies. Statistics of the location have been furnished by Brinton, Einhorn, and others, showing that the frequency of occurrence is in the following order: Posterior surface, lesser curvature, then the pylorus, and lastly, the anterior wall and fundus, even extending into the duodenum—his own personal cases having been located near the pylorus. While location is of much importance as to prognosis, unfortunately it cannot be determined clinically. The ulcer is usually conical or funnel-shaped in form, sometimes oval or sausage-shaped, the latter being usually more shallow than the former. When seen in its early stages it has the punched-out appearance, but in old ulcers this and also the conical form may be lost. The size of the ulceration varies very much, and secondary invasion is usually present in the very large ones, which may be as large as 10 cm. by 15 cm. As a rule the size of the acute ulceration is much smaller, according to Einhorn being not larger than a 25-cent piece, and in the author's experience not larger than a five-cent piece, but the matter of size is relatively of little importance, as it will vary if the stomach is contracted or dilated. The depth

of the ulcer varies, being usually increased by secondary infection, and the floor is usually covered by blood clot and inflammatory tissue. Perforation depends largely upon the extent of the ulcer, the rapidity of the process, and the location of the lesion. The author believed that there were a large number of cases of small ulcers which heal spontaneously without symptoms sufficiently marked to necessitate the calling in of a physician, his opinion being that the healing was due to granulations springing from the base rather than the sides of the ulcer. He also felt that gastric ulcer was sometimes followed by carcinoma.

Pathogenesis of Gastric Ulcer.—W. G. MACCULLUM (Baltimore, Md.) referred to the fact that Virchow as early as 1855 expressed the opinion that gastric ulcer was due to some circulatory disturbance, which would interfere with the blood-supply over a limited area. He referred to the work of Rote and Müller, who tied the arteries of the stomachs of dogs with absolutely no results, and that of Cohnheim by the injection of lead chromate until he filled the small branches of the arteries. He exhibited several specimens of the stomachs of dogs, upon which experiments had been made both by inserting a circular row of sutures around the stomach wall and by injection. The wounds heal in a short time and the dog usually dies of pneumonia. Embolism is not thought to be a frequent cause in human beings; nor are vascular changes, such as thrombus, hyaline degeneration, etc., as the condition frequently occurs in young persons in whom no vascular disease exists. Anemia, congestion and traumatism, as from long continued pressure, were also mentioned as probable causative factors; while other authors have stated that long continued disturbance of the central nervous system will produce hemorrhages and erosions in the stomach. As it occurs frequently in chlorotic girls, experiments have been made by bleeding dogs, which do not heal so rapidly. Hyperchlorhydria, he stated, was a frequent, although not a constant, symptom in gastric ulcer, and might also be found in other conditions, referring to the work done by Matas in this direction.

AMERICAN SURGICAL ASSOCIATION.

Twenty-fifth Annual Meeting, Held in St. Louis, June 14, 15, 16, and 17, 1904.

[Specially reported for *American Medicine*.]

The Association met in the assembly hall of the Board of Education, under the presidency of N. P. Dandridge, of Cincinnati, O.

President's Address.—President DANDRIDGE departed somewhat from the practice of his predecessors, and instead of bringing before the Association some medical topic based on his own work, or attempting a discussion of some subject of active interest, he took the members to the backwoods, and interested them in the life and exploits of a pioneer doctor. He depicted a man of high scientific attainments and true culture, with all the elements of character which become the doctor and the man. He gave an exhaustive sketch of Antoine Francois Saugrain de Vigni, who was born in Paris, February 17, 1763. He came from a long line of librarians, booksellers, and printers, who, as far back as Charles IX, in Lyons, and Henry of Navarre, had served the royal family of France. His knowledge of mineralogy made his advice often called for in the development of the mines in the Ohio Valley. In the wilderness he supplied himself with ink from a natural chalybeate water and an infusion of white oak bark, and when in need of a fire lighted it from a lens made by two watch crystals with clear water between. Dr. Saugrain gave notice of the first vaccine matter brought to St. Louis, and indigent persons were vaccinated gratuitously. He practised in St. Louis till his death, in 1820. He must have been eminently successful, for he left a large landed estate for the support of his wife and six children. His scientific work lives in tradition, and has gained for him the title of the "First Scientist of the Mississippi Valley."

What are the Minimum Requirements for Aseptic Surgical Operations in Hospitals where the Surgeon is Assisted by a Large Staff of Internes and by Nurses from a Training School?—This subject was discussed with great detail by GEORGE H. MONKS (Boston, Mass.).

Minimum Requirements for Aseptic Operating in a Hospital in which the Personnel of the Operating-room is Permanent.—A. J. OCHSNER (Chicago) pointed out the fact that with a permanent personnel a definite system could be developed, which was most satisfactory, because the observations which suggested changes as well as those which confirmed satisfactory methods, could be carried through a large continuous series of cases under unchanged external conditions. Stress was laid upon the importance of simplicity in the methods chosen. The less that was done in any given case the slighter was the likelihood of doing harmful things. There should be uniformity in carrying out a plan of work, in order that everyone connected with the system might know what had been done and what was to be done by the other members of the personnel in any given case. Above all things, the methods should be reasonable in their details. This would make the work more attractive, and consequently more satisfactory to those engaged

in its prosecution. The author then gave a detailed account of the system followed by him and his assistants at the Augustana Hospital, where he had had an opportunity to develop uniform methods with permanent conditions during a period of 15 years. The system comprised disinfection of patient, operator, assistants' and nurses' hands, instruments, silk, silk wormgut, horse-hair, drainage-tubes, hand brushes, dressings, implements, towels, sheets, etc. The author also discussed drainage and irrigation. Stress was laid particularly upon the danger arising from tying sutures too tightly, thus causing pressure necrosis, which favored the development of microorganisms accidentally introduced. The method of selecting assistants and nurses was described, and a table illustrating the manner in which each assistant recorded the progress of the wounds under his care was appended.

CHARLES HARRINGTON (Boston, Mass.) read a paper, by invitation, in which he detailed his studies in asepsis. These three papers were discussed jointly.

DEFOREST WILLARD (Philadelphia) said that surgeons who had to deal with the practical side of asepsis in surgical operations knew that their results satisfied them to a certain degree, but it must be confessed that they had failures, and it was very essential to know whether the failures were due to the method or methods employed, or whether there were difficulties which could not be overcome. Difficulties would beset surgeons, but the question resolved itself largely into one of extreme care on the part of everyone, from the surgeon down to the lowest assistant, who had the materials in charge or in preparation. There could be no doubt that a hospital which had permanent assistants, permanent nurses, was the one that was likely to secure the best results from operative procedures on the patients under its care. CHARLES B. NANCREDE (Ann Arbor, Mich.) emphasized two important parts, one of which was inhibition, and the other tissue resistance. A germ might be inhibited to the point that would render it safe in a given wound. JOHN E. OWENS (Chicago) stated that different results were reported by different surgeons after using the same methods, and he had often wondered whether some of them might not have been due largely to the habits of surgeons. So far as the disinfection of hands was concerned, a few years ago he was compelled to stop the use of corrosive sublimate on account of the condition of his hands, and since then he had been scrubbing them thoroughly with soap and water, keeping the nails of the fingers pared down, and afterward washing the hands with salt solution and alcohol, and he thought his results were as good in hospital work as where other chemicals for sterilization were used. W. W. KEEN (Philadelphia) spoke of his own method and the results which he had obtained by some experiments. He had adopted for several years past for the cleansing of his hands a method which was first directed to the attention of the profession by Weir, namely, the use of chlorid of lime and carbonate of soda. The hands were washed thoroughly with soap and water, and in order to do this he had in his own private hospital and at the clinic at Jefferson, little egg boilers, which were practically hour-glasses or sand-glasses that were reversible. These were marked "soft boiled, well done and hard boiled." Soft boiled corresponded to about three minutes; well done, five minutes, and hard boiled, seven minutes. He told his assistants that when they had scrubbed their hands until the sand had reached "well done," good and faithful servant, they should stop. Every person, who took an active part in his clinic, had a culture taken from under the thumb, or one or two finger-nails, particularly at the root of the nail, and from the free surface of the skin. During the last winter there were 213 cultures made, from the hands of himself and his assistants in the clinic at Jefferson. Of this number, there were only three cases in which any culture was obtained. This made practically a sterility of 97%, and an infection of about 3%. There was but one person who was free at every clinic, and that was the head nurse, who was a permanent official in the operating-room. All the other nurses, and all the assistants, except his principal assistant, changed every three months. He thought the method of keeping such a record of every person's hands served an admirable purpose by creating a sort of rivalry among those who were endeavoring to have clean hands before operation, and it was more to prophylaxis in preventing infection than in the results obtained he attributed the value of the method. W. B. COLEY (New York City) did not believe sufficient stress had been laid upon sterilization of the skin, and although some authorities maintained it could be done properly in a few moments before operation, his experiments showed that with careful preparation the day before operation, in addition to what was done on the day of operation, sterilization of the skin even then could not be said to be perfect. In 250 cases in which he had examined portions of the skin or Reverdin grafts, taken from the field of operation immediately before, 25, or 9%, of the cases showed all kinds of cultures, some of them being staphylococcus and streptococcus. The only case of suppuration in 200 cases showed a pure culture of the streptococcus. Carefully sterilizing the hands, using tincture of green soap, applied carefully, brushing and hot water, then washing thoroughly with 95% alcohol, with the use of rubber gloves, would give as good results as any of the measures which rendered the hands very hard. With reference to primary union, an important element in aseptic surgery was to guard against the bruising of tissues.

ABDOMINAL PAIN FROM UNSUSPECTED IRRITATION AT THE INTERNAL HERNIAL RING.¹

BY

CHARLES G. STOCKTON, M.D.,

of Buffalo, N. Y.

This paper has to do with a cause of abdominal pain, which, while it may not be unfamiliar to some, has nevertheless generally escaped description in literature and appears to be overlooked by the profession. The importance of the subject rests not so much in the severity of the pain experienced, although this at times is great enough to induce semiinvalidism, but in the fact that it explains pain which might otherwise be attributed to graver visceral lesions and for the relief of which fruitless exploratory incisions might be undertaken. Some of my cases have been regarded as instances of chronic appendicitis, nephrolithiasis and questionable affections of the colon. In my experience the condition has always appeared in male adults, usually men of relatively active life. I have seen it in advanced age, and in young men, but never in adolescence. The chief symptom complained of is pain, generally referred to the lower quadrants of the abdomen, but occasionally appearing in the upper quadrants as well. Sometimes this pain is described as colicky in character, sometimes as a continuous misery; at other times as burning in character and suggesting irritation to the peritoneum. There is rarely localized tenderness, although it sometimes occurs. Occasionally there is a sense of abdominal uneasiness complained of, a vague unrest that seems difficult to describe; at times the patient speaks of moderate disturbance of the intestine as though occasioned by intestinal flatus, and one patient suffered from severe gastric eructations. Generally these symptoms are relieved when the patient lies down; but this is not always the case, and some have experienced more pain when attempting to rest than when actively engaged in exercise. As a rule, exercise increases the distress, especially lifting or other efforts causing increased intraabdominal pressure. Several of my patients have been traveling men who complained that they suffered when riding on the cars, or in carrying in the hand sample cases or other heavy articles. These disagreeable sensations are sometimes persistent, at other times intermittent in appearance. For instance, an individual may be free from the sensation for a month, and then there is a return for some weeks, and again an intermission. Like other abdominal troubles it is likely to give rise to apprehension and nervousness on the part of the patient, and when the diagnosis is not made and the patient fails to experience relief from treatment he is likely to go from physician to physician. A number of my patients have been habitual drug-takers. The anatomic basis for these symptoms is to be found in a slightly over-patulous state of the internal hernial ring; not a condition so advanced as to admit of evident and easily recognized protrusion of the intestine or omentum, but one in which a slight bulging may be detected on palpation, when the patient undergoes abdominal strain such as is produced by bearing down or coughing. The sensation communicated to the palpating finger is often quite unlike that of ordinary hernia. It is as though a very thin and almost inappreciable membrane presented at the opening in the inguinal canal with a sensation of slight elasticity, as though a moderate gaseous pressure was operating behind it.

I go into these apparently insignificant details of

description for the reason that the condition is so easily overlooked, and in certain cases is difficult to recognize even when pointed out by one familiar with the condition. In some cases it would appear that the irritation is seated in the peritoneum alone; in others the small intestines would seem to be involved, but never have I seen in these patients those symptoms and signs which usually accompany ordinary inguinal hernia, and in only one of my cases has there ever occurred a recognized protrusion of the hernial sac. It is interesting to note that the symptoms described occasionally occur in those having an inguinal canal so small that one would scarcely suspect it as being the source of the trouble, many individuals having much more patulous inguinal rings without experiencing any inconvenience. The diagnosis, therefore, cannot rest on the mere question of the diameter of the internal ring, for the symptoms may arise in those in whom the ring is only moderately large; a condition of affairs that would not ordinarily be classed as abnormal.

In each of my cases perfect relief has been experienced by the wearing of a sufficiently carefully adjusted truss. Some patients have worn these for years, and inform me that if the truss is left off the old symptoms reappear after a few days, sometimes almost immediately. In one very aggravated case, not reported in this series, seen in consultation with Dr. Charles Cary who made the diagnosis, it was impossible to adjust a truss that would remain continuously in place, and for that reason it became necessary to resort to a surgical operation to lessen the caliber of the internal ring, after which procedure the symptoms were completely relieved.

I append the brief histories of 12 cases which represent only a proportion of those which have come under my observation during the past 10 years. Perhaps I should apologize for presenting that which may appear to some as a trivial subject for discussion, and one which probably is known to others; but as I have said, it is a condition sometimes causing great disturbance, although usually comparatively slight, is generally overlooked, even by good men, and finally, the discovery of this condition may occasionally save a patient from undergoing a useless abdominal section.

The following is one of my most interesting cases:

CASE I.—A. C. B., aged 62. The patient was rather stout, an active lawyer of New York City, a club man, highly intelligent, who subjected his symptoms to careful analysis. He complained most bitterly of disagreeable sensations in his abdomen. Many interviews and many pages of written accounts of his experiences were afforded me, but it remains impossible for me fully to understand what he attempted to explain. Among other things, he said he had a dull, aching pain during most of the time in various parts of the abdomen, accompanied sometimes by sharp twinges of pain, at other times by burning sensations. He also spoke feelingly of the distress accompanying intestinal peristalsis. He had a constant feeling of abdominal unrest. These sensations led to considerable mental uneasiness, so that he had consulted many physicians and tried various methods of cure initiated by himself. His symptoms were so vague that for a long time I failed to locate his difficulty and prescribed for him with little success at different times during a period of two years. Among other things, I recommended him to play golf, and while he found that this benefited his general health, it increased his abdominal suffering. This led to an examination of the inguinal regions, when I found a dilated right internal hernial ring, with slight bulging of what appeared to be the peritoneum. A truss was at once put on and the patient left the city. Immediately thereafter some friend recommended to him the use of a nostrum. His symptoms completely disappeared. He felt certain that it was the effect of the nostrum. I felt equally certain that the relief followed the wearing of the truss. I could not persuade him to stop the use of the nostrum and to try the truss alone. Matters proceeded in this way for over a year. Then he accidentally went without the truss for a short time, when the pain immediately recurred, although he took the nostrum constantly. After making some experiments on his own account, he wrote me that he was fully convinced that it was the truss and not the patent medicine which had relieved him. This is a somewhat remarkable case, in the complete relief which has followed this simple measure in a man who had great intelligence and who was convinced against his will.

CASE II.—L. D. P., contractor, aged 80, had pain and dis-

¹ Read before the Association of American Physicians, at Washington, D. C., May 11, 1904.

comfort of a vague character in both lower quadrants of the abdomen. He was in all other respects perfectly well. Found on both sides large internal rings; a truss was applied and relief obtained.

CASE III.—W. A. R., school teacher. Patient had been long constipated. For two years he had suffered from abdominal pain and soreness, the first intimation of it having followed unusual efforts while carrying his sick wife. He is a powerful man, and aside from the symptoms narrated, was perfectly well. I found a patulous right inguinal canal, and applied a truss, instructing him to keep his bowels open. The patient was relieved. Under date of March 14, 1904, he writes: "I followed your advice and found that the truss gave me relief as long as I continued to wear it, but it is necessary for me to wear it continuously."

CASE IV.—W. H. H., aged 28, worker in the oil fields; suffered from typhoid fever nine months before, and since has had pain occasionally, every two or three days, not always in the same part of the abdomen. A careful examination failed to discover anything wrong with him save the patulous inguinal canals, for which a double truss was applied. Relief was obtained at the time; but I have not been able to follow the subsequent history of the case.

CASE V.—E. L. H., aged 38, bookkeeper, man of delicate frame and loose tissues. Complained of pain in various parts of the body, especially in the right side of the abdomen and back; he also suffered from frequent urination. He has a floating right kidney and patulous inguinal canals. A double truss was applied with definite relief, but I have not been able to follow the subsequent history of the case.

CASE VI.—W. L. T., aged 45, office-holder, had suffered from abdominal pain for the past 20 months without assignable cause. His pain was not located in any definite point of the abdomen, but was felt in various locations. It was always worse at night and left him on rising in the morning; he had been constipated for five years; both inguinal canals were patulous. A suitable truss was fitted and four years later he reported that he had been entirely free from pain since wearing the support.

CASE VII.—H. C. R., aged 48, lumberman, had suffered for a long time past from a very disquieting but inconstant pain in the left lower quadrant of the abdomen. He was well in all other respects. He had a large hernial ring on the left side and a proper truss was applied. Six weeks later he reported that he had been entirely free from pain since wearing the truss.

CASE VIII.—F. J. C., aged 50, accountant, standing at desk. Had suffered for a long time with pain in both lower quadrants of the abdomen. There was considerable enlargement of the hernial rings with slight though palpable bulging, but no definite hernia. A double truss was applied, following which there was complete relief.

CASE IX.—Wm. G., aged 35, office work, had suffered from colicky pain in the abdomen for two years. His bowels were regular, digestion good, nothing could be found wrong with the man save that he had an over-patulous left inguinal canal with slight bulging. A truss was applied, and a year later he reported complete relief following the wearing of the truss.

CASE X.—W. R. F., aged 31, a storekeeper on docks. This patient had suffered for five or six years with noisy eructation of gas, which kept him awake at night. Of late he had been much worse. He also suffered from vague abdominal distress, poor capillary circulation and a suggestion of hypochondriasis. At one time he had an inguinal hernia which had been reduced. I immediately applied a truss and this was followed by relief of his symptoms. Nothing else seemed to have any effect upon his gaseous eructations. Here it will be seen that the disturbance was of motor as well as of sensory character.

CASE XI.—W. B., aged 60, a traveling railroad inspector. He was well until three months ago, when he began to suffer from pain in the abdomen and a sensation of dragging or pressure in the inguinal regions, slow action of the bowels, eructation of gas and a feeling of weakness or faintness in the epigastrium. The man was found to suffer from very marked chlorosis, having only 44% of hemoglobin, although the red blood count was between 4,000,000 or 5,000,000. There was found to be a right patulous internal ring. Treatment for chlorosis, while benefiting him generally, did not relieve the abdominal symptoms, so a truss was advised. He at once experienced relief, and wrote me, under date of March 9, saying, "The truss worn relieved me to a large extent from pain and aches I had on the right side of my abdomen." He goes on to say that his general health has not been improved by the remedies prescribed, and his chlorosis undoubtedly continues.

CASE XII.—A. W. H., aged 43, a traveling man. Patient had never been sick, had been a traveling man for 21 years. Complained of lumbar and abdominal pains from the border of the ribs on each side reaching down the flanks, not affecting the midabdominal regions. Careful examination revealed no reason for the pain except an incomplete right inguinal hernia for which a truss was applied and with relief. I have not been able to follow the subsequent history of the case.

A considerably larger number of cases might be reported, but this should be sufficient. It seems probable that inconspicuous umbilical or epigastric hernia may produce symptoms like those mentioned.

PRIMARY TYPHOIDAL CHOLECYSTITIS, WITH CALCULI.*

BY

FRANCIS T. STEWART, M.D.,

of Philadelphia.

Professor of Surgery, Philadelphia Polyclinic; Surgeon, Germantown Hospital; Assistant Surgeon, Jefferson Hospital; Out-patient Surgeon, Pennsylvania Hospital.

Although the condition has not attracted much attention until recently, cholecystitis occurring as a complication of typhoid fever was recognized by Louis.¹ It is probable that the bacillus of Eberth lodges in the gallbladder in the large majority of the cases of typhoid; in 66 autopsies of typhoid patients the bacilli were found in the gallbladder in 47.² It is not very unusual to find tenderness in the right hypochondrium during an attack of typhoid; less commonly a distinct swelling of the gallbladder may be felt. Most of these cases subside without surgical treatment. As with the appendix, within whose lumen bacteria perpetually dwell, so with the gallbladder, the presence of infectious organisms alone is not sufficient to give rise to serious trouble; there must be irritation from concretions or lack of proper drainage. Indeed *Bacillus typhosus* may reside in the gallbladder for years without causing symptoms. In Miller's³ case the germ was recovered from the bile 7 years after an attack of typhoid fever; Dungern⁴ isolated it after 14 years, Droba⁵ obtained it after 17 years, and Hunner⁶ found it 18 years after the primary infection. In cases of this sort the possibility of reinfection should be considered.

The relation of the clumped bacilli to cholelithiasis has been pointed out repeatedly. Although physiologists insist on its antiseptic properties, Fränkel, Krause,⁷ Miyaki⁸ and others have cultivated both the colon and the typhoid bacillus in the normal bile. It is probable that the bacilli enter the portal circulation from the intestine and are eliminated by the bile, thus gaining entrance to the gallbladder. Direct infection from the intestine by way of the choledochus and cysticus is possible, but in such an event the bacilli would have to fight their way up stream and would probably be contaminated with other microorganisms. The original demonstration of the possible pyogenic nature of *Bacillus typhosus* was made in 1887 by Fränkel,⁹ who obtained it in pure culture from a peritoneal abscess. Gilbert and Girode,¹⁰ in 1890, were the first to prove that it may produce suppurative cholecystitis. That *Bacillus typhosus* may cause a suppurative inflammation of the gallbladder in a patient who has never had typhoid fever has been noted only recently. In *Medicine*, October, 1903, Burley reports a case and gives a table of six other cases which he has collected from the literature; Richardson,¹¹ Cushing,¹ Pratt² (two cases), Mitchell,¹² Stockton and Lyte.¹³ I am indebted to Dr. Robert G. Le Conte for the privilege of operating upon and reporting the following case:

The patient, a woman, aged 26, was operated upon August 10, 1903, in the Pennsylvania Hospital. She had had three children, the last, two years before admission. Her health had always been good until ten years ago, when she experienced her first attack of gallstone colic. These attacks recurred with increasing frequency until the time of operation. There is no history of typhoid nor of any disease resembling typhoid. For three weeks before operation she was intensely jaundiced. On admission to the hospital the temperature was 101° F., and the pulse 100; there was tenderness and a slight fullness to palpation in the right hypochondrium. The examination of the rest of the abdomen was negative. Although the patient was deeply jaundiced the blood coagulated in one minute. The gallbladder was exposed by a longitudinal incision through the right rectus; it was elongated, thickened, sacculated near the duct and surrounded by a few recent adhesions. The distended fundus presented through the convex surface of the liver just above its margin and was opened at this point, giving exit to a small quantity of clear fluid and then a large quantity of sand and greenish-yellow pus. A stone about 2 inch in diameter was removed from the sacculum near the cystic duct.

*Read before the Philadelphia County Medical Society, March 23, 1904.

Although no stone could be felt in the common duct, it was incised and a probe passed up into the hepatic duct and into the duodenum without revealing any obstruction. The gallbladder was sutured to the abdominal wall with catgut and a gauze drain passed down to the opening in the common duct.

The patient made an uneventful recovery. The pus from the gallbladder gave a pure culture of *Bacillus typhosus* as is shown in the following report made by Dr. Longcope:

Cultures from gallbladder made at operation. Two agar slants. After 24 hours, incubation at 36.5° C., both show a growth of several delicate, gray, semitranslucent, small, raised colonies. All the colonies prove to be of the same variety. The organism is a delicate, actively motile bacillus which stains in a slightly irregular manner with anilin dyes and decolorizes by Gram's method. It grows delicately on agar, does not produce gas in glucose media, clouds bouillon diffusely but does not form a pellicle, produces a faint cream-colored moist growth on potato, acidifies milk very slightly after 24 hours, but causes no frothy change after a week's growth. It does not liquefy gelatin. Positive agglutination was obtained in 45 minutes with a 1 to 100 dilution of known typhoid serum.

After receiving the foregoing report some of the patient's blood was sent to the laboratory for the Widal test with a positive result.

THE PATHOLOGIC INCREASE OF URIC ACID.¹

BY

E. E. SMITH, M.D., PH.D.,
of New York City.

Fifteen years ago it was generally believed that the formation of uric acid in man was due to imperfect oxidation. This explanation was suggested by the relation of the formulas of urea and uric acid; urea was regarded as the normal, fully oxidized end-product of nitrogenous metabolism and uric acid as a less oxidized end-product, dependent for its formation on some deficiency in the process of oxidation, for which reason oxidation stops when the nitrogenous products are in the uric acid stage. In the early nineties this deficient oxidation theory gave way to the present nuclein theory.

A certain grouping of atoms occurs in true nucleins, and their derivatives which Fischer has aptly called the purin radical. This purin radical is the central group of atoms in the molecules of a large class of substances known as purin bodies. Besides uric acid, the class includes the various xanthins, the guanins, adenin, episcarin, and carnin that occur in the animal body. These have been variously termed xanthin bodies, nuclein bodies, and alloxuric bodies by different observers, but without question the term purin bodies given by the chemist who discovered their structural relationship is best adapted to indicate them. It is now known that because of the occurrence, chiefly in true nucleins and their derivatives, of the purin radical, that in the animal body uric acid and basic purin bodies are formed as end-products of destructive metabolism. According to this view, uric acid should be regarded as a product of the metabolic breakdown of those substances, chiefly the nucleins, in which the purin radical exists, preformed.

In view of the fact that nucleins occur largely in the cell nuclei, and the belief that the white blood corpuscles

are the cells that undergo the most extensive destruction in the body, it was anticipated that uric acid excretion would be found parallel to the number of leukocytes in the blood, increasing with a leukocytosis and diminishing with a leukopenia; however, exact observations disproved this idea. At least one disturbing factor in any such relationship is the fact, since discovered, that not only is uric acid derived from the nucleins of body tissues, but also from the nucleins of food. For convenience we have come to designate uric acid formed directly from the food as exogenous uric acid, and that formed by processes of metabolism within the body as endogenous uric acid. Eliminating the influence of exogenous uric acid, exact observations show that the endogenous uric acid is not always proportional to the blood leukocytes. Evidently, either the destruction of other cells participates actively in uric acid formation from purin containing antecedents, or we must look to some other source than the purin origin for a part of the uric acid production in the body.

I am well aware that in even suggesting that we look away from the purin-containing antecedents for a source of part of the uric acid excreted, I am going against current opinion. That all of the uric acid in man is derived from this source I think is neither proved nor is probable. That in health much of the uric acid may be from such origin has been demonstrated. Because of this, it has naturally been assumed that the increase in disease is due to an increase of the nuclein destruction, but this has not been proved. That a portion of the increase may be from nuclein breakdown is possible, but considerations to which I wish to direct attention lead to the opinion that at least some, and probably in many instances most of the pathologic increase owes its origin to an entirely different source.

Consideration of the clinical states in which the amount of uric acid excreted is found to be pathologically increased, will show that the one constant manifestation in such states is exhaustion. This condition of abnormal fatigue forms a part of the clinical picture in a large number of the diseases in which the uric acid output is pathologically increased. It is well known, even with our present incomplete knowledge of the subject, that the products of destructive metabolism differ during the condition of overfatigue from what they are in the normal state. Further, in muscle experimentally over-fatigued an increased amount of lactic acid is formed, and in a person overfatigued by muscular work, the action of the fatigue products is upon the central nervous system quite as much, or even more, than upon the over-tired muscles. It has also been shown that the experimental introduction of lactic acid into the body actually leads to an increase in uric acid output, the increase being due to uric acid formation by synthesis through the combining of the lactic acid with urea.

In view of these facts, we are naturally led to inquire, whether in disease the abnormal products of metabolism do not give rise to the accompanying pathologic increase of uric acid by synthetic uric acid formation. It is my conviction that this actually is the case; that the source of the increased uric acid output in disease is in many, if not in most instances, the synthesis of abnormal products of metabolism.

Let us test this suggestion by further consideration of clinical and experimental facts. If the view is correct, there should be a uric acid increase following prolonged muscular work, if the work is sufficient to produce a condition of abnormal fatigue. That such is the case is demonstrated by various observations. Results show that prolonged muscular exercise does not produce an increased elimination of uric acid when the subject is in proper physical condition, but when he is in poor physical condition for the muscular task there is a pronounced uric acid increase. The abnormal condition of fatigue and the production of products capable of forming uric acid by synthesis afford a natural explanation of

¹ Read at the symposium on uric acid at the meeting of the Medical Society of the County of New York, March 28, 1904.

this observed uric acid increase in the subject in poor training.

It has been observed that uric acid excretion is at times much increased by alcohol. I have noticed, in experiments demonstrating this, that it is not the absolute amount of alcohol that determines the increase but whether certain physiologic effects are produced. Thus, in an individual taking alcohol in the form of whisky there was no noticeable subjective effect and no pathologic uric acid increase, while in the same individual at another time when the same quantity of alcohol was taken in the form of champagne there was a distinct effect upon the nervous system and there was a well-marked pathologic uric acid increase, results consistent with the view which we have under consideration as to the origin of the pathologic uric acid.

We might profitably consider various diseases in which there are the clinical manifestations that suggest the abnormal metabolic condition on the one hand and in which there is a pathologic uric acid increase on the other. Thus, in fevers, neurasthenia, migraine and in the postconvulsive state of an epileptic seizure such a relation may exist.

I do not maintain that the products of metabolism are the only source of substances that give rise to synthetic uric acid formation. It seems to me probable that products formed by fermentation of food in alimentation may also at times be transformed into uric acid by synthesis, thus giving rise to a pathologic uric acid production. In fact, the regular occurrence of a pathologic increase in digestive disorders is very suggestive of this origin. What I do wish to be understood as maintaining is, that while it has been amply demonstrated that the endogenous uric acid excreted under ordinary conditions of health, and which we may designate as the physiologic uric acid, is to a considerable extent, perhaps, derived from nuclein breakdown in destructive metabolism; it has not been demonstrated that the uric acid constituting a pathologic increase is from this source and that a consideration of clinical and experimental data indicates that the pathologic increase in many instances is largely derived from synthetic uric acid formation from pathologic products in the body. The products of this kind that I have suggested may participate in this increase are the morbid products of a condition of abnormal metabolism, such for example as may be induced by overfatigue, and also possibly products formed by gastrointestinal fermentation.

PRIMARY STREPTOCOCCAL MEMBRANOUS LARYNGITIS IN AN ADULT.

BY

SAMUEL McCLINTOCK HAMILL, M.D.,

of Philadelphia.

A membranous laryngitis at any period of life is uncommon. It is especially uncommon in adult life. Membranous laryngitis, due to the streptococcus, is more uncommon than that due to the Klebs-Löffler bacillus. There are, however, a number of cases of the former on record, but the majority of these were secondary to infections of the upper air passages. As a complication of measles and occasionally scarlet fever in infancy, one sees primary laryngitis, due to the streptococcus.

In Park's extensive study of membranous conditions of the larynx, he records no cases of primary streptococcal laryngitis, and no cases of primary membranous laryngitis in the adult. A limited study of the literature relating to this subject, together with information obtained from men who have had wide experience in the study of diseases of the throat and nose, lead me to believe that the condition is very unusual.

For this reason, and because of the misleading char-

acter of the symptoms, I desire to report the following case:

M. H., a female, aged 52. One brother died of tuberculosis. Her family history was otherwise good. She has had hay-fever severely for many years, and after the birth of her oldest child, 23 years ago, she had a severe puerperal infection from which she made a slow but complete recovery. For some years she had frequently recurring attacks of gallstone colic, which have ceased. For two years she has had flitting joint and muscle pains, the phalangeal joints becoming moderately swollen and inflamed. For three months prior to the present illness, she had complained of a constant sense of fatigue, which was exaggerated by moderate exertion.

On the afternoon of Sunday, April 5, 1903, she developed a sore throat. She attended church in the evening. During the night she suffered severe pain, had a mild chill and fever. Early Monday morning she called in a nearby physician, who made a diagnosis of tonsillitis. Her temperature at this time was 103° F. The pain increased during the day.

I saw her at three o'clock in the afternoon. At that time, her temperature was 103.5°. She had intense pain on attempting to swallow and was regurgitating practically all food. Her voice was hoarse but not suggestive of membranous involvement of the larynx. She had no cough.

Examination of the throat showed nothing abnormal, the visible mucous membrane was not even reddened. She had no nasal symptoms and nothing abnormal in the appearance of the nasal mucous membranes. It was assumed that the difficult deglutition and the regurgitation were due to spasm of the pharyngeal muscles, reflexly induced by the laryngeal pain caused by swallowing.

By the following morning, the pain on deglutition and the difficulty in swallowing were more marked. The character of the voice was the same and the hoarseness was not more marked than is common in ordinary severe catarrhal laryngitis. The appearance of the visible portion of the throat continued normal. The temperature had risen to 104.5°.

Dr. Edsall saw her in consultation with me at this time and agreed in the diagnosis of catarrhal laryngitis, probably one of the manifestations of a severe influenza infection. At 3 p.m. the temperature was above 104°; at 5.30 p.m. it had fallen to 101.4°. The condition of the voice had improved, and the patient expressed herself as feeling very much better. The temperature continued to fall until at 10 p.m. it reached 100°. By the following morning it had risen to 100.4°, and (although there was no change in the appearance of the throat, and the general condition of the patient was improved) we thought it advisable, owing to the continued difficulty in swallowing and a scarcely perceptible obstruction to the entrance of air, to have Dr. Walter Freeman make an examination of her larynx. His report follows:

"The pharynx is in very fair condition, also the rhinopharynx. The epiglottis is swollen to six times its usual thickness and is covered with ecchymotic spots and dilated blood-vessels. The interior of the larynx is lined with a membranous deposit which seems to be very thick, and which has a dark base in the commissure. The examination of the interior of the larynx is difficult because of the swollen condition of the epiglottis."

Blood-serum cultures were made by Dr. Freeman during this examination, in tubes which had been brought to the house at the onset of the illness, but which had not been used, owing to the absence of any visible lesion in the throat. The tongue was protruded and held by the patient, the mirror introduced and the swab rubbed freely over the epiglottis. Cover-slip preparations from the swab and from the tubes after 24 hours' incubation, examined by Dr. Evans and confirmed by Dr. Ravenel, showed an overwhelming growth of a diplostreptococcus, with here and there a stray rod-like bacillus. A study of this latter microorganism showed it not to possess the cultural characteristics of the Klebs-Löffler bacillus. However, on the basis of Dr. Freeman's opinion that the condition was diphtheria and on the assumption that the Klebs-Löffler bacillus might not have been obtained by culture, the patient was treated with diphtheria antitoxin. The gradual improvement, which had begun, continued. The temperature reached normal on the sixth day of the illness. By this time the character of the voice had improved and the pain on swallowing had practically ceased, but there persisted a sense of soreness on the right side of the larynx.

On the eighth day of the illness (five days after the first examination) a second laryngeal examination was made. The swelling of the epiglottis had lessened, but there were considerable patches of very white membrane on the right arytenoid, the lower part of the posterior commissure, and in the trachea. Cultures were made from a small portion of membrane which was expectorated at this time, examination of which showed a pure growth of a diplostreptococcus. The membrane did not entirely disappear until almost two weeks after the beginning of the illness. There was never any redness nor exudate in the upper portion of the throat. There was only one of the cervical glands enlarged. There was a moderate amount of albumin present for a few days during the height of the illness. There were no complications, and the patient made a rapid and complete recovery. Her health since the attack, has been better than it had been for many months.

LITHIOMERCURIC IODID.

BY

RANDLE C. ROSENBERGER, M.D.,

AND

JOSEPH W. ENGLAND,

of Philadelphia.

From the laboratories of the Jefferson Medical College Hospital.

It has been generally assumed that the active radical of soluble mercuric salts (in their destructive action upon bacteria and bacterial products) is the mercurial, and that the higher the percentage of mercury, the more destructive the compound of bacteria. This theory is apparently confirmed by the fact that the average dose for the human being, of corrosive mercuric chlorid (which contains 74% of combined mercury) is one-half that of mercuric iodid (which contains only 44% of combined mercury). But, on the other hand, it is nullified by the fact that experiments, reported first by Dr. Eugene P. Bernard, of Philadelphia (1886), have shown that mercuric iodid is fully three or four times as powerful in its effects upon bacteria as corrosive mercuric chlorid, indicating that the combined iodine of mercuric iodid is as important a factor in the bactericidal action of the salt as the combined mercury, if not more so.

When used in the form of a germicidal solution, mercuric iodid is dissolved in water with the aid of potassium iodid, producing potassiomeric iodid. We have found that lithium iodid forms an analogous compound with mercuric iodid, possessing features of superior value. This compound contains, practically, 34% of mercury, 65% of iodine, and 1% of lithium. It is very soluble in water, and has a higher percentage of combined iodine and mercury than the potassium compound, which is due to the lower atomic weight of lithium compared with that of potassium (7:39).

As the solution of lithiomeric iodid is a much more delicate precipitant of alkaloids than mercuric chlorid or other soluble mercuric salts, it is reasonable to believe that, in view of the alkaloidal-like character of the toxins of microorganisms, it decomposes these poisonous principles more effectively than the other mercuric salts. Not being precipitated by fixed alkalies, the solution is not decomposed by the alkalies of the blood or blood-serum. Being a stronger germicide than mercuric salts generally, a less quantity is required to do a given amount of germicidal work; and hence, with its use, there is less danger of mercurial poison.

Bacteriologic tests were made of lithiomeric iodid, using solutions of the chemically pure anhydrous salt in a normal salt solution. The results of the several series of tests are given in tabular form. Growth is indicated by +; sterility by —. The experiments were controlled, and in every instance the controls grew luxuriantly.

2 min.	+	+	+	2 min.	+	+	+
3 min.	+	+	+	3 min.	+	+	+

Longer exposures were made in 1:1000 solutions, varying from 5 to 30 minutes. In the moist condition the organism was destroyed in 30 minutes; on the dried threads it was killed in 15 minutes.

As regards the antiseptic or bacterial inhibiting action of the reagent, it was found that a 1 to 16,000 solution readily inhibited the *B. coli*, *B. pyocyaneus*, *B. anthracis* and *Streptococcus pyogenes* for 24 hours.

The next experiment was to determine whether the reagent acted upon organisms in the presence of albumin, as well as in its absence. Solutions were made of the strength of 1 to 1,000, (using equal parts of a sterile normal salt solution and a 5% salt solution of a pleural exudate. The 5% solution of pleural fluid contained 2% of albumin, determined by Esbach's albuminometer.

Threads soaked for 24 hours in 48-hour old cultures of *Streptococcus pyogenes* and *B. anthracis* were used in a moist condition. No growths were demonstrable in 48 hours.

Our conclusions are that in lithiomeric iodid we have a germicide which is very much more powerful than mercuric chlorid or the usual mercuric salts in its destructive action on bacteria and their toxins, and that as it contains less combined mercury, it is, therefore, less liable to cause poisoning on absorption.

THE LARYNX IN BEGINNING PULMONARY TUBERCULOSIS.¹

BY

W. G. B. HARLAND, M.D.,

of Philadelphia.

Instructor in Laryngology, University of Pennsylvania; Surgeon, Ear and Throat Dispensary, Presbyterian Hospital; Laryngologist to Phipps' Institute for Tuberculosis.

A few typical cases will illustrate the practical value of an examination of the larynx in beginning tuberculosis of the lungs.

CASE I.—The patient, a young man, came because he thought he had nasal catarrh; he had been treated for it the preceding winter. Examination showed chronic catarrhal rhinitis and rhinopharyngitis; the vocal cords were red and granular. The latter, with the age of the patient and some suggestive symptoms, at once aroused suspicion of tuberculous infection. His

¹ Read before the University of Pennsylvania Medical Society, April 15, 1904.

lungs, which were examined by an expert, showed apical lesions. Under treatment this patient's health was greatly improved.

CASE II.—A young lady was sent for local treatment of the nose and throat. She had faulty action of the right vocal cord; the base of her tongue was swollen and coated. Examination of the lungs showed both apices involved. Under treatment this patient gained 22 pounds in less than four months.

CASE III.—A man with slight involvement of both apices was sent for laryngeal examination. The larynx was found greatly diseased—infiltration of ventricular bands and arytenoids, perichondritis of cricoid cartilage. Previous favorable prognosis was shown to be entirely erroneous; patient became rapidly worse in spite of treatment.

CASE IV.—Young man having had frequent colds in the head, was sent for nasal treatment. Cords were found congested and lung examination was advised. Physician said he had already found slight evidences of consolidation of the right apex, but not enough to warrant a diagnosis. Larynx examination made diagnosis possible.

From the foregoing it is evident that an examination of the larynx in all cases of tuberculosis can give important information. This may be positive or negative; in either case it will be of use in making a prognosis and may give valuable assistance in arriving at a diagnosis. A long-continued subacute laryngitis—a persistently congested vocal cord—may be the first clue in the detection of pulmonary tuberculosis and, on the other hand, we may find in a case otherwise deemed entirely curable, an advanced laryngeal lesion unquestionably pointing to a fatal ending.

To go into details, it may be said that quite frequently slight changes in the larynx are observed early in tuberculosis of the lungs. These changes may be classified under two heads: 1. Congestive. 2. Anemic. In the congestive class are those cases in which there is an apparently simple subacute laryngitis which persists. One or both cords are found reddened, and stay so; there may be partial paralysis of the tensor muscles of the cords. These conditions are probably due partly to cough, and partly to invasion of the deeper underlying tissues of the mucosa by tubercle bacilli, causing hyperemia and inflammatory impairment of function. Such changes are found more frequently when the tuberculous infection has followed grip or a series of colds. The local appearances, although not pathognomonic, should always suggest tuberculosis, and lead to a careful inquiry into the history and symptoms of the patient, and to an examination of the chest and sputum. The age of the patient, the persistence of the lesions, the absence of syphilis and of nasal changes that could explain the conditions present, the history of loss of weight, anorexia, etc., make the diagnosis not so difficult nor haphazard as at first sight it would seem to be.

The second class of cases includes those familiar to laryngologists, cases characterized by pallor of the mucosa of the larynx. The veins at the base of the tongue are swollen and the tongue covered with a whitish coating, indicative of gastrointestinal disorder. The vocal cords may appear congested or there may be some swelling of the tissues between the arytenoids. When infiltration has occurred it may form a reddened zone, contrasting markedly with the pallor of the adjacent mucosa; often, however, the tissues are pale from edema. In other cases, the cords are found thickened with superficial or deep ulcerations; also there may be present a club-shaped edematous infiltration of one or both arytenoids of the ventricular bands, or a turban-like swelling of the epiglottis, due to perichondritis. Infiltration in any of these localities may lead to ulceration. The lesions may exist in many combinations, so that no one picture can cover all types of the disease. A mound-like papillomatous projection of the mucosa between the arytenoids is suggestive of tuberculosis, rarely a paralysis of a vocal cord may be due to pressure on a recurrent nerve by an infiltrated apex or by enlarged glands. The following symptoms may be present: Cough, hoarseness, aphonia, dysphagia, depending upon the part of the larynx involved and nature of the lesion. Cough, however, is usually due to lung involvement. Aphonia

may be caused by physical weakness. The progress of the disease is slow, its chronic nature being of great diagnostic significance. The prognosis is unfavorable.

In conclusion, it may be said, that in the usual run of cases of beginning tuberculosis of the lungs an examination of the larynx may give the first clue to the presence of the lung infection; when the larynx is the chief seat of the disease the diagnosis and prognosis must be founded on the local appearances present. In all cases, the lesions observed in the larynx, as is true of those found elsewhere, will be of most value in making a diagnosis and prognosis when taken in connection with a thorough careful study of the case as a whole.

THREE POINTS OF INTEREST CONCERNING SMALLPOX AND VACCINATION.

BY

BERNARD KOHN, M.S., M.D.,
of Philadelphia.

In the discharge of my duties as assistant medical inspector for the city of Philadelphia, I recently encountered three cases in the same family, each of which illustrates an interesting point concerning smallpox and vaccination.

CASE I.—The first case was that of a school girl, aged 10. She had contracted smallpox, and had a fairly profuse eruption when I saw her. According to the history elicited from her mother, this girl had been vaccinated before being admitted to school some four or five years previously, and had been given a certificate of successful vaccination by the physician. Upon examination of her arms, no scars could be found.

Hence the first point to be emphasized is, that more care should be exercised in the issuing of vaccination certificates, and in admitting children to school on the strength of them.

CASE II.—Two or three days later this girl's uncle developed smallpox, the eruption in his case also being fairly profuse. According to his statement, he had been vaccinated for the first time in his life several weeks before contracting the smallpox, and had supposed that the vaccination was successful. On examination of his arm, a red patch was found, not pitted, and evidently not the result of a successful vaccination. His description of the course of the sore bore out the supposition that it had been a case of spurious vaccination due to poor virus, there having been no vesicle formation whatever.

Now here was a man who had done his duty in submitting to vaccination, and had become imbued with a false sense of security as to his immunity to smallpox. Hence my second point, that the manufacture of vaccine virus should be more carefully supervised by the government, in order to prevent the distribution of impotent virus. I should not be surprised if such distribution would account for numerous other cases of smallpox that have occurred during the present epidemic, for there has been a great deal of poor virus employed by physicians during the past two or three years.

CASE III.—The third case was perhaps the most interesting. The first patient had a young sister, a healthy, well-nourished baby, about 17 months old. The child had never been vaccinated, and of course I at once performed that operation. According to the custom in cases of exposure to smallpox, I vaccinated her in three different places, using a separate tube of virus for each site of inoculation. All three failed to show any signs of taking by the fifth day, and I repeated the operation with three more tubes. The lack of success still continuing, I vaccinated her twice again four days later, making eight trials in all. None of them took. The virus used was a very potent one that has been employed with great success by the New York and Philadelphia Boards of Health, and had produced excellent secondary takes in other members of the same family. So far as I can judge there was no serious fault in my technic of the operation. Despite intimate association with both patients whose cases are cited and despite close contact with her mother, who nursed the first patient for several days without taking any antiseptic precautions whatever, this baby did not develop smallpox, although countless opportunities for infection must certainly have been offered.

The inference cannot be avoided that this is one of those rare cases of natural immunity to smallpox, and hence to vaccinia also.

THE WORLD'S LATEST LITERATURE

Journal of the American Medical Association.

June 18, 1904. [Vol. XLII, No. 25.]

7. Notes on Curetage. With Report of a Case of Accidental Perforation of the Uterus. A. P. STONER.

2.—See *American Medicine*, Vol. VII, No. 24, p. 928.

5.—**Some Phases of Dental Education.**—A. E. Baldwin thinks the hope of dentistry lies in the schools connected with colleges and universities, and the elimination of those conducted by organized capital for income, or by organized professional bands, who, for notoriety or gain, carry them on, and are more anxious for numbers than intellectual prominence. [H.M.]

6.—**Dental Education.**—J. S. Marshall reviews the history of this specialty, the organization of societies; the elevation of the profession in public esteem, and discusses the need of higher preliminary requirements, the dangers of commercialism, and the necessity of placing dental schools under the control of the State or of the trustees of our great universities. [H.M.]

7.—**Curetage.**—A. P. Stoner uses the curet when the amount of retained secundines is small and the os contracted; with abundance of foreign tissue it is not reliable. In packing the uterus after curetage the gauze acts as a dam instead of a drain, and should be used only in hemorrhage. Gonorrheal endometritis should never be treated with the curet, as the tubes are already infected and the curet simply aids in spreading the disease. Comparatively few are skilled in using the curet, and cases are not properly selected. The cavity should be first explored with a dull wire curet, and then be systematically scraped with a sharp instrument. It should be washed with sterile water and no packing used, except in septic cases. A little loose iodoform gauze may be left in the vagina and changed daily. Preparation for curetage should be as careful as for vaginal section. [H.M.]

1.—See *American Medicine*, Vol. VII, No. 24, p. 933.2.—See *American Medicine*, Vol. VII, No. 24, p. 943.

3.—**The Caspar-Hirschmann Demonstration and Photographic Cystoscope.**—G. S. Whiteside calls particular attention to this new form of cystoscope. That form of cystoscope most frequently used is the one devised by Kelly. Its disadvantages are that the knee-chest position is tiresome and objectionable to an unethicized patient, and inconvenient in a completely etherized one; another is that the light used is reflected from a head mirror and the illumination is unsatisfactory. Its chief advantages are the large size of the tube, the fact that it is hollow, which permits the passage of instruments through it, and its comparatively small cost. The Caspar-Hirschmann instrument belongs to that class originally made practical by Nitze and it combines three valuable factors, namely, it may be used as a simple inspection cystoscope, or as a means of demonstrating and teaching cystoscopic and vesical pathology to students, or it may be used for taking permanent photographic records of interesting features in normal or diseased bladders. It is concerning its value as an instrument for teaching cystoscopy that the author speaks approvingly from the fact that both student and demonstrator can look through the instru-

ment at the same time. As an instrument for photographic use it is also very satisfactory. The author deals with the subject almost entirely in its relation to inspection of the female bladder. [A.B.C.]

4.—**Slavery a Preventive of Pulmonary Tuberculosis.**

—T. J. Mays reminds us that this disease was comparatively unknown among plantation slaves, while in cities in slavery days it was no more prevalent than among whites. The death-rate is now from 200% to 400% larger among negroes than among whites. The cause lies in the unequal struggle for existence with a more highly developed race. This has also increased insanity among them by 705%. Heavy economic and industrial burdens were placed on shoulders unprepared for them. This and their ignorance of the laws of physiology and hygiene, the lack of persistent employment, improper care when ill, alcoholism, and other vices, are responsible for the tremendous increase. Prevention consists in such efforts of education as will impress the masses with the importance of leading a life similar to that which made the slave practically immune. Cities should be divided into sections, each with a competent physician, whose duty it should be to make a general canvass once a month and impart advice as to food, clothing, shelter, habits, etc., to give medical counsel when needed, and send all cases needing active supervision to an institution. [H.M.]

Medical Record.

1. Myelopathic Albumosuria. S. J. MELTZER.
2. The Present Status of the Surgical Treatment of Chronic Bright's Disease. A. A. BERG.
3. A Few Words Concerning Radium. HENRY G. PIFFARD.
4. Hydrocele of the Cord. Report of Cases. A. JACOBY.

1.—**Myelopathic Albumosuria.**—S. J. Meltzer reports a case and states that, though the first case of myelopathic albumosuria was reported over 50 years ago, there are not more than 30 cases on record at the present time. These occur mostly in the German literature. The essential clinical points of the disease, to state them briefly at the outset, are: Pain of the bones, especially those of the trunk; the presence of Bence Jones albumose in the urine, and a more or less rapid decline, leading invariably to a fatal termination. The occurrence of the albumose in the urine is pathognomonic for this disease. The patient was a man of 45, who had previously enjoyed good health. He complained of pains recurring at intervals, especially in the ribs and vertebra. There was Bence Jones albumose in the urine, a rapid course, and fatal termination ensued. The essential diagnostic point was the presence of albumose in quantities in the urine. No blood-examination was made and no röntgen ray pictures were taken. The majority of writers have termed this disease multiple myeloma, the prognosis of which is exceedingly grave. So far as we know, the myeloma and the presence of albumose in the urine belong together, although there are some cases of myeloma in which no albumose has been found in the urine. The author reviews the literature of the subject, referring to various previously reported cases. He believes his case to have been the first one reported as having occurred in New York City. [A.B.C.]

2.—**Surgical Treatment of Chronic Bright's Disease.**—

A. A. Berg states that the proved value of surgical measures in the treatment of some cases of Bright's disease, has led Edebohl to advise operative treatment for all cases that are fit for surgical risk. To this Berg takes exception, and states that the etiology of Bright's disease, which is merely a generic term, is variable, depending upon a number of causes, and that, while some of these are suited for surgical interference, others are only made worse by it. As to whether surgical treatment shall be instituted depends upon the cause. It is evident that pathologic division of the cases does not afford a basis for fixing the indications for medical or surgical treatment. The author, therefore, suggests that cases conforming to the following rules only should be subjected to surgical treatment: 1. Those due to malposition, either congenital or acquired. 2. Those due to the irritation of a foreign body, as a stone. 3. Those due to the toxins of bacterial life, e. g., scarlatinal nephritis, nephritis of

measles, rheumatism, etc. 4. Those due to bacterial action, exclusive of the tubercle bacillus, *e. g.*, coli group, staphylococcus, streptococcus, etc. 5. Those due to general metabolic disturbances resulting in sclerosis of the internal organs, and bloodvessels. 6. Those due to newgrowths. 7. Those due to disturbances in the general circulatory system. 8. Those due to chronic suppuration and chronic exhaustive diseases. The subject is discussed at length, and the literature reviewed to some extent. It is possible in some cases to bring about an entire lasting cure of the chronic Bright's disease by operation. There are certain cases, however, in which the surgical therapy serves only to relieve some of the symptoms, and especially the pain and hematuria. Severe nephralgia and hematuria are often the only clinical evidences of the chronic nephritis; they are usually relieved by capsulectomy, though this operation may not in any way influence the disease process in the kidney. We practise four types of operation for the relief and cure of chronic nephritis, each of which has its indications. These operations are nephrolysis, decapsulation, nephrotomy, and nephrectomy. [A.B.C.]

3.—Concerning Radium.—Henry G. Piffard, in an interesting article, defines the nature of radium, its effects upon tissues, the mechanical apparatus best suited for its employment, and gives various valuable references upon the subject. As to the nature of radium he states that: According to the researches of Rutherford, Crookes, Ramsay, Mme. Curie, and others, radium emits both "radiations" and "emanations." The radiations or so-called rays are not simple and uniform in character, but are a mixture of rays exhibiting widely different physical phenomena, and by Rutherford have been called *alpha*, *beta*, and *gamma* rays. The *alpha* rays appear to be electrons, carrying a charge of positive electricity slightly deviable by the magnet. They constitute the largest proportion of the total, but possess but little penetrative power. Glass presents an almost insurmountable barrier to their passage. The *beta* rays are electrons carrying a negative charge and are strongly deviable by the magnet, but in a direction opposite to that of the *alpha* rays. They exist in a comparatively smaller proportion than the *alpha* rays, but possess a greater penetrative power. They appear to be similar to, if not identical with, the "rays" projected from the cathode of a Crookes' tube when excited by a suitable electric current. The *gamma* rays exist in a much smaller proportion than the others, are nondeviable and possess penetrating power to a high degree. They exhibit phenomena similar to, if not identical with, the röntgen rays. The so-called radioactivity of radium is due to the combined influence of the *alpha*, *beta*, and *gamma* rays. The *emanations* of radium differ wholly in character from the radiations above mentioned. The emanation is a gas continually given off by radium, and may be collected in a separate receptacle and its properties examined. This emanation is not only of itself radioactive, but possesses the power of exciting radioactivity in other bodies in its immediate neighborhood—that is, it confers on them the ability to emit Becquerel rays similar in character to those of radium. This induced or secondary activity is not permanent, but rapidly subsides and in a few days leaves but hardly appreciable traces. These emanations of radium will not pass through glass. [A.B.C.]

4.—Hydrocele of the Cord.—A. Jacoby (New Orleans) reports several cases of hydrocele of the cord, and contends that the condition occurs more frequently than is commonly supposed. Concerning three cases which were brought to his clinic, he states that in each instance a mistaken diagnosis of hernia had been made by the attending physicians. Hydrocele of the cord is due to a serous exudate in an unobliterated portion of the vaginal process; it may be either encysted or funicular. In the latter case, when the pelvis is raised the fluid flows back into the peritoneal cavity. In some cases the cyst is circumscribed, while in others it involves the entire length of the spermatic cord or inguinal canal. There seems to be no definite cause for this condition. Trauma plays a not infrequent part, and venereal disease may be a causative factor in some instances. The treatment may be divided into three classes: (1) The use of a truss; (2) the removal of the fluid, with or without the injection of an irritant; (3) the radical methods: (a) incision and drainage; (b) excision of the sac; (c) incision

of the sac, everting it, and suture. The first two methods are rarely employed at the present time, and are of doubtful value. The removal of the sac is not difficult, and it can be easily released from the cord and excised. This is the best plan of treatment. [A.B.C.]

4. The Fever of the Puerperium (Puerperal Infection). (Continued.) JAMES HAWLEY BURTENHAW.
5. Constitutional Low Arterial Tension. LOUIS FAUGERES BISHOP.

1.—Röntgen Rays in Epilepsy, etc.—J. H. Branth says that in epithelioma, rodent ulcer, lupus, and some other skin affections, the röntgen rays prove an almost certain remedy. A case of lupus of 15 years' standing is reported and photographs showing a cure presented. Upon the theory that röntgen rays stimulate protoplasm into greater vital activity, the author applied this remedy in cases of epilepsy. All cases are not amenable to this form of treatment, for instance, those in which decided degenerative processes in the brain have set in. Three treatments a week are given, beginning with 5 minutes' exposure at 15 inches distance, and by degrees increasing to 10 minutes' exposure at 10 inches distance. A different part of the skull is exposed at each sitting. It is a rule, with very few exceptions, that by this form of treatment the patient gains weight at a rate that is surprising. In the cases, both *grand mal* and *petit mal*, which were treated by this remedy, it was observed, in general, that the seizures became lighter and of shorter duration, the intervals became longer, and that when a seizure occurred less prostration followed. In patients with from 6 to 8 seizures a day, after receiving treatment for a few weeks, intervals of 2 and 3 weeks have been noticed. Radiographs are given, showing the value of röntgen rays in diagnosis. [C.A.O.]

2.—Fractures of the Radius.—Vertner Kenerson takes up in detail the fractures of the lower end of the radius. In reducing this fracture, he places the patient in a high office operating chair, in the upright sitting position, with the hand extended in front, the plane of the hand perpendicular to the floor, and with a skein of yarn looped over the wrist, with the loop knot fixed at a point on the upper side of the wrist as the hand is extended. He fixes the free end of the skein of yarn to a post or to the door jamb by means of a staple, at a height corresponding to the patient's shoulder. He then grasps the patient's forearm with the hand opposite to that which is injured in the patient and makes slow, but steadily increasing, countertraction on the arm until the arm is fully extended and the wrist is tired out somewhat, and then there will appear a lessening of the deformity, and usually a complete reduction of the fracture at the wrist, without touching the point of fracture. He says the lessening of the deformity will not remain unless with the fingers of the other hand you "jack back" the fragments of the broken radius, when perfect and permanent reposition can be secured. The hand should then be held in the forced extended position until the muscles have relaxed and then the strain can gradually be lessened and the fragments will stay in place. This method of reduction is applicable to all fractures at the wrist except the interarticular fractures, which should not receive any extension, but can be replaced usually by forcibly bending the wrist forward, that is, toward the palm of the hand. [C.A.O.]

3.—Crusade against Tuberculosis.—L. F. Flick says that dispensaries are the first essential asset in a voluntary crusade against tuberculosis. Such dispensaries will answer a threefold purpose: 1. Supply material to physicians for equipping themselves as experts. 2. Give poor people with tuberculosis, who still are able to work, an opportunity for recovery without too much sacrifice. 3. Will serve as a propaganda of knowledge of the prevention of tuberculosis. Such dispensaries must supply medicine, preventive measure supplies, and food when necessary, and they must supervise treatment in the homes of the patients through competent visiting inspec-

tors. They must be equipped to give baths, sterilize clothing, and do laundry work, where these are necessary for keeping the home sterile. As a matter of economy and efficient administration, hospitals for advanced cases of tuberculosis should be run in conjunction with dispensaries for walking cases. The next step in a voluntary campaign is to establish sanatoriums for curable cases of tuberculosis which need either comparative or absolute rest. [C.A.O.]

5.—Low Arterial Tension.—L. F. Bishop discusses low arterial tension, that is, a reflex of a constitutional condition. The condition is in all probability due to an inherent defect in the nervous system, whereby it has not the proper control of the bloodvessels. The same patients who suffer from this low arterial tension are very apt to manifest other symptoms of defective nervous control, and the removal of the underlying condition will bring about an improvement in the condition. The most important element of treatment is systematic exercise. Iron and arsenic improve the condition in some cases, in other cases very hot baths take the place of vigorous exercise, and improve the tone of the circulation. Cold bathing is not beneficial in these cases. [C.A.O.]

8. A New Instrument. W. A. SEDWICK.

1.—Management of Fever in Childhood.—E. W. Murray discusses the importance of understanding the normal mechanism of animal heat and the pathology of fever in order to have proper management. During acute fevers glandular activity and digestion are at a low ebb and the entire heat production is therefore probably due to oxidation in the muscles, hence wasting. Sleep is important in treatment and must not be disturbed except in sepsis and depressed brain action. Rousing from sopor is a necessity. If the fever is due to a germ, to local inflammatory conditions, or to the disease *per se*, the first duty is to keep the patient cool and quiet. A temperature of 105° F. or 106° F. can be sustained for a short time without damage, while 101° long continued is serious to heart muscles and nervous system. Strychnin, caffeine, cocain and atropin increase muscular and cerebral activity and atropin prevents perspiration. Alcohol and nicotin relax the bloodvessels and increase perspiration, morphin diminishes heat production by preventing glandular and molecular activity. The profuse perspiration from antipyrin is often very prostrating. Phenacetin is less depressing and can be used in short fevers, but cold is safer. Ingestion of ice or cold water diminishes temperature. Rectal irrigation gives good results. The ice-cap and sheet-pack may be employed. Insolation requires immersion in cold water gradually made colder by ice. In toxic fevers due to fermentation the essential in treatment is diet. Inanition fever is due to insufficient or improper food. The author discusses the best methods of feeding. [H.M.]

2.—Paralysis of the Ulnar Nerve.—J. H. Lloyd believes isolated paralysis of this nerve is infrequent. The majority of cases are due to trauma, sometimes from pressure in sleep, drunkenness, ether anesthesia, or unconsciousness from disease. The selective action of a systemic poison for one nerve is extremely rare. Lead selects the interosseous and some other branches of the musculospiral nerve, and wood alcohol the ganglion cells of the retina. An effort has been made to show that typhoid poison has a selective action for the peroneal and ulnar nerves. The writer formerly reported a multiple neuritis following typhoid, but now suspects excessive alcoholic stimulation and cold baths may have been largely responsible.

He reports an ulnar paralysis occurring during typhoid convalescence, describing and illustrating the motor and sensorial changes, electric reactions, and atrophy, and queries whether the lesion is due to the specific poison or to pressure during the delirium and unconsciousness of the profound intoxication. The second case reported resulted from daily pressure against the edge of a desk. [H.M.]

3.—Apparatus for Nitrous Oxid Ether Anesthesia.—Weller VanHook states that the advantages gained by the preceding ether anesthesia with nitrous oxid are, that the patient goes to sleep in from one to three minutes, the beginning of the anesthesia is not unpleasant, and the total amount of ether required for anesthesia is much diminished. For some time the author has used this method in his clinical work and private practice. A desire to obtain a very simple apparatus has induced him to devise an attachment for an ordinary nitrous oxid face piece, so that the ether vapor can be substituted for nitrous oxid gas at will. Several illustrations explaining the device accompany the article, which cannot be explained in abstract. [A.B.C.]

5.—Vesical Retention of Urine.—Ferd C. Valentine and T. M. Townsend state that in retention of urine from any cause, provided that danger to life is not imminent, and also provided that the patient is not too unmanageable for temporization, as during alcoholic inebriety, the ordinary domestic incitors to urination may prove successful. They are: 1. Exposing the patient to the sound of running water. 2. Causing him to suddenly plunge one or both hands into cold water. 3. Prolonged hot sitz baths or general baths. The article, which is of some length, is devoted to the various causes of retention, the operative and nonoperative methods of interference and the instruments to be used in treatment. The authors' conclusions are: 1. When danger to life is not imminent, the domestic methods ordinarily employed may relieve the vesical retention, provided no mechanical obstacle exists. 2. Diuretics, diluents, and antispasmodics are of no use in vesical retention of urine. 3. Opiates and general anesthesia are useful only under certain circumstances. 4. Capital surgical intervention may be necessary to cure the basic condition, but the urgent symptoms can, in most instances, be relieved without life-endangering procedures. 5. Even the youngest general practitioner can carry every case of vesical retention of urine to a successful issue. 6. The cause of the retention must in each case be ascertained. 7. Only most exceptionally does a case present which cannot be relieved by minor procedures. 8. No bladder should be suddenly entirely emptied because of the danger of hemorrhage *ex vacuo*. [A.B.C.]

6.—Opium in Infancy.—T. D. Crothers states that the sedative action of opium is that of palsy, in which the cell functions and the cells themselves are disturbed and diminished, and it is impossible to tell whether this checking may not become permanent, producing change and perversion that continues all through after life. The higher the organism the more pronounced the effect from small doses in infants as well as adults. Nursing infants are affected by opium taken by the mother; growth is retarded, the organism is defective, and a tendency is created to use some form of opium in later life. Continuous sedation or palsy of the sensory centers in early life is never repaired. Development of other organs may do much to repair the injury, but the defect appears in adult life in feeble pain centers and low power of resistance. [H.M.]

7.—Water Anesthesia in Surgery.—Joseph Clements recounts a number of instances in which distilled water was injected locally into tissues for the purpose of producing local anesthesia. This was successful in the surgical treatment of hemorrhoids, each "pile" being injected and at once emptied, clamped, tied, and cut away with entire success. Fistulas were treated in this manner, being cut and scraped. In one instance a laparotomy was performed and eight inches of the colon resected, using only distilled water for local anesthesia. The anesthetic effect is attributed to mechanical pressure upon cell protoplasm. The author says: The "property," the therapeutic, or whatever action arises, is protoplasmic. In the specific instance of anesthesia, in the cases referred to, the distention, the pressure, was mechanical, and effective in the suppression of cell respiration. Here we have what may be termed

negative results in suppressed protoplasmic activities, forestalling the cellular and protoplasmic action which occasions pain. [A.B.C.]

CLINICAL MEDICINE

DAVID RIESMAN

A. O. J. KELLY

REVIEW OF LITERATURE

Trichinosis and Eosinophilia.—The paper of I. Schleif¹ is based on the study of a number of cases occurring in an epidemic of trichinosis in Homberg and vicinity. A positive diagnosis cannot be made from the clinical symptoms alone. The blood investigation is the most valuable means of diagnosis, as other diseases which exhibit an increase in the eosinophiles have quite different clinical pictures. The eosinophilia is of marked degree in almost all cases of trichinosis, while the neutrophile cells undergo an absolute as well as relative diminution. During convalescence, however, the lymphocytes are markedly increased, and the blood swarms with blood-platelets. At the same time the eosinophiles are diminished, and the neutrophiles tend to regain their normal number. These changes in the leukocytes are no doubt due to the action of the lymphatic tissues of the metabolic products arising from the trichinas. Interstitial myositis is widespread in this disease; it occurs in foci, which are characterized by an accumulation of eosinophile cells. As eosinophilia occurs in all vermicular parasitic diseases, it is probable that this condition is caused by a chemotactic influence exerted by the worms. [B.K.]

Serum Diagnosis of Carcinoma.—V. E. Mertens² reports experiments which he has performed during the last three years to determine the presence of specific substances in the blood of carcinoma patients. The first experiments were performed with a carcinoma bouillon, which was injected into rabbits subcutaneously, but without producing any specific substances in the serum so gained. In the next experiments two forms of serum were used, one to precipitate the normal albumins of the blood, another to test for carcinoma precipitins. Ascitic fluid of cardiac cases fulfilled the first condition, ascitic fluid from carcinoma the second; they were injected intravenously. In other experiments, only the second serum was employed. After this method the blood of 50 patients was examined, 19 of whom had carcinoma. Of the latter, 10 patients reacted positively, 9 negatively. Of the 31 noncarcinomatous patients, one, a patient with tuberculous lymph glands of the neck, not yet broken down, gave a positive reaction. Other methods were employed, but all of them with about the same results. Proof therefore for the presence of specific substances in the blood of individuals suffering with carcinoma was not produced by these experiments. It would be of great practical importance to be able to prove the presence of carcinoma poison in the blood or other fluids of cancer patients, as knowing its presence, its action in producing cachexia could be prevented to an extent. Further experiments on the subject will be performed and reported as soon as completed. [E.L.]

Asylum Dysentery in Relation to *Bacillus Dysenteriae*.—J. W. H. Eyre³ presents a number of cases illustrative of the subject under discussion and concludes that the number of cases reported is obviously too few to admit of any generalization as to the etiology of asylum dysentery, but the following conclusions seem warranted: 1. That a bacillus identical with *Bacillus dysenteriae* described by Shiga as the specific cause of acute dysentery in Japan, can be isolated from the stools of many cases of asylum dysentery. 2. That the blood-serum of some of these cases of asylum dysentery possesses a specific agglutinative action when tested against *Bacillus dysenteriae*, isolated from the stools of other similar cases, and also against other strains of *Bacillus dysenteriae* isolated from cases of dysentery in tropical countries. On the other hand, the experience of an extended series of examinations of the stools of patients suffering from asylum dysentery seems to warrant the following: 3. In order to detect *Bacillus dysenteriae* the stools must be examined when fresh. 4. Postmortem material must

be collected and examined as soon after death as possible, as in a few hours' delay, even in quite acute cases, *Bacillus coli* becomes the predominant organism in the intestinal canal. 5. Under these conditions (3 and 4) the isolation of *Bacillus dysenteriae* from the stools of patients suffering from acute asylum dysentery is comparatively easy by the method indicated; that is, when these stools are, to the naked eye, typically dysenteric. 6. That in cases of chronic asylum dysentery *Bacillus dysenteriae*, if present, is so outnumbered by *Bacillus coli* and other intestinal saprophytes as to render its isolation a matter of extreme difficulty. [A.B.C.]

Heat Regulation in Fever.—Babak,⁴ as the result of calorimetric studies made in children suffering with various febrile conditions, comes to the following conclusions: The heat-regulating apparatus shows decided disturbances during the course of fever. These may affect the physical regulation of heat (regulation of heat dissipation) or its chemic regulation (regulation of heat production). In the majority of cases, the former is the more disturbed. This disturbance manifests itself in an abnormally diminished heat dissipation. With a normal heat production, or with one slightly diminished, the bodily temperature rises; but fever is more readily produced when, with diminished heat dissipation, the heat production is increased. Disturbance in the chemic regulation of heat may manifest itself in diminished heat production, in which case it is necessary to have a decided reduction in heat dissipation in order to produce fever. There are, however, cases in which heat dissipation is increased, but not sufficiently to carry off the heat generated by the increased heat production. [D.R.]

Improvement of a Case of Mycosis Fungoides Through the Röntgen Rays.—Brocq² showed a patient to the dermatologic society of Paris who for 12 years had been suffering from mycosis fungoides associated with violent itching. He was exposed to the röntgen rays more than 100 times. After each treatment an increased action was noticed; the tumors gradually diminished, and many of them disappeared altogether. This improvement is to be distinctly separated from the spontaneous improvement occasionally noticed in mycosis fungoides, as in it a few tumors may disappear, but new ones are constantly appearing. There is no method which equals in efficacy radiotherapy in mycosis fungoides. He employed the rays also in two cases of sarcoma of the back, noticing distinct improvement already after the third treatment. [E.L.]

GENERAL SURGERY

MARTIN B. TINKER

C. A. ORR

REVIEW OF LITERATURE

The Use of Radium in Rodent Ulcer.—J. A. B. Hammond³ reports the unsuccessful use of radium in the treatment of epithelioma of the face. The patient was a man of 85, and the malignant growth appeared on the right side of the face, in the distribution of the second division of the fifth nerve, and the growth had been in progress for three years when the author attempted treatment with a tube of radium. For a time it appeared that the growth took on a more healthy appearance, pain was relieved to some extent, the patient's condition improved somewhat, but he tired of the treatment, and refused further sittings. He then grew rapidly worse and died. The author used a tube containing 5 mg. of the radium bromid, giving exposures daily of 15 minutes each, holding the tube within half an inch of the ulcer, without any screen, and slowly moving it over the surface. There were no visible effects for five days, and then the patient complained less of pain, the exposures being increased to twice a day, and the discharge became markedly less, the granulations more healthy, but the edges of the ulcer remained unaffected, the treatment having been persisted in for six weeks with the results which have been enumerated. [A.B.C.]

Cholecystectomy.—B. G. A. Moynihan,⁴ in a paper pub-

¹ Deut. Archiv f. klin. Med., Bd. lxxx, p. 1.

³ British Medical Journal, April 23, 1904.

⁴ The Lancet, April 30, 1904.

lished in 1902, laid down a series of conditions indicating cholecystectomy, rather than cholecystotomy. Additional experience has led him to believe that in almost all cases of operations for gallstones, cholecystectomy is the proper procedure. The plea that the need for drainage is opposed to the routine removal of the gallbladder is answered by the fact that when the gallbladder is removed the need for drainage does not often exist, and by the fact that if drainage of the ducts is desirable, or necessary, it can be carried out without difficulty, even though the gallbladder be removed. The appearance of the gallbladder during abdominal operation will indicate at once whether there be stones present. If that viscus is blue, it is healthy, if opaque and gray, or yellow, there are, or have been, stones and inflammation around them. The advantages of cholecystectomy are that the operation removes the chief source of the disease; that it prevents, in great measure, a recurrence of stones, or of the inflammation which indicates their presence; that growths in the gallbladder, or adhesions around it, are subsequently impossible. His method of procedure in cholecystectomy is given in detail. The abdominal incision is the vertical incision near the outer border of the right rectus, the incision being prolonged toward the xiphoid cartilage if necessary, as is done by Mayo Robson. The technic of effectual removal of the gallbladder is very similar to that advocated by the Mayo brothers, of Rochester, namely: Ligation of the common duct, cutting through the same and stripping off the gallbladder from the direction of the severed common duct toward the fundus; a cuff of peritoneum covers the stump of the severed common duct, unless drainage is placed therein. [A.B.C.]

One Hundred Operations for Appendicitis.—Leonard Freeman¹ reports 100 cases of appendicitis operated upon since the introduction of the Ochsner principle of treatment to which he has adhered in nearly all instances where it was indicated. His experience leads him to endorse in every particular that method of treatment. There were 8 deaths in the series, but 3 should not be included in the statistics for reasons that are appended. The cases are classified as: Interval operations, 46, with 1 death; early operations (36 to 40 hours), 20, no deaths; intermediate (second to fifth day), 2, with 2 deaths; abscesses, 29, with 3 deaths; diffuse peritonitis, 2, both died. The technic of operation is: McBurney incision (separation of muscles), ligation of appendix, cauterization of stump with carbolic acid and burying in cecum by means of a pursestring suture, union of incision in layers, subcutaneous suture, collodion dressing. Rubber gloves are almost invariably worn. [A.G.E.]

Recent Electrotherapeutic Work.—John MacIntyre² discusses the relative merits of radium, the Finsen light, and röntgen rays. With radium many workers have shown that therapeutic results can be had in cases of lupus and rodent ulcer, but the use of radium for ordinary purposes is not likely to displace the Finsen light and röntgen rays. The limits are discussed as to the use of these agents in the treatment of lupus, rodent ulcer, and malignant disease, as where one of these agents has been employed with benefit, the other two can be shown to have had some success. Finsen light is the oldest of these, and according to the reports of Finsen, himself, there can be no question of its efficacy in the diseases mentioned. The main drawback in its use is the long time required to effect a cure, but notwithstanding this many prefer it to the röntgen rays. The best results are undoubtedly obtained with the use of the large lamps, Finsen, himself, claiming that his results are better than others because of his use of the large lamps and his attention to details. The writer believes, however, that the most striking results in the diseases mentioned have thus far been obtained in the therapeutic use of the röntgen rays, and this, where only one of the methods can be conveniently used, he unquestionably advocates. Many patients with lupus which surgeons have operated upon with poor success, have been cured by treatment with the röntgen rays. [A.B.C.]

Practical Value of Cryoscopy.—H. W. Cattell³ concludes

that cryoscopy has a valuable though somewhat limited use among laboratory methods. Repeated examinations of the urine in conjunction with those of the blood are valuable in determining the presence or absence of renal or cardiac insufficiency; separate catheterization of the ureters increases the value of the test. In doubtful kidney cases, cryoscopy should be supplemented by other wellknown laboratory methods. T. Tiekens¹ reports the results of examination of the blood and urine in 338 cases. He concludes that cryoscopy of the urine possesses no great advantage over the well-established chemic and microscopic methods. In the single specimen it is of no value whatever; in the mixed 24-hour output it furnishes nothing in addition to chemic analysis; in specimens obtained by ureteral catheterization it does render assistance. In doubtful cases of surgical disease of the kidney Tiekens recommends cryoscopic examination of the blood, of urine obtained from the respective ureters, and of the mixed 24-hour output. This, in addition, to the usual methods, may be of value in both diagnosis and prognosis. [A.G.E.]

GYNECOLOGY AND OBSTETRICS

WILMER KRUSEN

FRANK C. HAMMOND

REVIEW OF LITERATURE

Increase of Arterial Pressure in Acute Lead-poisoning; Uremia and Eclampsia, and Their Sequels.—Increase in arterial pressure is of great importance in the complications arising during the course of acute lead-poisoning, uremia and eclampsia; (amaurosis, hemianopsia, transitory aphasia, convulsions, sudden death). Vaquez² found that in the diseases mentioned the appearance of these complications is usually associated with considerable increase in blood-pressure; it amounts to as much as 250 mm. to 300 mm. of mercury. The amaurosis of these diseases coming on with headache is independent of the retinitis and often improves very quickly again. It usually coincides with the highest point of the blood-pressure. In one case of Bright's disease with hemianopsia the blood-pressure amounted to 290 mm. Similar increases in pressure were noticed in the transitory aphasia, occurring during acute lead-poisoning, uremia and eclampsia, as well as during a case of maniac delirium, occurring during chronic nephritis. Before and during the convulsions of these diseases the pressure also rises. In four cases sudden death was preceded by considerable blood-pressure increase. Sudden death may occur in any case in which blood-pressure is kept for some time above 250 mm. mercury, and is therefore noted oftenest in uremia, and rarely in acute lead-poisoning, as here the high blood-pressure is but transient. All the complications may be said to be due to the high blood-pressure. It is due to the action of the products of the internal secretion, probably of the suprarenal glands. In a patient with Bright's disease and high blood-pressure of longer duration, which gradually returned to normal, the autopsy revealed hypertrophy and fatty degeneration of one of the suprarenal glands. [E.L.]

Source of Infection during Operation not Sufficiently Recognized.—Mendes de Leon³ believes that a source of infection generally ignored is the saliva emitted by the operator when speaking. By careful experiment he found that in speaking while operating multitudes of infectious germs are emitted from the mouth, some of which may be projected into the wound. Among the germs found were streptococcus, staphylococcus and diplococcus. Convinced of this danger he has devised a kind of respirator, in which a small quantity of cotton wool wadding is placed between two metal plates which are perforated with small holes. This does not interfere with speech while the microbes are intercepted by the wadding. His conclusion then is that while we take so much trouble in sterilizing our hands, instruments and the whole area of operation, as well as the room in which it is done, and everything which comes near the patient, we should also guard against the

risk of infection from saliva emitted from the mouth while speaking. [W.K.]

The Diminishing Birthrate.—J. W. Taylor¹ presents statistics showing a diminishing birthrate in Great Britain and Europe, excluding Russia, in which country and Japan it is notably rising. The marriage rate in the United Kingdom has at the same time been slowly rising. That the type is not improving is shown by criminal statistics, and lunacy and idiocy have almost doubled in 20 years. Alcoholism also is increasing. Figures show that intellectual and artistic culture has materially diminished. The mentally better stock of the nation is not reproducing itself as of old. This is due to deliberate prevention of conception. Both acute and chronic disease follow the methods generally employed. Seminal fluid has a function beyond reproduction, its absorption by the uterus probably allaying the exhaustion of intercourse and thus preventing neurasthenia, etc. Pregnancy provides periods of ovarian rest. The storing up of semen in the male is of value in the economy. Prevention is injurious not only to the race, but to those who practise it. Incomplete congress resembles self-abuse. Restraint adds power to the man, which is transmitted to the children. "Prevision" and "precaution" reverse the progress from the brute. The solitary child is self-centered and illy-prepared for the battle of life. It is the refusal of life by the French which is at the bottom of the antisemite feeling, the Hebrews rising not only individually but racially. The State should establish pensions, remissions of taxation, etc., to encourage large families. Susceptibility to pain increases with civilization, and mothers of today need greater help during pregnancy and lactation than those of former years. Much may be done through hygiene and a more liberal diet. [H.M.]

Removal of Stones from the Ureters.—R. Gradenwitz² gives the history of a patient suffering from stones in the ureters, and a detailed description of their removal by the vaginal route. The patient left the hospital in three weeks, both ureters performing their function without any hindrance and the two vaginal sutures scarcely perceptible. On the ground of this experience the writer recommends the vaginal removal of stones from the ureters as the best method. [W.K.]

Gonorrhea in Childbed.—Martin,³ in the 191 cases operated upon for pus-tubes, examined 97; in only 14 of these did he find the gonococcus present. From his observations, he is able to say that, in spite of a chronic gonorrhea, pregnancy may occur and terminate at term. [J.F.]

TREATMENT

SOLOMON SOLIS COHEN

E. LINDAUER

REVIEW OF LITERATURE

Painless Copper Sulfate in the Treatment of Granular Conjunctivitis.⁴

Copper sulfate	1 gm. (15 gr.)
Orthoform	0.5 gm. (7½ gr.)
Holocain hydrochlorate	0.4 gm. (6 gr.)
Gum tragacanth	0.1 gm. (1½ gr.)
Water, a sufficient quantity.	

To be made into one stick 5 cm. long and containing half its weight of copper sulfate.

This preparation has the advantages of being caustic and painless. Holocain hydrochlorate acts as an anesthetic on the inflamed mucous membrane; orthoform has a slow and persistent action. Excellent results have been obtained with this preparation. [L.F.A.]

The Dangers of Suprarenal Treatment in Hemoptysis. J. Gray Duncanson⁵ reports the case of a man of 36, a heavy drinker, who had suffered twice previously from hemorrhages from the lungs; two years having elapsed since the last. He had lost a pint of blood when Duncanson saw him and was still bleeding freely. He at once administered, by mouth, .92 cc.

(15 m.) adrenalin chlorid solution 1 to 1,000 in a little water and ordered .15 cc. (2½ m.) suprarenal liquid with potassium bromid and Tolu syrup every hour, and after 4 hours gave .3 cc. (5m.) every 1½ hours. The bleeding ceased in 6 hours. Next day the pulse, which had been rapid, soft and slightly irregular, was regular (72 to the minute), wiry and not easily compressible. The amount of suprarenal liquid was reduced on the third day, the pulse was still higher (80 to the minute). That afternoon a hemorrhage to the extent of a half pint took place. Adrenalin chlorid was again administered (1 to 1,000) every 2 hours in combination with iron; on the fourth day bleeding again occurred. The suprarenal treatment was discontinued and the man made an uninterrupted recovery. It has been shown that the active principle of the suprarenal gland not only fails to produce contraction of the pulmonary vessels but causes decided dilation. Duncanson is certain that in hemoptysis, suprarenal treatment should be withheld, unless the questionable procedure of spraying a solution of the adrenalin products from an atomizer be tried. [A.B.C.]

Plasmon.—This is a new preparation for use in conditions of malnutrition, and in cases requiring forced feeding. It is a lactated albumen. Baccelli,¹ Rossoni, and Galli, having made tests of it in the laboratory of clinical medicine of the Royal University of Rome, announced that: 1. It never causes gastrointestinal irregularities however long administered. 2. There is never produced any albuminuria. 3. Plasmon is entirely assimilable, and is assimilated. [T.H.E.]

Chinopyrin in Malaria.—Chinopyrin is a combination of two parts antipyrin and three parts muriate of quinin. It is recommended by Laveran for hypodermic use in malaria. He prescribes the remedy thus: Antipyrin, 2.0; chinin. muriat., 3.0; aq. dest tepidae, 6.0; mix. A syringe under the skin is the dose. A. K. Zikar² tested 51 cases of malaria with chinopyrin with excellent results, which he ascribes to the quinin, the antipyrin simply favoring the solution and absorption of the quinin. At the site of injection a reaction takes place in the form of indurations, which are usually painless, but apt to persist for several weeks. [L.J.]

A Nontoxic Preparation of Iodin.—V. H. Wyatt Wingrave³ has effected a combination of iodine with other drugs which has given what he terms a nontoxic preparation, and which has been highly satisfactory in the treatment of certain conditions requiring iodine. His formula is iodine, 2½ gm.; tannic acid, 4 gm.; alcohol (90%), 38 cc.; syrup, sufficient to make 75 cc.; the iodine is dissolved in the alcohol, the tannic acid and 30 cc. of the syrup are added, and the solution is heated to just below boiling point until it affords no evidence of free iodine with a starch reaction (about 20 minutes); it is then cooled and the remainder of the syrup is added with flavoring; each dram contains two grains of iodine. It may be given in doses of from ½ dr. to 2 dr. in water or wine, before meals. He has found that children tolerate it well, and it has proved specially useful in cases of chronic lymphadenitis associated with or independent of enlarged tonsils and adenoids, especially when the enlarged cervical glands persist after tonsillotomy. It is also indicated in those children who possess but slightly enlarged faucial and pharyngeal tonsils in which operation is contraindicated or is objected to. In chronic rhinitis it affords gratifying results, especially when combined with arsenic. Such an organic combination of iodine, says the writer, is not new, since it was introduced many years ago in the form of a wine—"Vin Nourry." [A.B.C.]

Treatment of Hepatic Colic.—Chauffard⁴ recommends the following emulsion in the treatment of hepatic colic:

Olive oil	150 gm. to 400 gm. (5 oz. to 13 oz.)
Cognac	15 gm. (4 dr.)
Yolk of egg, No. 2	
Menthol	0.5 gm. (7½ gr.)

To be taken in the morning in 2 doses, 15 minutes apart. [L.F.A.]

 Bullet—extraction, 366, 700; hole and homicide vs. suicide, 996; track, Kaiserling's method to show, 70
 Bullous dermatoses, eosinophiles in, etiologic value, 798
 Bunions, treatment, 118, 672
 Burial alive, 454, 804
 Burns, cutaneous, pathology, 163
 Burt, Stephen Smith: Diagnosis and treatment of thoracic aneurysm, 339
 Bursa, hygroma of, 568
 Butler, typhoid at, 1
 Butter—keeping quality of, 1000; typhoid bacilli in, 363
 Buttermilk, 362
 Cadodyl cyanid, 418
 Caisson illness and diver's palsy, 74
 Calcarine, cortical, projection of retina upon, 80
 Calculus—of ureter, 273; prostatic, 683; renal, 239, 898; vesical, 172; with primary typhoid chole-cystitis, 1018
 Camfire, 690
 Camphor—medieval knowledge, 690; mostly a Japanese product, 689; physiologic and therapeutic effects, 689; therapeutic uses, 690
 Cancer (see carcinoma)—377, 638; coincidental, or metastatic, 500; corset, 834; gastric, 93, 364, 446, 522, 645, 678, 905; inoperable uterine, surgery, 609; mortality in Thames valley, 795; of Australia, treatment, specific, 645; of breast, 569; of intestine, 873; of uterus, 367, 609, 798, 924; rectal, 194; research, failure in, 453; serum diagnosis, 1026; uterine neck extension, 1010
 Cancerous metamorphosis of dermoid cysts, 449
 Canteen, army, 8, 123, 181
 Capitalizing mystery, 841
 Car—hospital, railway, 611; service, street, sanitary, 640; ventilation, passenger, 801
 Carbolic acid, antitodal effects on, 722
 Carbon monoxid poisoning, brain affections following, 286
 Caruncle contracted in barber shop, 166
 Carcinoma (see cancer)—489, 696; basocellulare, 580, 996; implanted, 695; late recedive, 695; of choroid, metastatic, 78; of colon, 795; of esophagus, 773; of extremities, primary, 161; of gall ducts, 488; of intestines, 243; of lung, 155, 638; of retained testis, 833; of uterus, 119, 203, 264, 529, 924; of vagina, primary, 608; peribulbar, 80; stomach and rectum, 734; treatment, 119, 322, 570, 609, 696; ventriculi, transitional forms in, 800
 Cardia, physiology, 605
 Cardiac—disease, treatment, 160; displacement, 154; inhibition, reflex, 476; orifice, stenosis of, 682; rhythm, irregularity, estimating significance of, 675; syphilis, 359; toxemia of pneumonia, 115
 Cardiolytic, 696
 Cardiovascular system, effect of digitalis on, 443
 Carditis of children, treatment, 408
 Carotid area, external, operation for malignancy in, 923
 Carpal scaphoid, dislocation, 240, 241
 Cars, sleeping, sanitary, new, 573
 Cartridges, blank, wounds from, 365
 Case III and Case IV, 650
 Casualties, loss of life by, 30
 Catalysis, 834
 Cataract—is bilateral operation justifiable?, 1009; extraction, 80, 647
 Cat—and dog law, 488; pest and Congress, 806
 Catarrh—epidemic, on shipboard, 723; in infants, gastrointestinal, 363; nervous, 605; with jaundice and cholelithiasis, 244
 Catheterization, ureteral, 721, 953
 Catgut—Claudius', 831, 870; sterilizing, ammonium sulfate method, 833
 Cauda equina, tumors involving, 520
 Caverly, Charles S.: Anomalous condition of the kidneys, 296
 Cavernous sinus, thrombosis of, 698
 Cavities, bone, closure, 607
 Cecum—excision of, 118; inflammation, acute, 447
 Celiotomy, successful, for ectopic gestation and forced abandonment of placenta, 120
 Cell diagnosis, technic of, 195
 Cells—and eosinophile granulations, 799; in blood, neoplastic, 798
 Cellulitis, orbital, and cerebral abscess, 274
 Cerebral—centers of divergence and convergence, 647; diplegia, 693; reflexes and tendon phenomena, 71; rheumatism, 282; thrombosis, 1010; tumors, 285, 568
 Cerebrospinal—fever, 729; fluid, lymphocytosis of, 195; liquor, cytodagnostic investigation of, 800; symptoms in infectious diseases, 422
 "Cereopathy," 43
 Certificates, medical, abuse of, 2
 Cervical—adenitis, treatment, 351; incisions in labor, 203; incision in labor, deep, after-effects, 531; lymphatic glands, tuberculosis, 556; sympathetic ganglions in glaucoma, 318
 Cervix—lacerations, 325, 602; stenosis of, 590, 837; uteri, lacerations, 201, 885
 Cesarean section, 202, 203, 325, 326, 361, 368, 757, 970
 Champions of retrogression, 248
 Chancres—and chancroid diagnosis, 485; pathology, 564
 Chancroid, inoculation of monkeys with, 363
 Charities, legal aid, 371
 Cheek, lymph-glands in, 162
 Chemicals, adulterations of, 329
 Chemistry—at Washington, D. C., bureau of, 169; in infant feeding, 760; physical versus biology in immunity, 792
 Chest—cold compresses to, 326; contour and lung capacity, 927; in empyema, drainage in, 268; tuberculous disease of, unusual form, 109
 Chickenpox and smallpox, 73
 Child—atypical, 248; bearing process and neuritis, 860; demands of, by virtue of right, 924; labor, 333, 334, 810; saving laws sustained, 663
 Children—appendicitis in, 561, 759, 1007; broncho-pneumonia in, 760, 761; carditis of, treatment, 408; cerebrospinal meningitis in, 848; congenital occlusion of lacrimal canal, 971; diabetes mellitus and myxedema, 229; diphtheria, 291; diarrheas, 737; empyema, metapneumonic, 430; fever, 281; fever, management, 1025; gonorrhea in, 1028; hernia in, 110, 278, 319; hemorrhoids in, 608; inflammatory diseases, aural examination, 1008; intestinal invagination in, 608; intestinal obstruction, 1008; lymph-nodes, enlarged, 1008; marantic, 116; nervous system of, and uncorrected refractive errors and muscular imbalance, 971; perinephritis, 1008; pneumonia, 760; protection, 330, 331; sarcoma of choroid, 80; school, eyes of, 42; test-characters for, 77; tuberculosis in, 642; typhoid, 114, 200
 Chinopryrin in malaria, 1028
 Chlorotone, 610; chinopryrin in malaria, 1028
 Chlorin as antiseptic, 73
 Chloroform—apparent death, resuscitation, 690; therapeutic uses, 403
 Chloroma and leukemia, 849
 Chlorosis, treatment, 833
 Cholangitis, 360
 Cholecystectomy—1026; vs. cholecystotomy, 350, 597; stump after, condition, 696
 Cholecystitis, primary typhoid, 1018
 Cholecystotomy—new method, 528; vs. cholecystectomy, 350, 597
 Cholelithiasis—and catarrhal jaundice, 244; infective, 444
 Cholera, prevent, inoculation, 736
 Chorda venerea, 33
 Chorea, fatal, 237, 282; Huntington's, 720
 Chorionepithelioma, 489, 910, 924, 953
 Choreiform movements, treatment, 926
 Chorioectodermal epithelioma, 529
 Choroid—carcinoma of, 78; sarcoma of, in child, 80; tuberculosis of,iliary, 79
 Christmas gift, novel, 42
 Chromatophores, 927
 Cigarets harmful, smoke of, 170
 Circulation—and cyclic albuminuria, 277; effect of aspidospermin on, 245; effects, digitalis, 443; heart, anastomotic, 363
 Circulatory organs, diphtheria toxin on, 78
 Circumcision, 125
 Cirrhosis—hepatic, 365, 762, 927; of stomach, 693
 Citarin, 39
 Cities—American, expenditure for health purposes of, 840; water supply, 803
 City—consultants, 764; "Hall and court-house spustistics," 248
 Claudius' catgut, 831, 870
 Cleft palate and harelip, 645
 Clements, Joseph: Medicine, an exact science: query, 715
 Climate in genitourinary tuberculosis, 116
 Climatology of mountain heights of Malvern Range, 868
 Clinical—prejudices, 611; recognition of gastric ulcer, 1015; side, myocardial change from, 954
 Clinics, Philadelphia, and demonstrations, 767
 Club-foot, treatment, 411, 570
 Coagulation of blood, 798, 837
 Coarctation of aorta, incomplete, 798
 Cocain, 208
 Cocainomania, increase, 129, 167
 Coffee and slush, 332
 Cohen, Solomon Solis: Can our procedures for the judicial determination of the cause of death be bettered?, 54
 Cold—and paroxysmal hemoglobinuria, 566; "in head," treatment, 458; in ocular therapeutics, 368
 Colectomy and colotomy, 159
 Coley, William B.: Amputation of the hip-joint for sarcoma, with a report of seven cases, without mortality; subsequent history of patients, 51
 Colic—biliary, and acute flexion of gallbladder, 70; hepatic, treatment, 327, 1028
 Colitis, 606, 607, 682, 734, 872
 Collapse, treatment, 674, 794
 Collargol, 39, 121
 Colleague, misfortune of, 208
 College courses and needs of prospective students of medicine, 493
 Colon—and abdominal tumors, 325; and rectum, 157; carcinoma of, 795
 Colorado Medical Legislative League, 287
 Column, vertebral, luxation of, articulations, 567
 Commonwealth, and physicians, 415
 Condyloma acuminata, 280
 Confidence, too limited, disadvantages, 830
 Conflagrations, eddyism, and insurance underwriters, 765
 Congenital—absence of common bile-duct, 800; bronchiectasis and situs inversus, 682; condition of skin, rare, 572; deformities, and intrauterine poliomyelitis and neuritis, 97; dislocation of hip, 394, 410, 760, 904, 979; dislocation of shoulder, 411; glaucoma, 648; hypertrophic stenosis of pylorus, 682; hypertrophy, 486; imperforate duodenum, 907; intrauterine poliomyelitis and neuritis, 97; malformations, and mortality, 491; narrowness of pylorus and chronic gastric disease, 681; occlusion of lacrimal canal, 971; orbital endothelioma, 114; phimosi, 200; torticollis, manipulative correction, 451; transposition of viscera, 491
 Congress on Tuberculosis, Bell's vindication of, 42

- Conjunctival—reflexes, 670; tuberculosis, 79
 Conjunctivitis—due to fast driving, 79; granular, 1028; purulent and blindness, 1013; streptococcus, panophthalmitis following, 80
 Constipation—and uterine disease, 279; habitual, chronic, 874; in infant, chronic, 970; treatment, 876
 Consultants, city, thoughtlessness of, 764
 Consumption—fraud, 878, 879; "rows" and "lung blocks," 611
 Contagious diseases, 362, 582
 Contagiousness of pneumonia, 760
 Contract medical practice, 640
 Coon, Clarence E.: Röntgen ray treatment of disease, 313

 Criminals, 766, 915
 Cruager, Edw. A.: Rheumatism, 734
 Crutcher, Howard: Medical treatment sought by eddyites, 8
 Cryoscopy—in chronic pleural exudates, 906; practical value of, 1027
 Cumston, Charles Greene: The medicolegal aspects of autoabortion, 177
 Cure—for migraine, 1001; meaning of word, 538; mind, scientific basis, 437
 Curet, passing of, 189
 Curetage, 1023
 Curetment, uterine, 561
 Curriculum, medical, standard, plea for, 962
 Cutaneous—burns, pathology, 163; infection, and specific antibodies, 491; surfaces, normal, and electricity of high tension and frequency, 158
 Cutter, Ephraim: Formation of the red blood corpuscles in the spleen and lymphatic glands, 50
 Cystitis, postoperative, 909
 Cystocele, etiology and pathology, treatment, new, operative, 970
 Cystotomy—suprapubic, 522; vaginal, 290
 Cystoscope, 416, 639, 767, 1023
 Cysts—and sarcoma, 837; dentigerous, 793; dermoid, 449, 685; echinococcus, 998; of ascending mesocolon, chylous, 324; of Bartholin's glands, 1010; of jaw, 974; of liver, echinococcus, 194; of long bones, 199; ovarian, 120, 521; pancreatic, 608, 638; traumatic pyeloparaneuric, 442.
 Cytodiagnosis, 195, 900
 Cytologic tests of effusions, diagnostic value, 489
 Cytotoxins, 796
 Cytotoxins, somatogenic nonspecificity, 580
 Dacryocystitis, 602
 Dairy—inspection and pasteurized milk, 1002; inspectors, 730
 Day, Grafton E.: The army saloon, 193
 D. D., M. D., and Q. D.: businesses combined, 917
 Deaver, John B. and George P. Müller: The pathology and surgical treatment of pancreatic diseases, 466
 Death—and saline solution, 487; cause, judicial determination, 54; due to rupture of spleen in acute leukemia, 888; in anesthesia, 168, 680
 Deathrate—497, 617, 766, 768, 881; lowered, victory of, 574; lowest, 46; in Boston, 88; in Cambridge, 88; in Chicago, 125; in cities of 200,000 and over, 46; in French army, 180; in Massachusetts, 871; in New York, 250; of railway employees, accidental, 916
 Decapsulation, renal, 274, 836, 871, 873
 Definitions, new, 873
 Deformities—rachitic, treatment, 409; congenital, 97, 973; pelvic, diagnosis and treatment, 969
 Degeneration and alcoholism, 797; and deviation, 194; of elastic tissue and fatty metamorphosis, 162; of spinal cord, diffuse (combined) 31; retinal symptoms, 304
 Delirium—hysterical, 978; tremens, 196
 Delivery—cervix suture, fifth day after, 885; fracture of humerus of child in, 582; vaginal section in, 903
 Dementia præcox, 926
 Dental—disease in ocular disturbance, 601; education, some phases, 1023; irritation and neuralgia, 441; origin, reflex neuroses of, 166; pulp, 153, 338
 Dentigerous cysts, 793
 Dentistry, 678, 977
 De profundis, 765
 Dermum's disease, 524
 Dermatitis—herpetiformis, 1012; röntgen ray' and idiosyncrasy, 155
 Dermatology and pathology, 161
 Dermatoses, bullous, eosinophiles in, etiologic value, 798
 Deviation and degeneracy, 194
 DeWitt, E.: Treatment of diphtheria in children, 294
 Diabetes—and gangrene, 905; and glycolysis, 197; and obscure physiology, 273; and skin disease, 572; and stomach disorders, 277; and surgery, 120; and wound healing, 898; arteriosclerosis in, 564; diet in, 559, 682; glycosuria, 471; in childhood, 882; insipidus, 75, 245, 847; levulose, 73, 842; metabolism, 927; myopia in, 78; myxedema, 220; operations, 645, 905; pathogenesis, 229; treatment, 301, 321, 483
 Diagnosis, cell, technic of, 195; clinical, laboratory aids in, 791; diastolic murmur, 794; in stomach diseases, 896; of arteriosclerosis, 9; serum, of carcinoma, 1026; serum, 621; tuberculin in, 865; value of cystoscope, 639
 Diaphragmatic phenomenon of Litten, 197
 Diarrhea—in children, 116, 737, 971; summer, 971
 Diastolic murmur in diagnosis, 794
 Dickinson, Robert L.: "Urethral labia," or "urethral hymen," pathologic structures, due to repeated traction, 347
 Diet—diabetic, 559, 682; in hepatic diseases, 912; lactovegetarian, 122
 Dietetics—of arteriosclerosis, 320; of atonic dilation of stomach, 559; of diabetics, 682
 Digestion of hemoglobin, 838
 Digestive antipathies, 456
 Digitalis—and cardiac hypertrophy, 926; chemie principles, 443; cumulative action, 610; effect on cardiovascular system, 443; effect on circulation, 443; in shock and collapse, 674; nomenclature, 442; older therapeutics, 442
 Dilation—of esophagus, 690, 682; of stomach, 848; of stomach, atonic, dietetics of, 559, 848; therapeutic uses, 848
 Dilator, Bossi's, 911
 Diller, Theodore: An investigation of certain of the reflexes and sensory phenomena and the condition of the eye-grounds, based on a study of 103 healthy young men: knee-jerks, achilles-jerks, conjunctival and pharyngeal reflexes, pupillary reflexes, stereognostic appreciation, muscular and spacing senses, 670; Need of a ward in general hospitals for insane patients 184; Two fatal cases of "Landry's paralysis," with autopsy findings in one of them, 747
 Dillingham, Frederick H.: Alopecia areata, 433
 Diminishing birthrate, 1028
 Diphtheria—151, 334, 375, 539; and antitoxins, 377; antitoxin, manufacture, 123, 127, 134; bacilli, new stain, 486; bacilli, similar organisms in cow's milk, 161; diagnosis, bacteriologic, 486; epidemic on steamship, 900; of nose, 318; of vagina, 391; physical signs, and sore throats, 772; toxin, effect on circulatory organs, 73; treatment, 294, 331, 642
 Diphtheric—sore throat, "abolish term," 763; toxin, immunization of man with, 480
 Diplegia—cerebral, 603; spastic in pertussis, 973
 Diplococcus pneumoniae in pure culture, capsule formation of, 797
 Disclaimer, 512
 Discovery, scientific, promoting, 889
 Disease—abdominal, points in, 243; germs, and boots and shoes, 538; and protozoa, 576; chronic, hospitals for, 414; dissemination, and theatrical profession, 524; in army, 123, 131; infectious, 948; in New York, 128; in West Indies, 654; drunkenness, and post canteen, 181; in the horse, 291; of children, importance of early aural examination, 1008; of stomach, 896; skin, comparison of treatment in, 1012; tramp as distributor of, 85; treatment by röntgen ray, 813, 1012; "ultramicroscopic" organisms of, 487
 Disinfectant, surgical, mercuric cyanid as, 164
 Dislocation—fracture of spine, 146; carpal scaphoid, 240; hip, congenital, 410, 719, 760, 904, 979; of patella, slipping or recurrent, 440; of shoulder, congenital, 411; of shoulder, anterior, treatment, 886; of spine, fracture, 146; treatment, 644
 Dispensary for tuberculosis, 371
 Displacement, cardiac, 154
 Dissection, and Roman Catholic Church, 248
 Dissensions, how they grow, 208
 Distomum sinense in intrahepatic bile ducts, 225
 Divers palsy and caisson illness, 74
 Diverticulum—intestinal, 201; of esophagus, 244; Meckel's, gangrene of, 278
 "Division of the spoils," new method, devised by manufacturer, 2
 Dock, George: Prognosis: Its theory and practice, 989, 991
 Doctor—country, and good roads, 165; "drug-store" competition with, while "soliciting patronage," 651; many-sided, of ancient times, 658; the income of, 250; witch, of Pennsylvania, 904
 Dollars to doctors, 454
 Donnellan, P. S.: Further experience with intra-tracheal medication, 786; The substitution of potassium cyanid for ammonium carbonate, with fatal result, 379
 Dormiol, 75
 Double—gangrene, 875; vagina, 685
 Douche, passing of, 189
 Drainage—for infection, 189; hepatic, 446; in biliary infection, hepatic, 286; of biliary passages in surgery, 1036; of chest in empyema, 288; vaginal, 324
 Drinking, moderate, 440
 Dress reform for men, 415
 Dressings—antiseptic, 240; moist, use and value, 644
 Dropsy, 604
 Drug—analyses, national, systematic, postponement, 857; exanthems resembling syphilis, 572; habit, 442, 640, 973; poisonous, new, 416
 "Drug-store" competition with doctor while "soliciting patronage," 651
 Druggist physicians, 617
 Drugs—abuse, 903; hypnotic, in mental disease, 975; in hemorrhage, 976; irritant to kidneys, 1012; supervision, federal, 928; vilely adulterated, 653
 Drunkenness—and crime, 208; disease, and post canteen, 181; in army, 123, 131
 Duct—choledochus, operations, 248; common, gallstone in, 798, 1009; surgery of, 662, 759
 Ductus arteriosus, pathology, 489
 Duodenum, imperforate, of congenital origin, 907
 Dysentery—and Shiga bacillus, 84; asylum, in relation to *Bacillus dysenteriae*, 1026; bacillus, 485, 581, 757; chronic, and allied conditions, 432; infantile, 971
 Dysmenorrhea and sterility, 580, 837
 Dyspnea, toxialimentary, in tuberculous patients, 204
 Egleton, Wells P.: Influence of old age, diabetes, arterial sclerosis, and gout on the healing of wounds, 898

 Ewald's laxative powder, 40
 Excision of cecum, 118
 Excochleation of prostate, 527
 Exercise—and function, 327; and schools, 487; muscular, necessity for, 451; therapeutic uses, 369, 567; walking and running as, 569
 Exohysteropexy, 762
 Exophoria, ocular gymnastics in, 407
 Exophthalmos—847; and loss of eye, through blow, 81; intermittent, 972; pulsating, 909, 972
 Experimental—biology and medicine, society for, 789; pancreatitis in man, 853
 Extirpation of hypertrophied prostate, total, 200
 Extraperitoneal route to ureter, 904
 Extrauterine gestation, 113, 119, 120, 272, 911, 1007
 Extremities—amputated, possible restoration, 364; carcinoma of, primary, 161; fractures of, comparative study, 144; loss, and spinal cord changes, 284
 Exudates, pleural, chronic, prognosis of, cryoscopy in, 906
 Eye—and physiology of sympathetic, 235; astigmatic changes, 479; cataract extraction, 639; cerebral centers of divergence and convergence, 647; congenital occlusion of lacrimal canal, 971; crystalline lens, foreign body in, 81; disease, external, and rheumatism, 722; diseases, 842; excessive use and loss of vision, 360; foreign bodies in, 81; grounds, reflexes, etc., 670; gummatous tumors of sclera, 648; human, background, to photograph, 655; in school children, 42; insufficiency of convergence and exophoria, 407; intermittent exophthalmos, 972; latticed corneal opacities, 648; loss, from blow, 81; ophthalmic therapeutics, 972; orbit, foreign bodies in, 601, 700; orbit, tumors of, 648, 972; postdiphtheric, paralysis of accommodation, 484; postoperative infection, 925; pulsating exophthalmos, 972; pupillary reflexes, 670; pupils, paradoxical, 558; time for extraction of second cataract, 1009; treatment of, 33; uncorrected refractive errors and muscular imbalance, 970
 Eyelids—eczema of, 160; restoration, 78
 Eyestrain—and epilepsy, 585; and lateral curvature, 639; and torticollis, 513, 818; asthenopia and headache from, 522; sentence, death, burial, and requiescat, 650; spinal curvature, 513, 818
- F**acial—atrophy, 720; operations, 55; paralysis, 266, 858
 Faciohypoglossal nerve anastomosis, 401
 Factory inspectors, report of, 600
 Fallopian tubes, tuberculous disease of, 448
 "Familiarity breeds contempt," 329
 Family periodic paralysis, 708
 Fascia, perirenal, 482
 Fasciculus of Türk, 284
 Fat—cause of painful knee-joint, 885; necrosis, 72
 Faucal tonsil, removal, improved snare for, 171
 Fecal drowning, during etherization, 562
 Feces—incontinence, 644; soluble proteids, excretion of, 799
 Feeble-minded women, 207
 Feeding—infant, 760, 970; subcutaneous artificial, 738
 Fees—division of, 205; maximum and minimum, 258; tuition, higher, 960; versus presents, 329
 Feet, polydactylism of, 411
 Felix mas and optic nerve, 570
 Female—leukocytosis in pelvic disease, 887; urethra, gummatous affection of, 37; surgery of, 884
- Femoral—hernia, strangulated, containing appendix, 992; neck, fracture of, 521; vein, thrombosis following aseptic laparotomy, 49
 Femur, sarcoma of, 70, 602
 Fermentation, intestinal, and surgeon, 31
 Fetterolf, George: Reflex cardiac inhibition resulting from irritation of the peripheral fibers of the trifacial nerve and occurring in the course of an operation for chronic empyema of the frontal sinus, 476
 Fetus—artificial turning of, in cranial presentation, 202; growth of, in pelvis, 37
 Fever (see also typhoid, scarlatina, etc.)—black-water, 488; heat regulation in, 1026; in children, treatment, 281; metabolism in, 791, 1025; spotted, 770, 844; typhoid, throat complications in, 1011; undiagnosed, and rabies, 620
 Fibroids, 37, 38, 154, 543, 1014
 Fibromas—nasopharyngeal, 32; of spermatic cord, 529; of tunica vaginalis, 684; uterine, and pregnancy, 531
 Fibromyomas of uterus, 449, 870
 Ficker diagnosticum, 643
 Filariasis, pathologic manifestations, 641
 Filbert, Charles E.: Effects of an overdose of bromoform, 254
 Financier, convicted, suicide of, 288
 Finger injuries and epilepsy, 50
 Finsen light, therapeutic uses, 114, 119
 First aid, dog carriers, 461
 Fish—bacteriologic study, intestines, 152; "hypothesis" and leprosy, 841
 Fistula—Eck's, 579; esophageotracheal, and aerophagy, 279; vesicovaginal, 37, 201
 Fits, uncinate group, in epilepsy, 474
 Flagellas—somatic agglutinins, 582; staining, 754
 Flatfoot—408, 882; herpes progenitalis and pain in pelvic region, caused by, 411
 Flatfootedness, 408
 Fletcher, Robert, work of, 127
 Floral antipathies, 455
 Fluorescent media—in transillumination of stomach, 721, 761; therapeutic applications, 582
 Flushing, intrauterine, for infection, 189
 Food—adulterated, 400, 616, 691, 764; arsenic in, 334; bill, pure, Hepburn, 88, 165, 168; gluten, 253; passage from stomach, 1010; patented, value, 236; preservatives, 275, 320, 904
 Foot of American negro, 411
 Football in 1903, 207
 Forceps—Knapp's roller, 648; obstetric, use of, 440
 Ford, Willis E.: Fifteen years' experience with uterine fibroids, 543
 Foreign bodies—esophagotomy, external, for, 908; in abdomen, 416, 685; in bladder, entrance and removal, 699; in knee-joint, 243, 696; in brain, 615; in eye, 81, 601; tolerance of tissues to, 113; in heart, 366; in system for 16 years, 375; in vagina, 502
 Forel, statement by, 691
 Formaldehyd and urine, 441
 Formic acid of ant and anthill, 43
 Fourth of July—768, 806; responsibility of the authorities, 1000; tetanus, 999
 Fowler, George Ryerson: The unification of the medical profession in the State of New York, 91
 Fracture—dislocation of spine, 146; involving joints, 114; of femoral neck, 521; of humerus of child in delivery, 582; of extremities, comparative study, 144; of patella, pathology and treatment, 997; of radius, 1024; of skull, 684, 873, 875; subcutaneous, bone suturing in, 732; treatment, 241, 323, 608, 644

 Freyer's method, prostatic enlargement by, treatment, 406
 Fulton, William Stewart: Typhoid perforation, 699
 Function and exercise, 327
 Funeral, "unionized," 1
 Furniss, Henry Dawson: Varicocele, 691
 Furunculosis, treatment, 121
 Fyshe, J. C.: Acute lobar pneumonia: An analysis of 486 cases, and of 100 autopsies, 135
- G**allant, A. Ernest: The puerpera—her care and comfort during convalescence, particularly the prevention of viscereal prolapse, 783
 Gallbladder—acute flexion and biliary colic, 70; and duct, surgery of, 562, 697; diseases, 30, 116, 603; perforation of, 38, 243; surgery, importance of drainage, 1006
 Gallstone—diagnosis and treatment, 173; disease, 80, 116, 603; evacuation, flushing biliary passages, 323; examining stools for, 115; in common duct, 793, 1006; removal, operative, 697; treatment, 115, 173, 883
 Ganglions—of palm of hand, 241; sympathetic cervical, resection in glaucoma, 318
 Gangrene—double, after typhoid, 875; in diabetes mellitus, 905; of hollow viscera, 723; of Meckel's diverticulum, 278
 Gas, illuminating, poisoning by, 847
- Gastric—analysis, indicators, 568; cancer, 364; digestion and pernicious anemia, 921; disease, anomalous cases, 444; disease, chronic, 681; tetany, 239, 364; ulcer, bibliography of, 1015; ulcer cases, after-history, 406; ulcer, pathogenesis of, 1016; ulcer, pathologic anatomy of, 1015; ulcer, perforating, 75, 482, 684; ulcer, symposium on, 1015; ulcer, treatment, 684, 912, 969; ulcer unusual form, 364
 Gastritis—"nevertheless," 611; treatment, 686
 Gastroenteritis of infants, acute, treatment, 369
 Gastroenterostomy—aseptic, experimental method, 448; for cancer of stomach, 522; operation for, 762; operation of von Hacker, modification of, Mattoli in, 833; posterior and enteroenterostomy, 864; posterior, Maunsell's method, 312; twine in lieu of elastic ligature, 968; without "loop," 604
 Gastrointestinal—atoncy, treatment, 245; canal, newer physiology of, 1012; catarrh in infants, 363; troubles, treatment, 274
 "Gastrophore," in operations on stomach and intestines, 241
 Gastroptosis, surgical treatment, 684
 Gastroscorrbhea and tetanic attacks, and chronic ulcer of stomach, 761
 Gastrotomy, therapeutic uses, 848
 Gelatin—hemostatic effect, 197; therapeutic uses, 911
 General physician and specialist, 1001
 Genital herpes, 906
 Genitourinary tuberculosis, climate in, 116
 Germs—in filthy money, 497; in water, toxicogenic, 638
 Gessner, Herman B.: Hernioplasty, 338
 Gest, John Marshall: Maximum and minimum fees, 253
 Gestation—ectopic, atypical symptoms, 1007; extra-uterine, 119, 202, 911; hematology of, 449
 Gies, William J.: A criticism for Moor's claims for "urine" and his method for the quantitative determination of urea, 130; The society for experimental biology and medicine, 111, 480, 789, 950
 Gilbride, John J.: The early diagnosis of tuberculosis, 295
 Gilliam operation, 326
 Gland—cervical lymphatic, tuberculosis of, 556; Bartholin, anatomy of, 1010; parathyroid, human, 488; salivary, tumors of, 406; thyroid, infantile independent of, 723; thyroid, removal of one-half, 639; tuberculous, treatment, 237
 Glass, metric, new medicine, 735
 Glaucoma—congenital, 648; resection, cervical sympathetic ganglions, 318
 Gleet, urethra in, packing, 788
 Glioma—of sella turcica, 581; primary, 590
 Gloginger, Andrew B.: Some abnormal positions of the appendix, 658
 Gloves, dispensing with, 521; in obstetrics, 529
 Gluten foods, 253
 Glycerin, antiseptic and germicidal properties, 163
 Glycolysis and diabetes mellitus, 197
 Glycosuria—diabetic, 882; diabetic and nondiabetic in one person, 471
 Goiter, treatment, surgical, 719
 Goldthwait, Joel E.: The preliminary report of a series of metabolism observations made in atrophic arthritis, hypertrophic arthritis, osteitis deformans and the normal, 547, 590
 Gonococcus metastasis, 601
 Gonorrhea—and female generative organs, 930; history and treatment, 378; in childhood, 1028; in female, 368, 531, 762; in male, treatment, 485; peri-arthritis in child, multiple, 871; prostatitis, chronic, 201; urethra in, packing, 788; treatment, 1014; vaginitis, 122
 Gordon, Alfred: Acute anterior poliomyelitis in adults, with report of a case in which there also was a peripheral facial palsy and p. radocis pupils complicated with hippus, 858; A note on cerebrospinal symptoms in infectious diseases apropos of a case of typhoid, 422; Myxedema complicated with diabetes mellitus occurring in two children. Effect of thyroid extract upon both diseases, remarks on the pathogenesis of diabetes, 229; The problem of potassium iodid, 461

 Hartley method, 312
 Hay-fever—and chemistry of saliva and secretions, 974; nature and treatment, 39; treatment, 570, 849
 Head—cold in, treatment, 450; detached in parametrium, 680; injuries, after-effects, 643; lesions of, radiodiagnosis in, 679; malposition (torticollis, canted or tilted head), 818; wounds of, bullet, hyperalgesic zones in, 200
 Healing—of laparotomy wounds, 448; of wounds and diseases, 898
 Health—and bovine tuberculosis, 794; and changed methods of living, 169; and morality in Porto Rico, 880; and physical overexertion, 148; boards in towns and small cities, 830; boards of, 420; department, typhoid, and smallpox, 954; individual, and marriage, 372; of London, 129; of Navy and Marine Corps for 1902, 4; of Winnipeg, 129; public, 920; public, and marriage, 371; public and tuberculosis, 618; purposes, expenditure for, 840; records, domiciliary, 725; records in Camden, 49; resorts, hygiene of, 882
 Healthy, the apparently, albuminuria in, 835
 Heart—apex, movability, 643; bullet extracted from, 396; circulation, anastomotic, 863; disease, an obstetric complication, 969; disease, treatment, 606, 643; disease, valvular, 523; failure in toxic conditions, 405; failure, theory, 444; lesions, and different radial pulse, 807; rhythm, 642; stimulation, 560; surgery of, 1003; typhoid effect, 631
 Heat regulation in fever, 126
 Heathenism, revivals of, modern, 453
 Hebotomy, 202
 Heineberg, Alfred: New device for administering ether, 50
 Hemangioma—(cavernosum) of orbit, 580; treatment, 30
 Hematemesis, postoperative, 568
 Hematocele, 825, 721
 Hematology of gestation, 440
 Hematoma—extradural, 488; intrapelvic, 585; of sternomastoid muscles, 402
 Hematuria—earliest or only symptom of infantile scurvy, 10, 8; idiopathic, surgical treatment, 527
 Hemorrhagic, and liver abscess, 581
 Hemianopia, following ptomain poisoning, 81
 Hemiplegia, 278, 338, 973
 Hemmeter, John C.: The use and the abuse of the imagination in the experiments and observations in medicine, 558
 Hemoglobin—digestion and absorption, 838; therapy, 643
 Hemoglobinuria, paroxysmal and colds, 566
 Hemoglobinuric fever, treatment, 986
 Hemolymph nodes, 580
 Hemolymphotoxin, 681
 Hemolysis, human urine in, 579
 Hemophilia, pathology, 800
 Hemoptysis—parasitic, 768; treatment, 870, 1028
 Hemorrhage—after tonsillotomy, 72, 769; cortical, following scarlet fever, 1010; in carcinoma uteri, 529; in epilepsy, subcutaneous, 474; internal, drug treatment, 976; into bursa of patella, 159; of larynx, 1010; postpartum, treatment, 290; retinal, and severe anemia, 648; subcutaneous, and ulcerative endocarditis, 642; tonsillar spontaneous, 1011; treatment, 911
 Hemorrhagic—diatheses, causing loss of eye through blow against temple, 81; diseases, pathology and classification, 156; pancreatitis, pathogenesis and therapy, 240; septicemia in animals in Philippines, 354; septicemia of carabao, bacillus of, pulmonary lesions produced by, 711; type of typhoid, 761
 Hemorrhoids—in children, 608; treatment, 570
 Hemostasis, sutures for, temporary, 713
 Hepatectomy, therapeutic uses, 678
 Hepatic—artery, aneurysm of, 523; colic, treatment, 827, 1028; diseases, diet in, 912; drainage, 446; extract, 762
 Hepatopexy in hepatoptosis, 697
 Hepatoptosis, treatment, surgical, 697
 Hepburn pure food bill, 88, 165, 168
 Hereditary—optic atrophy, 79; dwarfism; ethnic achondroplasia, 163; syphilis, 84, 36
 Heredity and tuberculosis, 907
 Herpes, genital, 906
 Hernia—274; diaphragmatic, acquired, true, 278; epigastric, 793; femoral, thigh, truss for, 297; gangrenous, 366; in young children, 110, 278, 319; inguinal, treatment, 242, 366, 567, 677; of lungs, traumatic, 324; radical operations for, 874; strangulated, 245, 367, 401, 484, 992; treatment of, 242, 245, 278, 366, 367, 567, 734, 811, 874
 Hernial ring, irritation of, causing abdominal pain, 1017
 Herter lectures, 5, 6, 650, 688, 792
 Hess, Julius: A case of acute leukemia, with death due to rupture of the spleen, 388
 Heterogeneous catalysis, 834
 Heterophoria, tenotomy for, fallacies, 647
 Hewson, Addinell: Description of method of preparing brains used in class demonstration, 335
 High frequency current, therapeutic uses, 79, 359
 Hip—amputations, 57, 323, 602; deformity, 409; disease, 499; disease among outpatients, 409; disease, simulated, 836; dislocation, congenital, 394, 401, 410, 760, 904, 979; joint, exposing, Larghi's carved incision in, 241; replacements, bloodless, 719
 Hippus, 758
 Hirst, B. C.: A modified and improved metranoliter, 886
 Hodgkin's disease, 438, 489, 831
 "Holiness society," 453

 Hookworm disease, 722
 Homicide versus suicide, and burn and bullet hole, 996
 Homicides, Bitzer, 31
 Homogeneous catalysis, 834
 Horsley, J. Shelton: Fracture-dislocation of the spine, 146
 Horwitz, Orville: A study of 91 operations for the relief of various forms of hernia, with their complications, 811
 Hospital—Albany, pavilion F., 802; bookkeeping, 249; car, railway, 611; deficits, remedies for, 83; for chronic diseases, 414; general, and the otologist and ophthalmologist, 192; general ward in, and mental disorders, 49, 134; isolation of scarlet fever, 445, New York deficits of, 83; pay patient department, 247; private State supervision, 574; railway car, 453; statistics, purification of, 88; "they shan't cut you up in," 765; training for unmarried girls, 845
 Hot air, therapeutic uses, 120
 Hot-water bed for operating table, 85
 Hour-glass contraction of uterus, 315
 House in hygienic progress, 615
 Housing problem, London, 652
 Howard, William Travis, Jr.: A bacteriologic investigation of commercial vaccine virus, 12
 Howell's, W. J.: The care of the insane, 900
 Hoyt, Arthur H.: Gluten foods, 233
 Human—bile, characteristics, 800; efficiency, advancing through physical education, 761
 Hunger, physiology of, 441
 Hunner, Guy L.: Surgery of urinary tuberculosis in women, 701
 Huntington's chorea, 720
 Hurty, J. N.: Cause of increase in pneumonia, 657
 Hutchinson's "fish hypothesis" and leprosy, 841
 Hydrocele of spermatic cord, 1024
 Hydrocephalus, surgery of, 983
 Hydronephrosis, intermittent, uterine fibroid, 154
 Hydrophobia with autopsy, 213
 Hydrophthalmus, acquired, 567
 Hydrotherapy—and psychoses, 563; prescriptions, 601
 Hygiene—hygienic suggestion as to, 917; of Japanese, 655; of kissing, 44; of schools, 252
 Hygienic—education, people's, great agency in, 801; significance of marriage, 894; surgery, 762
 Hygroma, 448, 568
 Hyoscin hydrobromate and ether anesthesia, 114
 Hyperalgesic zones in bullet wounds of head, 200
 Hyperemia of liver, chronic, treatment, 160
 Hyperidrosis, 572, 929
 Hypernephromas, 928
 Hyperplasia of pharyngeal tonsil, etiology, 20
 Hypertension, arterial, 120, 975
 Hypertrophic—arthritis, metabolism observations, 647, 590; stenosis of pylorus, congenital, 682
 Hypertrophies about urinary meatus, 884
 Hypertrophy—cardiac, and digitalis, 123; congenital, 486; prostatic, 200, 324, 500, 722, 723, 792
 Hypnotic, the bromine as, 281
 Hypnotics, 281, 869
 Hypnotism—75; stammering treated by, 75
 Hypodermoclysis, submammary, 274
 Hysterectomies, 635
 Hysterectomy—685; abdominal, 325; abdominal, in carcinoma, 609; for fibroids, 37; for infectious diseases, 115; vaginal, versus abdominal, 276
 Hysteria—and organic disease, 678; major, 834; male, 848; traumatic, visual fields in, 81

Hysteric—movements, 926; pathologic sleep, 233
 Hysteroneuroses, 870
Ichthyol compounds, therapeutics of, 610
 Icterus—565; and pancreatic duct, 526; and syphilitic anemia, 445; lithogenic, 868; postoperative benign, 199
 Idiocy—and imbecility, 830; amaurotic family, 579
 Idiosyncrasy and röntgen ray dermatitis, 155
 Ileum—occlusion of, 323; strangulation, 528
 Ill-health and suicide, 916
 Illegitimacy, an economic problem, 758
 Illiterates, test-characters for, 77
 Ilman, G. Morton: A case of hydrophobia with autopsy, 213
 Imagination in medicine, 558
 Imbecility and idiocy, 830
 Immigrants—and their diseases, 251; Italian, 840
 Immigration problem of United States, 287
 Immunity—and infection, 955; physical chemistry and biology in, 792
 Impotence and tobaccoism, 445
 Impregnation, site of, 911
 India, results in, of Haff's prophylactic, 239
 Inebriety, 461
 Infancy—congenital misplacement of hip, 394; diarrhoea of, 737; metapneumonic empyema in, 430; nephritis in, 227; opium in, 1025
 Infant—chronic constipation in, 970; cranial depression, 279; congenital orbital endothelioma in, 114; gastroenteritis, treatment, 869; gastrointestinal catarrh, 363; mortality, 882, 900
 Infantile—bronchitis, 319; paranoia, 285; scurvy, hematuria symptom, 1008; spastic paralysis, 410; tuberculosis and malnutrition, 925
 Infantism independent of thyroid gland, 723
 Infection—acute and nitrogenous excretion, 605; acute and optic neuritis, 646; acute, red bone marrow in, 157; and immunity, 955; and pulmonary tuberculosis, 907; and status lymphaticus, 163; bacterial, and eosinophilic granulation of cells, 848; biliary, hepatic drainage in, 236; eye, postoperative, 925; in gastric and intestinal operations, and resistance of peritoneum, 733; in tuberculosis, 565; intrauterine flushing and drainage for, 189; malarial pathology at autopsy, 799; nasal, and corneal ulceration, 588; of lung, aspergillus, 163; operative, unrecognized source, 1027; postpartum, of uterus, 367; puerperal, 201, 258; renal ascending, 202; retroperitoneal, and appendicitis, 342; rheumatic clinical aspects, 643; scarlatinal, 568; with Bacillus aerogenes capsulatus, 640
 Infectious—angina pectoris, 643; arthritis, 676; diseases, 948; diseases, acute, arteriosclerosis from, 967; diseases and leukemia, 34; diseases apropos of typhoid, cerebrophthal symptoms in, 422; diseases, epidemics, 362; disease, hysterectomy for, 115; neuritis, 848
 Infective cholelithiasis, 444
 Inflammation—about urinary meatus, 884; of appendix, pain and tenderness in, 244; of cecum, acute, 447; of intestinal diverticulum, 201; of Meckel's diverticulum, 200; of pancreas, 697; pelvic, and appendicitis, 629
 Inflammatory—areas of, and arteries of bones, 117; diseases, acute, in children, aural examination, 1008; strictures of large intestines, 201
 Influenza—and appendicitis, 565; bacilli, symbiosis of, 491
 Inguinal—adenitis, treatment, 684; hernia in young, operation, 110
 Inhibition, reflex cardiac, 476
 Injections—epidural, 85; intraspinal, of lyso, 832; intratracheal, in asthma, 407; subconjunctival, 76; subcutaneous, paraffin, 624
 Injuries—during labor, oracular, 646; head, after-effects, 643; to pelvic floor, treatment, 883; to perineum, 885; value of, 483
 Inoculation, antityphoid, 605
 Insane—459; care of, 900; in Maryland, 251; in New York, 250; ward in general hospitals for, 134
 Insanity—626; and alcohol, 47; and complexions, 729; and eye, 288; circular, 791; epileptic, experimental, treatment, 62; increase, 124, 288; in Ireland, 285; therapeutics of, 676
 Insomnia, 860, 838
 Inspection of schools, medical, 846
 Interilioabdominal amputation for sarcoma of ileum, 628
 Interstate reciprocity in medical licensure, 961
 Interstitial—extrauterine pregnancy, 419; nephritis and malaria, 107
 Intestinal—anastomosis, 237, 505, 522, 568, 909, 969; diverticulum, inflammation, 201; fermentation and surgeon, 81; infection by Bacillus dysenteriae, 485; invagination, 242; obstruction, 180, 200, 326, 366, 401, 723, 1008; origin, abdominal pain, 820; varicosis of man, 974; perforation in typhoid, 406, 869; perforation, treatment, 159
 Intestine—large inflammatory strictures of, 201; lipoma of, 324; part, occlusion of, 240; perforation of, in typhoid in children, 200; resection in gangrenous hernia, 886; small, rupture of, traumatic, 836
 Intestines—and stomach, "gastrophore" in operations, 241; carcinoma of, 218, 873; diseases of, treatment, 610; fish, bacteriology, 152; in infants, Shiga bacillus infection, 441
 Insurance—and tuberculosis, 869; underwriters, eddyism, and conflagrations, 765
 Intoxication amblyopia, examination, 80

Intraabdominal—operations, 590; rupture of ovarian cysts, 521
 Intracranial toxins, 491, 1010
 Intracranial syphilis, syndrome of, diagnostic, 881
 Intracranial radiote and radium, 820
 Intraneural injection of antitoxin, 871
 Intrascapulothoracic amputation for sarcoma, 196
 Intratracheal medication, 407, 786
 Intrauterine—flushing and drainage for infection, 189; poliomyelitis, congenital, 97
 Intubation cases, unusual, 1011
 Intussusception—154, 872; of appendix, 279
 Insufficiencia pylori, 676, 759
 Invagination, intestinal, 242, 608
 Iodids—772; lithiomericuric, 1021
 Iodin—absorption and elimination, 1012; nontoxic preparation of, 1028
 Iodism, prevention, 570
 Ireland, insanity in, 285
 Iris—sarcoma of, primary, 80; sphincter, contracture, 80; tuberculosis of, treatment, 79
 Iritis, double—following mumps, 78
 Iron—blood, 686; pharmacology of, modern, 423, 501
 Irrigation, uterine, in puerperal fever, 202
 Isomorphous substances, 834
 Isthmian Canal, and sanitary problems, 333
 Italian immigrant, 840
 Ithaca, typhoid at, 67
 Ivy poisoning, treatment, 39

 Pseudoappendicitis and membranous enterocolitis, 196
 Pseudoarthrosis, healing, 732
 Psoriasis—and affections of joints, 571; and mucous membrane of mouth, 572
 Psorospore cutanée végétante folliculaire, 976
 Psychic—disturbance from abscess in temporal lobe, 697; force, 973
 Psychoses and hydrotherapy, 563
 Ptomain poisoning with result of hemianopsia, 81
 Puberty, albuminuria of, 363, 445
 Public—baths, free, 969; health in Philippines, 169; should pay physician for work in preventive medicine, 958
 Puerpera, the, care and comfort during convalescence, and prevention of visceral prolapse, 783
 Puerperal—eclampsia, 280, 762, 885, 910; eclampsia and internal secretions, 975; fever uterine irrigation in, 202; infection, prevention and treatment, 256; sepsis, 201, 237, 530, 907; se: sis, prophylaxis, 720; septicemia, treatment of, 39
 Puerperium, fibromyoma in pregnancy and placental formation as well as in, 280
 Pugh, Winfield S.: Death under nitrous oxid anesthesia, 298
 Pulmonary—abscess surgical treatment, 954; disease, education against, 526; embolism, fatal, 517; lesions produced by the bacillus of hemorrhagic septicemia of carabao, 711; tuberculosis, blood in, 798; tuberculosis, larynx in beginning, 1021; tuberculosis, morbid anatomy, etc., 26
 Pulp—dental, 153; technic, 30
 Pulse—and life insurance examiner, 722; extrapresystolic, intermittent, 566; in nephritis, 847; radial, different, and heart lesions, 907
 Puncture, lumbar, acciden due to, 121
 Pupil, Argyll-Robertson, 647
 Pupillary reflexes, 670
 Pupils not reacting to light, contracture of iris in, 80
 Purinemia, 215
 Purulent—conjunctivitis and blindness, 1013; ophthalmia, 925; pericarditis, 275
 Pus in urine, 523
 Pyelitis—and pregnancy, 884; primary, in infants, 522
 Pyeloparaneuric cyst, traumatic, 442
 Pyemia, 156
 Pylorus—cancer of, operation in, radical, 694; congenital narrowness of, 681; insufficient, 759; normal large, palpation and auscultation of, 157; stenosis of, 200, 682
 Pyosalpinx, double, operating for, should uterus and ovaries be removed, 368
 Quack—compelled to "move on," 43; nursing schools, 496
 Quackery, 770
 Quarantine—768; regulation, 603
 Quinin, 615
 Rabies—444, 693; and undiagnosed fever, 620
 Race—question, 208; suicide, 376, 459, 730
 Race, odor of, 995
 Rachitis, etiology, 403, 906
 Radial diaphysis, and ivory rod, 567
 Radioactivity—electricity, and radiotherapy, 381; induced, 155; in solutions, 904; in thorium, 195
 Radiode, intragastric, and radium, 820
 Radiodiagnosis, 679
 Radiograph, therapeutic uses, 954
 Radioscopy of peristaltic movements, 277
 Radiotherapy, 319, 381, 1012
 Radium—47, 209, 904, 929, 1024; and intragastric radiode, 820; and radiant energy, 273; and röntgen rays, 483; bromid treatment, 275; effect on agglutination, 799; effect on vegetable organisms, 800; rays and vision, 617; therapeutic uses, 322, 1026
 Radius, fractures, 1024
 Railroad—car hospitals, 458; casualties, 375, 916; employes, ocular and aural requirements, 401
 Rats—877; and microbes, 683
 Raynaud's disease—518; and erythromelalgia, 83
 Reading in bed, 85
 Reciprocity—demand for, 763; interstate, in medical licensure, 961; national, method, 886
 Reclination of lens, justifiable operation, 1069
 Rectal—cancer, operative treatment, 194; diseases, anesthetics in, 365; segment of ureter, 639
 Rectum—and colon, 157; carcinoma of, 194, 734; colargolum administration, 121; diphtheria of, 391; diseases of, anesthetics, 365; ulcer of, tuberculous, 617
 Red Cross—American, controversy, 840, 844; organization, 766; reorganization of, 917
 Red light, therapeutic uses, 686, 795
 Reducing agents, detecting and differentiating, 758
 Reed, Walter, memorial to, 915
 "Ref. D.," 289
 Reflex—aortic, 542; Babinski's toe, 285; disturbances and adherent prepuce, 795; neuroses of dental origin, 186
 Reflexes—and sensory phenomena and condition of eye-grounds, 670; cerebral, and tendon phenomena, 71; conjunctival, pharyngeal, pupillary, 670
 Reforms in prisons and jails, 688
 Registration—area and improvement of vital statistics, 575; of nurses, State, 993
 Remedies, proprietary, and physicians, 923
 Remick, Dr., misfortune of, 206, 214
 Removal of septal spurs and the correction of deviations of the septum by more rational methods, 749
 Renal—affections, surgery, 527; bloodvessels, poisons on, 913; calculus, diagnosis, 893; calculus, treatment, 239; decapsulation, 871; decapsulation and experimental nephritis, 836; decapsulation from pathologist's point of view, 873; decapsulation in puerperal eclampsia, 885; disease, diagnosis, ureteral catheterism, 721; disease, ureterocystoscopy in, 360; infection, ascending, 202; skiagraphy, 875; tuberculosis, 722
 Resection—of cervical sympathetic ganglions in glaucoma, 318;—of eolidymis, 200; of intestine in gangrenous hernia, 366; of nasal septum, 31, 758
 Respiration, effect of aspidospermin upon, 245
 Restaurant kitchens, etc., sanitary regulations, 533
 Resuscitation in apparent death in chloroform anesthesia, 630
 Retention of urine, vesical, 1025
 Retina—central artery of embolism of, 78; detachment, operation for, 78; projection of, upon cortical calcarine, 80
 Retinal—hemorrhage, in severe anemia, 648; symptoms of vascular degeneration, 304
 Retinitis, leukemic, 79
 Retrodeviation, uterine suspension for, 685
 Retrodisplacements of uterus, 676
 Retroflexio uteri, clinical importance, 609
 Retrogression, champions of, 248
 Retroperitoneal—infection, and appendicitis, 342; tumor operation, 1006
 Retrouterine hematocle, 721
 Retroversion of gravid uterus, treatment, 910
 Reversional vestiges in human pharynx, 975

Toxicogenic germs in water, 638

Toxicologic examination of organs in fatal strychnin poisoning, 990

Toxins—and antitoxin, 792; diphtheria, effect on circulatory organs, 73; diphtheric, immunization of man with, 480; from liver cells, 719; government inspection of establishments, 541; intracellular, 491, 719; 1010; of chancroid bacillus, 798

Trachelorrhaphy, primary, 603

Trachoma—79; epidemic, 677; treatment, 79, 647, 648

Tracheostenosis, thymic, 602

Trades-union spirit, another inequity of, 125

Tramp, distributor of disease, 85

Transillumination of stomach, 721, 761

Transplantation—bone, for pseudoarthrosis or bone defects, 732; of tendons of thigh, 410; of thyroid gland in man, 835

Trauma—and tabes, 234; in movable kidney, 318

Traumatic—asphyxia, 800; hysteria, visual field in, 81; pyeloparaneurphic cyst, 442; rupture of intestine, small, 836; rupture of liver, 637; sclerosis, 926

Traumatism—abdominal, 185; of circumflex nerve in shoulder-joint injuries, 645

Trendelenburg position, 118, 906

Trephining—for epilepsy, 273; in America, prehistoric, 3; of savage of present day, primitive, 3; prehistoric, 2

Trichinosis and eosinophilia, 1026

Trochanteris spina, line, 733

Tropical—diseases, 89, 539; liver abscess, 908

Truncate's serum, therapeutic value, 281, 361

Truss, thigh, for femoral hernia, 297

Trypanosomes—agglutination and filtration, 849; cultivation, artificial, 161; diseases caused by, 580; surra, of Philippines, 904

Tubercle bacilli—32; chemico constitution, 797; early recognition in lungs, 998; human and bovine, 160, 800; human origin, virulence of differently bred, 74; immunization against, 581; in lungs, early recognition, 998; virulence for monkeys, 162

Tuberculin—from different races of bacilli, 581; in surgical diagnosis, 365

Tuberculoma of liver, treatment, 678

Tuberculosis—5, 46, 127, 170, 211, 293, 334, 388, 361, 376, 404, 459, 460, 475, 482, 498, 538, 539, 580, 604, 611, 615, 678, 693, 843, 845, 880, 988; age incidence of, 239; crusade against, 85, 1024; administrative control, 873; arteriosclerosis and, 564; and daily hygiene, 976; and heredity, 907; and insurance, 869; and Marmorek's serum, 918; and Santa Cruz mountains of Jamaica, West Indies, 868; and typhoid, 907; and vaccination against, 603; arteriosclerosis and diabetes, 564; bone and joint, diagnosis, 409; bovine, and human health, 162, 196, 287, 364, 794, 918; bovine, and public health, 613; congress of, Bell's vindication, 42; congress situation, meeting in Baltimore to discuss, 84; diagnosis, early, 235, 998; election in, 72; eradication, 211; etiology, 198; exposition, 209, 210; fever of, 893; genitourinary, climate in, 116; human and bovine, 210, 364, 482; house infection, 210; incipient, treatment, sanatorium, 606; immunization against, 405, 681; in children, 642; infantile and malnutrition, 925; in Germany, 89; in hens, 46; in man and animals, 490; in New York, 905; in street cleaners, 763; in this country, organization to study, 588; infection of houses, 361; infection in, 565; inoculations, 642; intestinal origin, 363; laryngeal, treatment, 750; miners, 850; of cervical lymphatic glands, 556; of choroid, military, 79; of conjunctiva, treatment, 79; of hernial sac, 240; of iris, treatment, 79; of kidney, operation in, 732; of kidney, primary, treatment, 884; of nervous system, 928; of peritoneum, 682; of spinal column, 490, 640; of testis, treatment, 833; of tonsil, primary, 34; of urinary bladder, 833; of urinary apparatus, descending, 242; of urinary system in women, 609; of uterus and appendages, 449; predispositions to, 32; prevention, 185; prevention, Pennsylvania society for, 186; pulmonary, 641, 767; pulmonary, and infection, 907; pulmonary, and nose and throat diseases, 32; pulmonary, blood in, 482, 798; pulmonary, diagnosis, 115, 486; pulmonary, incipient, curability of, 454; pulmonary, jugular thrombosis in, 484; pulmonary, larynx in, early, 197, 1021; pulmonary, lime dust inhalation, 198; pulmonary, morbid anatomy and histology, and general pathology and clinical manifestations, 23; pulmonary, origin, 404; pulmonary, pneumothorax in, 439; pulmonary, treatment, 203, 204, 327, 371, 569, 570; pulmonary, varieties, 679; rationale and arrest, 440; renal, 722; statistical laws, 210; surgical serum treatment, 912; temperature in, 239; treatment, 117, 158, 263, 204, 275, 281, 322, 327, 371, 402, 569, 570, 646, 886; treatment, Arctic localities, in 607; treatment of, Manson's condemnation, 7; turtle, bacillus of, 489; United States Association for, 635; urinary, in

- women, surgery of, 701; virulence of bacillus for monkeys, 162; why not cured, 89
- Tuberculosis—at Fort Stanton, N. M., treatment, 686; camps, greed and establishment, 287; deposits in tonsils, 627; disease, education against, 526; disease of chest, unusual form, 109; disease of fallopian tubes, 448; gland, treatment, 237; joints, 318; justice to, 71; laryngitis, prognosis and treatment, 1011; lung, should it be excised, 363; maxims for, 32; meningitis in adults, 870; naval employes, camp for, 4; patient, 640; patients, new pavilions for, 209; patients, sputum of, 65; patients, toxialimentary dyspnea in, 204; pericarditis, 981; peritonitis, treatment, 527; rheumatism, acute, diagnosis, 117; Santa Cruz mountains of Jamaica, West Indies for, 868; tonsils and uvula in, 163
- Tubes—in menstruation, 792; operations on, 590
- Tubism, 48
- Tuition fees, higher, 960
- Tumefactions of climacteric breast, 37
- Tumor—brain, blindness, 973; cerebral, history, after removal, 285; cerebral, surgery of, 568; colon and abdominal, 325; epithelial, of skin, 580; fibroid, treatment, 870; involving cauda equina, 520; malignant, congenital, 367; malignant, treatment, rational, 659; mixed, of parotid gland, 758; of brain and right lateral ventricle, 236; of breast, benign, treatment, surgical, 923; of eye orbit, 972; of liver, operation in, 447; of salivary glands, mixed, 406; of sclera, gummatous, 648; of sex glands, 489; of thyroid body with metastases, 645; of spinal cord, 283; orbital, diagnosis, 648; retroperitoneal, operation, 1006; uterine, fibroid, indications for operation, 1014
- Tunica vaginalis, fibromas of, 684
- Türk, fasciculus of, 284
- Typhilitis, acute primary, 199
- Typhoid (see enteric fever)—89, 169, 170, 185, 250, 272, 320, 321, 333, 334, 376, 417, 459, 498, 616, 617, 676, 780, 805, 954; and pregnancy, 37; and scarlatina, 907; anomalies and diagnosis in, 72; and filters, 539; and malarial fevers, 997; and tuberculosis, 907; and unusual complication, 922; at Butler, I., at Ithaca, 67; bacilli in butter, 363; bacilli in milk and its products, 444; epidemics, 72; fever patients, discharges of, 167; Ficker diagnosticum, 643; hemorrhagic type, 761; in children, 114, 200, 639; infectious disease, cerebrospinal symptoms in, 422; intestinal perforation in, 159, 869; inoculation against, 196; laryngeal complications in, 72; leukocyte count in, 561; lymph-glands, 895; mother, negative Widal in newborn, 117; nervous complications, 595; 327 new cases in one week, 725; on heart and vessels, 681; perforations, 200, 405, 601, 699, 921; perforation of gallbladder, 36; prevention, 903; polyuria in, 809; rupture of mesenteric glands simulating perforation, 969; spine, 721; statistics, 802; throat complications in, 1011; treatment, 5, 72, 73, 154, 722, 760, 974; venous thrombosis in, 809
- Uganda, sleeping sickness in, 613
- Uter—bearing area, in gastric ulcer, excision, 969; chronic of stomach, 761; gastric, after history, 406; gastric, bibliography of, 1015; gastric, of lesser curvatures, 738; gastric, pathogenesis of, 1016; gastric, pathologic anatomy of, 1015; gastric perforating, 75, 241, 482, 684; gastric, surgical standpoint, 678; gastric, symposium on, 1015; gastric, treatment, 912; gastric, unusual form, 364; of cornea, 508; of duodenum, 75; of leg, treatment, 954; of rectum, tuberculous, 607; rodent, radium in, 1026
- Ulcerative—colitis, 607; endocarditis, 810
- Ulnar nerve, paralysis of, 875, 1025
- Ultramicroscope, achievements, 649; and organisms of disease, 487
- Ultraviolet rays in tuberculosis, 402
- Uncinariasis—60; in Porto Rico, 206; in South, 973
- Uncinate group of fits, 474
- Underfed, the treatment of, 156
- Union in New York, 84, 165
- United States—Army, medical department of, efficiency, to increase, 576; immigration problem, 257
- University—of Pennsylvania, laboratories, medical, dedication, 962; students in France, 753
- Unsanitary conditions at Panama and Colon, 418
- Urachus, fistula of, in adult, 528
- Urea—determination, Moor's method, 130; excretion in gout and lithemia, 677
- "Ureine" Moor's claim for, 130
- Uremia—increased of arterial pressure, 1027; spinal puncture in, 34
- Ureter—calculus of, 278; catheterization, 681, 721, 953; extraperitoneal route to, 904; rectal segment of, 689; removal of stones from, 1028; sheath and infection in uterine cancer, 1010; surgery of, 241
- Uterocystoscope in renal disease, 380
- Uterolithotomy, 884
- Urethra—disease of and eruptive skin diseases, 33; female, gummatous affection of, 37; female, strictures of, 601; female, surgery of, 884; in gonorrhea, gleet, and stricture, 788; stricture of, 282, 561
- Urethral—hymen, 347; labia, 347
- Urethritis, nongonorrheal metastatic, 447
- Urethrotomy by combined use of anterior and posterior sound, 113
- Uric acid—gout, and lithemia, 759; pathologic increase, 1019; question, 818
- Urinalysis—and diagnosis of contracted kidney, 402 in infantile diarrhea, 116
- Urinary—apparatus, descending, tuberculosis of, 242; bladder, tuberculosis of, 833; meatus, hypertrophies and inflammations about, 984; tuberculosis in women, surgery of, 609, 701
- Urine—albumin in, test for, 906; and formaldehyde, 441; bile pigment in, detection, 163; black, significance, 643; day and night, 319; green, 439; in acute infections, 605; incontinence, acquired, treatment, surgical, 156; Kollmann five glass test, 602; nitrogen in, in ophthalmic conditions, 33, 605; pus and blood in, 523; sugar in, 364; vesical retention of, 1025
- Urobilin, clinical test for, 490
- Uterine carcinoma, 119, 733; curement, 561; disease and constipation, 279; fibroid, 38, 154, 543; fibroma and pregnancy, 531; irrigation in puerperal fever, 202; prolapse, treatment, 970; suspension for retrodeviation, 685
- Uterus—bilocular, and bifid vagina, 1007; carcinoma of, 264, 367, 924; fibroid tumors, indications for operation, 1014; fibromyoma of, and visceral metastases, 449; gravid, bilocular, overdistention, 368; gravid, myomectomy on, 911; gravid, retroversion of, treatment, 910; hour-glass contraction of, 315; implantation of human ovum into, 978; infection of, postpartum, 367; inverted, reduction, 326; myoma, of, 909; perforations, accidental, 638; retrorotations of, 676; single, and double vagina, 685; tuberculosis of, and appendages, 449; ventrofixation of, 837
- Uvula, in tuberculous, 163
- Vaccination—5, 333, 376, 539, 617, 844, 881; and corporations, 124; and exclusion from schools, 2; and smallpox, 1022; and tuberculosis, 603, 844; condition of entrance, 247; in Cuba, 34; of calves, 209; scars, false, vile crime encouraged, 41
- Vaccine—927; and serum products, 379; and serums, manufacture, 502; bodies, 581; virus and tetanus, 489; virus, commercial, bacteriologic investigation, 12; virus, preparation, 484
- Vaccinia—796; and variola, 874; etiology and pathologic anatomy, 796
- Vagina—bifid and bilocular uterus, 1007; carcinoma of, primary diagnosis, 608; diphtheria of, 391; double, with single uterus, 685; foreign body in, 502; rupture of, 203
- Vaginal—cesarean section, 325, 326; cystotomy for stone in bladder, 240; drainage, 324; hysterectomy, versus abdominal, 276; operation without anesthesia, 367; prolapse, treatment, 970; route in ectopic gestation, 120, 202; section in delivery, 903
- Vaginitis, gonorrheal, treatment, local, 122
- Valvular—aorta, construction, 955; disease of heart, 523
- Vanity and persistence in, 612
- Varices, lymphatic, 601
- Varicocoele, 891
- Variola (see smallpox)—796; and vaccinia, 874; blood in, infectiousness, 796; blood-serum, 796; in monkey, experimental, 796; leukocyte reaction, 796; nervous system in, 796
- Vascular degeneration, retinal symptoms of, 904
- Vas deferens, senile calcification, 243
- Vasomotor—pressure in blood-pressure, 850; stability in estimating significance of irregularity of cardiac rhythm, 675
- Vegetable organisms, effect of radium on, 800
- Veins—femoral, thrombosis after aseptic laparotomy, 49, 367; ossification, and sclerosis, 760; renal, thrombosis of, symptomatology, 322
- Veneral disease—651, 929, 967; and medical profession, 929; and military life, 205; and prostitution, 235; military, cost, to British taxpayer, 205
- Venous thrombosis, in typhoid, 809
- Ventricle, right lateral, and tumor of brain, 236
- Ventrofixation—530; bladder in, 955; of uterus, 837
- Verdict, the, 614
- Veronal, 610
- Vertebral column, luxation of any articulations, 567
- Vesical—calculus and multiple adenoma of prostate, 172; retention of urine, 1025
- Vesicovaginal fistulas, 37, 201
- Vesicular mole, 529
- Vice, schools in, 687
- Virus—government inspection of manufacturing establishments, 541; vaccine, commercial, bacteriologic investigation, 12
- Viscera—hollow, spontaneous gangrene of, 723; transposition of, congenital, 491
- Visceral—crises in erythema group of skin diseases, 565, 908; prolapse, prevention, in care of puerpera, 783
- Vision—and radium rays, 647; binocular singular, conservation, 78; hallucinations of, loss; and excessive eye use, 360
